1 Proceedings	1
MEMR: A Margin Equipped Monotone Retargeting Framework for Ranking. <i>Sreangsu Acharyya, Joydeep Ghosh</i>	1
On Convergence and Optimality of Best-Response Learning with Policy Types in Multiagent Systems. <i>Stefano Albrecht, Subramanian Ramamoorthy</i>	12
Accelerating MCMC via Parallel Predictive Prefetching. <i>Elaine Angelino, Eddie Kohler, Margo Seltzer, Amos Waterland, Ryan Adams</i>	22
A variational approach to stable principal component pursuit. <i>Aleksandr Aravkin, Stephen Becker, Volkan Cevher, Peder Olsen</i>	32
Markov Network Structure Learning via Ensemble-of-Forests Models. <i>Eirini Arvaniti, Manfred Claassen</i>	42
Can(Plan)+: Extending the Operational Semantics of the BDI architecture to deal with Uncertain Information. <i>Kim Bauters, Weiru Liu, Jun Hong, Carles Sierra, Lluis Godo</i>	52
Message Passing for Soft Constraint Dual Decomposition. <i>David Belanger, Alexandre Passos, Sebastian Riedel, Andrew McCallum</i>	62
Bayesian Interactive Decision Support for Multi-Attribute Problems with Even Swaps. <i>Debarun Bhattacharjya, Jeffrey Kephart</i>	72
Learning to Predict from Crowdsourced Data. <i>Wei Bi, Liwei Wang, James Kwok, Zhuowen Tu</i>	82
Lifted Tree-Reweighted Variational Inference. <i>Hung Bui, Tuyen Huynh, David Sontag</i>	92
Approximate Decentralized Bayesian Inference. <i>Trevor Campbell, Jonathan How</i>	102
Inferring latent structures via information inequalities. <i>Rafael Chaves, Lukas Luft, Thiago Maciel, David Gross, Dominik Janzing, Bernhard Schölkopf</i>	112
Near-optimal Adaptive Pool-based Active Learning with General Loss. <i>Nguyen Viet Cuong, Wee Sun Lee, Nan Ye</i>	122
A Permutation-Based Kernel Conditional Independence Test. <i>Gary Doran, Krikamol Muandet, Kun Zhang, Bernhard Schölkopf</i>	132
Parallel Markov Chain Monte Carlo for Pitman-Yor Mixture Models. <i>Kumar Dubey, Sinead Williamson, Eric Xing</i>	142

Market Making with Decreasing Utility for Information. <i>Miroslav Dudik, Rafael Frongillo, Jennifer Wortman Vaughan</i>	152
Universal Convexification via Risk-Aversion. <i>Krishnamurthy Dvijotham, Maryam Fazel, Emanuel Todorov</i>	162
Structured Proportional Jump Processes. <i>Tal El-Hay, Omer Weissbrod, Elad Eban, Maurizio Zazzi, Francesca Incardona</i>	172
Electing the Most Probable Without Eliminating the Irrational: Voting Over Intransitive Domains. <i>Edith Elkind, Nisarg Shah</i>	182
Iterative Splits of Quadratic Bounds for Scalable Binary Tensor Factorization. <i>Beyza Ermis, Guillaume Bouchard</i>	192
Finding Optimal Bayesian Network Structures with Constraints Learned from Data. <i>Xiannian Fan, Brandon Malone, Changhe Yuan</i>	200
Bisimulation Metrics are Optimal Value Functions. <i>Norm Ferns, Doina Precup</i>	210
Annealing Paths for the Evaluation of Topic Models. <i>James Foulds, Padhraic Smyth</i>	220
Active Learning of Linear Embeddings for Gaussian Processes. <i>Roman Garnett, Michael Osborne, Philipp Hennig</i>	230
Estimating Causal Effects by Bounding Confounding. <i>Philipp Geiger, Dominik Janzing, Bernhard Schölkopf</i>	240
Bayesian Optimization with Unknown Constraints. <i>Michael Gelbart, Jasper Snoek, Ryan Adams</i>	250
Nonparametric Clustering with Distance Dependent Hierarchies. <i>Soumya Ghosh, Michalis Raptis, Leonid Sigal, Erik Sudderth</i>	260
Transformation-based Probabilistic Clustering with Supervision. <i>Siddharth Gopal, Yiming Yang</i>	270
Understanding the Complexity of Lifted Inference and Asymmetric Weighted Model Counting. <i>Eric Gribkoff, Guy Van Den Broeck, Dan Suciu</i>	280
Interactive Learning from Unlabeled Instructions. <i>Jonathan Grizou, Iñaki Iturrate, Luis Montesano, Pierre-Yves Oudeyer, Manuel Lopes</i>	290
Batch-Mode Active Learning via Error Bound Minimization. <i>Quanquan Gu, Tong Zhang, Jiawei Han</i>	300
Efficient Bayesian Nonparametric Modelling of Structured Point Processes. <i>Tom Gunter, Chris Lloyd, Michael Osborne, Stephen Roberts</i>	310
Learning Peptide-Spectrum Alignment Models for Tandem Mass Spectrometry. <i>John Halloran, Jeffrey Bilmes, William Noble</i>	320
Off-policy TD(λ) with a true online equivalence. <i>Hado Van Hasselt, Rupam Mahmood, Rich Sutton</i>	330
Constraint-based Causal Discovery: Conflict Resolution with Answer Set Programming. <i>Antti Hyttinen, Frederick Eberhardt, Matti Järvisalo</i>	340
Generating structure of latent variable models for nested data. <i>Masakazu Ishihata, Tomoharu Iwata</i>	350
Monotone Closure of Relaxed Constraints in Submodular Optimization: Connections Between Minimization and Maximization. <i>Rishabh Iyer, Stefanie Jegelka, Jeffrey Bilmes</i>	360
Min- d -Occur: Ensuring Future Occurrences in Streaming Sets. <i>Vidit Jain, Sainyam Galhotra</i>	370
Instance Label Prediction by Dirichlet Process Multiple Instance Learning. <i>Melih Kandemir, Fred Hamprecht</i>	380
Closed-form Solutions to a Subclass of Continuous Stochastic Games via Symbolic Dynamic Programming. <i>Shamin Kinathil, Scott Sanner, Nicolás Della Penna</i>	390
Recursive Best-First AND/OR Search for Optimization in Graphical Models. <i>Akihiro Kishimoto, Radu Marinescu</i>	400

Saturated Conditional Independence with Fixed and Undetermined Sets of Incomplete Random Variables.	
<i>Henning Koehler, Sebastian Link</i>	410
Matroid Bandits: Fast Combinatorial Optimization with Learning.	
<i>Branislav Kveton, Zheng Wen, Azin Ashkan, Hoda Eydgahi, Brian Eriksson</i>	420
Multi-label Image Classification with A Probabilistic Label Enhancement Model.	
<i>Xin Li, Feipeng Zhao, Yuhong Guo</i>	430
Sequential Model-Based Ensemble Optimization.	
<i>Alexandre Lacoste, Hugo Larochelle, Mario Marchand, François Laviolette</i>	440
Position-Aware ListMLE: A Sequential Learning Process for Ranking.	
<i>Yanyan Lan, Yadong Zhu, Jiafeng Guo, Shuzi Niu, Xueqi Cheng</i>	449
Continuously indexed Potts models on unoriented graphs.	
<i>Loic Landrieu, Guillaume Obozinski</i>	459
Efficient Inference of Gaussian-Process-Modulated Renewal Processes with Application to Medical Event Data.	
<i>Thomas Lasko</i>	469
Optimal Resource Allocation with Semi-Bandit Feedback.	
<i>Tor Lattimore, Koby Crammer, Csaba Szepesvari</i>	477
Quantifying Nonlocal Informativeness in High-Dimensional, Loopy Gaussian Graphical Models.	
<i>Daniel Levine, Jonathan How</i>	487
CoRE Kernels.	
<i>Ping Li</i>	496
Efficient Sparse Recovery via Adaptive Non-Convex Regularizers with Oracle Property.	
<i>Ming Lin, Rong Jin, Changshui Zhang</i>	505
Nuclear Norm Regularized Least Squares Optimization on Grassmannian Manifolds.	
<i>Yuanyuan Liu, Fanhua Shang, Hong Cheng, James Cheng</i>	515
Fast Ridge Regression with Randomized Principal Component Analysis and Gradient Descent.	
<i>Yichao Lu, Dean Foster</i>	525
Adaptive Monotone Shrinkage for Regression.	
<i>Zhuang Ma, Dean Foster, Robert Stine</i>	533
Firefly Monte Carlo: Exact MCMC with Subsets of Data.	
<i>Dougal Maclaurin, Ryan Adams</i>	543
Sequential Bayesian Optimisation for Spatial-Temporal Monitoring.	
<i>Roman Marchant, Fabio Ramos, Scott Sanner</i>	553
AND/OR Search for Marginal MAP.	
<i>Radu Marinescu, Rina Dechter, Alexander Ihler</i>	563
Stochastic Discriminative EM.	
<i>Andres Masegosa</i>	573
Latent Kullback Leibler Control for Continuous-State Systems using Probabilistic Graphical Models.	
<i>Takamitsu Matsubara, Vicenç Gomez, Hilbert Kappen</i>	583
GPS-ABC: Gaussian Process Surrogate Approximate Bayesian Computation.	
<i>Edward Meeds, Max Welling</i>	593
Lifted Message Passing as Reparametrization of Graphical Models.	
<i>Martin Mladenov, Amir Globerson, Kristian Kersting</i>	603
Fast Gaussian Process Posteriors with Product Trees.	
<i>David Moore, Stuart Russell</i>	613
Asymptotically Exact, Embarrassingly Parallel MCMC.	
<i>Willie Neiswanger, Eric Xing, Chong Wang</i>	623
Modeling Citation Networks Using Latent Random Offsets.	
<i>Willie Neiswanger, Chong Wang, Qirong Ho, Eric Xing</i>	633
Collaborative Multi-output Gaussian Processes.	
<i>Trung Nguyen, Edwin Bonilla</i>	643
Combining predictions from linear models when training and test inputs differ.	
<i>Thijs Van Ommen</i>	653

Optimal amortized regret in every interval. <i>Rina Panigrahy, Preyas Popat</i>	663
Learning Partial Policies to Speedup MDP Tree Search. <i>Jervis Pinto, Alan Fern</i>	672
Estimating Accuracy from Unlabeled Data. <i>Emmanouil Antonios Platanios, Avrim Blum, Tom Mitchell</i>	682
k-NN Regression on Functional Data with Incomplete Observations. <i>Sashank J. Reddi, Barnabas Poczos</i>	692
Bayesian Inference in Treewidth-Bounded Graphical Models Without Indegree Constraints. <i>Daniel J. Rosenkrantz, Madhav V. Marathe, S. S. Ravi, Anil K. Vullikanti</i>	702
SPPM: Sparse Privacy Preserving Mappings. <i>Salman Salamatian, Nadia Fawaz, Branislav Kveton, Nina Taft</i>	712
Correlated Compressive Sensing for Networked Data. <i>Tianlin Shi, Da Tang, Liwen Xu, Thomas Moscibroda</i>	722
Improved Densification of One Permutation Hashing. <i>Anshumali Shrivastava, Ping Li</i>	732
First-Order Open-Universe POMDPs. <i>Siddharth Srivastava, Stuart Russell, Paul Ruan, Xiang Cheng</i>	742
A Hierarchical Switching Linear Dynamical System Applied to the Detection of Sepsis in Neonatal Condition Monitoring. <i>Ioan Stanculescu, Christopher K.I. Williams, Yvonne Freer</i>	752
A Spectral Algorithm for Learning Class-Based n -gram Models of Natural Language. <i>Karl Stratos, Do-kyum Kim, Michael Collins, Daniel Hsu</i>	762
Inference Complexity in Continuous Time Bayesian Networks. <i>Liesman Sturlaugson, John Sheppard</i>	772
Model Regularization for Stable Sample Rollouts. <i>Erik Talvitie</i>	780
HELM: Highly Efficient Learning of Mixed copula networks. <i>Yaniv Tenzer, Gal Elidan</i>	790
Metrics for Probabilistic Geometries. <i>Alessandra Tosi, Søren Hauberg, Alfredo Vellido, Neil Lawrence</i>	800
Efficient Regret Bounds for Online Bid Optimisation in Budget-Limited Sponsored Search Auctions. <i>Long Tran-Thanh, Lampros Stavrogiannis, Victor Naroditskiy, Valentin Robu, Nicholas Jennings, Peter Key</i>	809
A Consistent Estimator of the Expected Gradient Outerproduct. <i>Shubhendu Trivedi, Jialei Wang, Samory Kpotufe, Gregory Shakhnarovich</i>	819
Venn-Abers Predictors. <i>Vladimir Vovk, Ivan Petej</i>	829
Tightness Results for Local Consistency Relaxations in Continuous MRFs. <i>Yoav Wald, Amir Globerson</i>	839
Bayesian Filtering with Online Gaussian Process Latent Variable Models. <i>Yali Wang, Marcus Brubaker, Brahim Chaib-draa, Raquel Urtasun</i>	849
Approximating the Bethe Partition Function. <i>Adrian Weller, Tony Jebara</i>	858
Understanding the Bethe Approximation: When and How can it go Wrong?. <i>Adrian Weller, Kui Tang, Tony Jebara, David Sontag</i>	868
A Bayesian Nonparametric Model for Spectral Estimation of Metastable Systems. <i>Hao Wu</i>	878
Fast Newton methods for the group fused lasso. <i>Matt Wytock, Suvrit Sra, J. Zico Kolter</i>	888
Learning from Point Sets with Observational Bias. <i>Liang Xiong, Jeff Schneider</i>	898
Constructing Separators and Adjustment Sets in Ancestral Graphs. <i>Benito van der Zander, Maciej Liskiewicz, Johannes Textor</i>	907

Belief-Kinematics Jeffrey's Rules in the Theory of Evidence.
Chunlai Zhou, Mingyue Wang, Biao Qin 917

Preface

The Conference on Uncertainty in Artificial Intelligence (UAI) is the premier international conference on research related to representation, inference, learning and decision making in the presence of uncertainty within the field of Artificial Intelligence. This volume contains all papers that were accepted for the 30th UAI Conference, held in Quebec City, Quebec, Canada, from July 23rd to 27th 2014. Papers appearing in this volume were subjected to a rigorous review process. 292 papers were submitted to the conference and each was peer-reviewed by 3 or more reviewers with the supervision by one Senior Program Committee member. A total of 94 papers were accepted, 24 for oral presentation and 70 for poster presentation, for an acceptance rate of 32%. We are very grateful to the program committee and senior program committee members for their diligent efforts. We are confident that the proceedings, like past UAI conference proceedings, will become an important archival reference for the field.

We are pleased to announce that the Microsoft Best Paper Award was given to Dougal Maclaurin and Ryan Adams for their paper “Firefly Monte Carlo: Exact MCMC with Subsets of Data”. The IBM Best Student Paper Award was given to Benito van der Zander (co-authored with Maciej Liskiewicz and Johannes Textor) for their paper “Constructing Separators and Adjustment Sets in Ancestral Graphs”. The Google Best Student Paper Award was given to Nguyen Viet Cuong (co-authored with Wee Sun Lee and Nan Ye) for their paper “Near-optimal Adaptive Pool-based Active Learning with General Loss”. The Facebook Best Student Paper Award was given to Krishnamurthy Dvijotham (co-authored with Maryam Fazel and Emanuel Todorov) for their paper “Universal Convexification via Risk-Aversion”. And the Best Paper Runner-Up was “Optimal Resource Allocation with Semi-Bandit Feedback” by Tor Lattimore, Koby Crammer, and Csaba Szepesvari.

In addition to the presentation of technical papers, we were very pleased to have five distinguished invited speakers at UAI 2014: David M. Blei (Columbia University), Craig Boutilier (University of Toronto), Michael L. Littman (Brown University), Andrew Ng (Stanford University), and, as Banquet Speaker, Yann LeCun (Facebook and NYU). Another interesting addition to the conference program was the Fifth UAI Probabilistic Inference Competition, organized by Vibhav Gogate.

The UAI 2014 tutorials program, chaired by Vibhav Gogate, consisted of four tutorials: “Random Perturbations for Inference” by Tamir Hazan, “Learning Tractable Probabilistic Models” by Pedro Domingos and Daniel Lowd, “Probabilistic Programming” by Avi Pfeffer, and “Probabilistic Inference in Relational Models” by Dan Suciu and Guy Van den Broeck.

UAI 2014 also hosted two one-day workshops (organized by workshops chair John Mark Agosta): “11th Bayesian Applications Workshop” and “Causal Inference: Learning and Prediction”.

Publicity Chair

Changhe Yuan, City University of New York, USA

Acknowledgments

The success of a conference such as UAI depends greatly on the efforts of many individuals who volunteer their time to provide expert and detailed reviews of submitted papers. In particular, the Program Committee and Senior Program Committee for UAI 2014 were responsible for generating reviews and recommendations for the 292 submissions to the conference. Each submitted paper was reviewed by at least 3 members of the Program Committee. The Senior Program Committee then assessed the individual reviews for each paper, moderated discussion among Program Committee members if needed, and generated meta-reviews and recommendations for the program chairs. We are extremely grateful for the efforts of all of the individuals listed below.

Senior Program Committee

Jeff Bilmes	University of Washington

Additional Acknowledgments

A number of other people have made significant contributions towards making UAI 2014 possible. We acknowledge and thank:

- Fabio Cozman, Nando de Freitas, Peter Grunwald, David Poole, Prakash Shenoy and Padhraic Smyth for general advice and assistance related to UAI organization.
- Rina Dechter and Gal Elidan for initiating the inference competition.
- Thao Hoang for creating and maintaining the UAI 2014 Web site.
- Ewelina Akehurst for providing assistance to the general chair
- Karen Wong for assistance in setting up UAI 2014 Website.
- Kilian Weinberger for setting up the automatic paper formatting checker.

Sponsors

We gratefully acknowledge the generous support provided by our sponsors, including support for student best paper awards. Without our sponsors' support it would not be feasible to organize a conference such as UAI 2014 without charging much higher registration fees.

MEMR: A Margin Equipped Monotone Retargeting Framework for Ranking

Sreangsu Acharyya *

Abstract

We bring to bear the tools of convexity, margins and the newly proposed technique of monotone retargeting upon the task of learning permutations from examples. This leads to novel and efficient algorithms with guaranteed prediction performance in the online setting and on global optimality and the rate of convergence in the batch setting. Monotone retargeting efficiently optimizes over all possible monotone transformations as well as the finite dimensional parameters of the model. As a result we obtain an effective algorithm to learn transitive relationships over items. It captures the inherent combinatorial characteristics of the output space yet it has a computational burden not much more than that of a generalized linear model.

1 INTRODUCTION

Many applications require items to be ordered correctly. Prototypical examples of such applications are information retrieval and recommender systems. In most cases, however, the quality measure that actually defines the *transitive relation* of interest can be accessed only through examples. This lack of direct access to the ordering relation motivates learning the quality measure from the covariates of the items. We distinguish this task from a related and easier one of learning binary pairwise relations where transitivity is not required by the application.

Existing techniques of learning to rank (LETOR) fall under 3 categories: (i) point-wise methods, (ii) pair-wise methods and (iii) list-wise methods. In point-wise methods, higher ranked items are assigned higher target scores. The method ignores the combinatorial

structure of the output space and regresses the scores directly. Pair-wise methods capture some structure by trying to classify for a pair whether the first item in the pair out-ranks the second. Their predictions need not be transitive and an *order-reconciliation step* is necessary to enforce it. This is NP hard [8], necessitating approximations and heuristics. Finally, there are list-wise methods that model the full combinatorial structure and need to solve formidable optimization problems. They have to cut corners for scalability. Notable approaches include sampling [25], approximations [2], and resorting to point-wise methods [6].

An ideal LETOR formulation should (i) capture combinatorial structure like list-wise methods, but with (ii) algorithms as simple as point-wise methods. While this seems too much to ask, the recently proposed monotone retargeting (MR) technique is one way how this may be approached [1]. MR outperforms several state of the art ranking algorithms such as Listnet [6] and RankCosine, even after improving those algorithms for statistical consistency as proposed by Ravikumar et. al. [21].

MR efficiently reduces, the LETOR problem to a generalized linear model (GLM) with no loss in generality. It subsumes *statistically consistent* methods of [21]. The distinguishing characteristic of MR is its *“retargeting” paradigm*, where instead of fitting training scores exactly, it tries to fit any score that captures the desired order. Recall that our task is to retrieve the correct order and not the training scores. In this setting, retrieving the specified training scores are an unnecessary burden. The specified training scores may be particularly difficult to fit for the chosen family of regression function class, but there might exist score assignments that capture the desired order and also simultaneously lie in the range space of the regression function class being used. The MR framework tries to find such score assignments by formulating it as a Bregman divergence minimization problem.

In this paper we push the *retargeting* idea further.

*Authors acknowledge NSF grant IIS-1017614

This is facilitated by (i) a remarkably efficient finite time optimization over the infinite space of all monotonic transformations and (ii) properties of Bregman divergences particularly suited for learning orders.

Let us draw a few analogies from classification. A pointwise approach to a $\{-1, 1\}$ encoded classification problem would try to fit the $\{-1, 1\}$ training scores exactly, possibly enriching the approximating function class till the quality of the fit is acceptable. Most successful classifiers, however, fit values that are discriminable, ignoring, entirely, whether they are close to the training scores of $\{-1, 1\}$ in value.

The MR cost function consists of two parts: a loss and a regularization. Similar to perceptrons, the moment MR predictions retrieve the training ranks, its loss drops to zero. Experience in classification has taught us that losses that continue to be active after training error has dropped to zero yield better accuracy, for example, SVMs, logistic regression and boosting. In our paper we equip MR with such a margin-like property. This can be done in a few different ways. Our intent is not to champion one over another. This paper is not about advocacy, but about exploring how margin may be incorporated into the “*retargeting*” paradigm.

In this paper (i) we introduce large and fixed margin variants of the MR approach. Without margins the MR cost function is degenerate, an aspect that is not developed in the previous work [1]. Unlike the previous approach, we model the requirement of a margin explicitly in this paper. (ii) Unlike [1] we are able to model the notion that ordering errors at the top are worse than those at the bottom. (iii) It was shown that MR cost function is jointly convex *iff* the Bregman divergence chosen is squared Euclidean. We extend the formulation to enable joint convexity to all strongly convex Bregman divergence, not to advocate non-Euclidean divergences but to explore them.

Joint convexity has two important ramifications: one affects ease of evaluation of the technique, the other affects efficiency of training. The initialization independence of the optimum, gained as a result of convexity induced uniqueness, makes comparing different Bregman divergences easier, eliminating the need for multiple initializations during training. (iv) On the other hand for training, joint convexity allows us to replace *exact* coordinate-wise updates that were used in [1] with more efficient gradient updates with guarantees on global optimality. (v) This yields efficient online algorithms with regret bounds over permutations. Finally, (vi) we provide rates of convergence guarantees, an aspect missing from the previous work.

To date many cost functions have been designed to *evaluate* rankings, for example, discounted cumula-

tive gain (DCG), normalized discounted cumulative gain (NDCG) [13], expected reciprocal rank (ERR) [7], mean average precision (MAP) [3]. They are functions of permutations and capture the notion that positional accuracy at the top is more important than at the bottom. They are reasonably easy to compute given a ranking, but to optimize them in training is notoriously intractable. Our formulation, on the other hand, introduces a family of cost functions that have characteristics desired in ranking: dependence on order not on scores and the ability to capture the importance of non-uniform positional accuracy, but at the same time optimized *globally* with ease. These aspects set our work apart from other approaches of learning to rank.

We follow the **notation** used in the MR paper. Vectors are denoted by bold lower case letters, matrices are capitalized. \mathbf{x}^\dagger is \mathbf{x} transposed and $\|\mathbf{x}\|$ its L_2 norm. Adj-Diff(\cdot) is the adjacent difference operator, and Cum-Sum(Adj-Diff(\mathbf{x})) = \mathbf{x} . \mathbf{x} is in *descending order* if $x_i \geq x_j$ when $i > j$. the set of such vectors is \mathcal{R}_\downarrow . \mathbf{x} is isotonic with \mathbf{y} if $x_i \geq x_j$ implies $y_i \geq y_j$. Δ denotes an unit simplex and Δ_ϵ its subset with members component-wise bounded away from 0 by ϵ . \mathbb{R}_+^d is the positive orthant and R_ϵ^d its subset similarly bounded away from 0 by ϵ . Interior is denoted by int .

2 BACKGROUND

We will use **Bregman Divergences** to construct our cost function. Let $\phi : \Theta \mapsto \mathbb{R}$, $\Theta = \text{dom } \phi \subseteq \mathbb{R}^d$ be a strictly convex, closed function, differentiable on $\text{int } \Theta$. The corresponding Bregman divergence $D_\phi(\cdot || \cdot) : \text{dom}(\phi) \times \text{int}(\text{dom}(\phi)) \mapsto \mathbb{R}_+$ is defined as $D_\phi(\mathbf{x} || \mathbf{y}) \triangleq \phi(\mathbf{x}) - \phi(\mathbf{y}) - \langle \mathbf{x} - \mathbf{y}, \nabla \phi(\mathbf{y}) \rangle$. From strict convexity it follows that $D_\phi(\mathbf{x} || \mathbf{y}) \geq 0$ and $D_\phi(\mathbf{x} || \mathbf{y}) = 0$ iff $\mathbf{x} = \mathbf{y}$. Bregman divergences are (strictly) convex in their first argument, but not necessarily convex in their second.

In this paper we only consider functions $\phi(\cdot) : \mathbb{R}^n \ni \mathbf{x} \mapsto \sum_i w_i \phi(x_i)$ that are weighted sums of *identical* scalar convex functions applied to each component, the former referred to as *weighted, identically separable (WIS)* or **IS** if the weights are equal. [1] and [21] identify this class to have properties particularly suited for ranking. The MR approach, in concert with Bregman divergences can provide compelling guarantees that includes convergence, parallelizability, statistical consistency, and avoids solving a linear assignment problem in every iteration of their training loop. Many LETOR algorithms [24], [25] fall prey to the latter.

Monotone Retargeting: The ranking problem in-

volves set of queries $\mathcal{Q} = \{q_1, q_i \dots q_{|\mathcal{Q}|}\}$ and a set of training items \mathcal{V} . For every query q_i , the elements of $\mathcal{V}_i \subset \mathcal{V}$ are ordered based on their relevance to the query. This ordering is expressed through a rank score vector $\tilde{\mathbf{r}}_i \in \mathbb{R}^{|\mathcal{V}_i|}$ whose components \tilde{r}_{ij} correspond to items in \mathcal{V}_i . Beyond establishing the order, the actual values are irrelevant. In our formulation, however, one may choose whether to treat these as irrelevant or incorporate them in the *retargeting* step, making the formulation more flexible.

For a query q_i the index j of \tilde{r}_{ij} is local to \mathcal{V}_i and assigned such that \tilde{r}_{ij} are in descending order for any \mathcal{V}_i . For every pair $\{q_i, v_{ij}\}$ a feature vector $\mathbb{R}^n \ni \mathbf{a}_{ij} = F(q_i, v_{ij})$ is an input to the algorithm, \mathbf{A}_i is a matrix whose j^{th} row is \mathbf{a}_{ij}^\dagger . The following formulation seems suitable for ranking:

$$\min_{\mathbf{w}, \Upsilon_i \in \mathcal{M}} \sum_i D_i(\tilde{\mathbf{r}}_i, \Upsilon_i \circ f(\mathbf{A}_i, \mathbf{w})), \quad (1)$$

where $D_i : \mathbb{R}^{|\mathcal{V}_i|} \times \mathbb{R}^{|\mathcal{V}_i|} \mapsto \mathbb{R}_+$ is some distance-like loss function, $f : \mathbb{R}^{|\mathcal{V}_i| \times n} \times \mathbb{R}^n \mapsto \mathbb{R}^{|\mathcal{V}_i|}$ is some parametric form with the parameter \mathbf{w} and $\Upsilon_i : \mathbb{R}^{|\mathcal{V}_i|} \mapsto \mathbb{R}^{|\mathcal{V}_i|}$ is a mapping that transforms the components by a scalar, strictly monotonic increasing function Υ_i , and \mathcal{M} is the class of all such functions. Formulation (1) avoids the problem that adversely affects point-wise-methods: solving an unnecessarily hard problem of matching the scores by value.

To avoid working in the space of \mathcal{M} which is infinite dimensional, MR solves a qualitative equivalent

$$\min_{\mathbf{w}, \mathbf{r} \in \mathcal{R}_{\downarrow_i}} \sum_i D_i(\mathbf{r}_i, f(\mathbf{A}_i, \mathbf{w})) \text{ s.t. } \mathcal{R}_{\downarrow_i} = \{\mathbf{r} \mid \exists \mathbf{M} \in \mathcal{M} \text{ } \mathbf{M}(\tilde{\mathbf{r}}_i) = \mathbf{r}\}. \quad (2)$$

Let us take a closer look at the constraint set used in formulation (2): Instead of considering all strictly increasing monotonic transforms Υ_i of the right argument, MR considers all inverse monotonic transformations of the left argument. This, remarkably, is a finite dimensional optimization problem because $\mathcal{R}_{\downarrow_i}$, the set of all vectors isotonic with $\tilde{\mathbf{r}}_i$ is a finitely characterizable convex cone. Motivated by convexity, MR chooses $D_i(\cdot, \cdot)$ to be a Bregman divergence $D_\phi(\cdot \parallel \cdot)$ and $f(\mathbf{A}_i, \mathbf{w})$ to be $(\nabla\phi)^{-1}(\mathbf{A}_i\mathbf{w})$ to obtain¹

$$\min_{\beta_i, \mathbf{w}, \mathbf{r}_i \in \mathcal{R}_{\downarrow_i} \cap \mathcal{S}_i} \sum_{i=1}^{|\mathcal{Q}|} \frac{1}{|\mathcal{V}_i|} D_\phi(\mathbf{r}_i \parallel (\nabla\phi)^{-1}(\mathbf{A}_i\mathbf{w} + \beta_i\mathbf{1})) + \frac{C}{2} \|\mathbf{w}\|^2. \quad (3)$$

¹We take a shortcut of writing $D_\phi(\cdot \parallel (\nabla\phi)^{-1}(\cdot))$ instead of $D_{\phi_i}(\cdot, (\nabla\phi)^{-1})$ where ϕ_i indicates a separable convex function of an input dimension d_i built from component-wise sum of scalar function $\phi(\cdot)$.

$$\mathbf{P}_i^{t+1} = \underset{\pi}{\text{Argmin}} D_\phi(\mathbf{r}_i^t \parallel (\nabla\phi)^{-1}(\pi\mathbf{A}_i\mathbf{w}^t + \beta_i^t)) \quad \forall i \quad (4)$$

$$\mathbf{r}_i^{t+1} = \underset{\mathbf{r} \in \mathcal{R}_{\downarrow_i} \cap \mathcal{S}_i}{\text{Argmin}} D_\phi(\mathbf{r} \parallel (\nabla\phi)^{-1}(\mathbf{P}_i^{t+1}\mathbf{A}_i\mathbf{w}^t + \beta_i^t)) \quad \forall i \quad (5)$$

$$\mathbf{w}^{t+1}, \{\beta_i^{t+1}\} = \underset{\mathbf{w}, \{\beta_i\}}{\text{Argmin}} \sum_{i=1}^{|\mathcal{Q}|} D_\phi(\mathbf{r}_i^{t+1} \parallel (\nabla\phi)^{-1}(\mathbf{P}_i^{t+1}\mathbf{A}_i\mathbf{w} + \beta_i^t)) \frac{C}{2} \|\mathbf{w}\|^2 \quad (7)$$

Figure 1: Updates of Monotone Retargeting

where $(\nabla\phi)^{-1}$ is the inverse of the gradient mapping, \mathcal{S}_i is a convenient convex set excluding $\mathbf{0}$, that is necessary only for technical reasons.

In practice, even if \mathcal{V}_i is totally ordered, it is common to have a part of that information erased by quantization in the scores $\tilde{\mathbf{r}}$. MR deals with this by optimizing over block diagonal permutation matrices \mathbf{P}_i that permute contiguous blocks of indices that correspond to items whose relative order have been erased. The model is trained by iterating over the updates (4), (5) and (7) shown in Figure 1. It has been shown that these *exact coordinate-wise minimizations* updates converge to a local minimum (*or global for square loss* [1]) of function (3). Update (4) is accomplished by sorting. This turns out to be so because of special properties of separable Bregman divergences (see [1] for details). Update (5) uses the exponentiated gradient algorithm [15] and (7) is the same problem as estimating the parameters of a generalized linear model [19]. A quasi-Newton method (LBFGS [17]) was used to solve (7). In the rest of the paper the block diagonal permutation matrices \mathbf{P}_i will be suppressed. Our extensions continue to be effective for partial order via updates that correspond to (4), but this is not elaborated further for brevity.

3 FORMULATION

The rest of the paper describes our contribution. Its prominent features are: (i) formulation of fixed and large margin aspects, (ii) *joint* convexity of the cost function in the targets \mathbf{r} and the parameters \mathbf{w} , which yields (iii) guarantees on performance in the online setting and super-linear convergence in the batch setting.

Since there are multiple moving parts in our formulation, it is easy to get lost in the details. To preempt that we lay out the flow of our arguments. We explain the formulation by modifying the cost function (3) suc-

cessively. We conclude each subsection with summary of what has been achieved in the subsection so far.

Convexity: We equip the cost function with strong and joint convexity, aspects missing in the original work. We pick a *matching* form of the regularizer so that it adds no extra computational burden and quantify the amount of regularization that is sufficient to guarantee joint convexity. It may not be surprising that regularization extends convexity properties to MR losses other than squared Euclidean. What is surprising, however, is that this convexity applies jointly to \mathbf{r} and \mathbf{w} although the regularizers themselves are separated. Strong joint convexity and smoothness thus gained lead to the performance and convergence guarantees. This is the topic of section 3.1.

Margins: Second we plug a loophole in the MR cost function by ensuring margins between all adjacent target scores $r_{i,j}, r_{i,j+1}$. Without this, the cost function (3) is degenerate: one can achieve zero loss by setting $\mathbf{w}, \beta = \mathbf{0}$. We provide different ways of ensuring this: (i) directly by setting constraints, and (ii) indirectly by rewarding margins. Since both the constraints and the rewards are linear, this does not disrupt joint convexity. The key is to optimize the modified cost function efficiently. This is the topic of section 3.3.

3.1 Convexity, Smoothness and Optimization

MR ensures joint convexity *only* if squared Euclidean distance is used. We incorporate joint convexity into the cost function (3). This benefits us in two ways: (i) it removes initialization dependence of the training method and (ii) as we shall see, allows for a more efficient method of training, both online and batch with excellent convergence rates. We know that strong convexity together with smooth gradients (and Hessians for second order methods) admit efficient minimization: gradient descent achieves linear rate of convergence, quasi-Newton (truncated-Newton) achieves superlinear rates. We examine conditions under which our ranking formulations have these properties.

3.1.1 Joint Convexity

Let $\phi(\cdot)$ be s strongly convex [5]. Consider the term:

$$F_i(\mathbf{r}_i, \mathbf{w}) = \frac{1}{|\mathcal{V}_i|} \left(D_\phi(\mathbf{r}_i \parallel (\nabla\phi)^{-1}(\mathbf{A}_i\mathbf{w})) + \underbrace{C_{r_i} D_\phi(\mathbf{r}_i \parallel \mathbf{q}_i) + \frac{C_{w_i}}{2} \|\mathbf{w}\|_{A_i}^2}_{\text{Regularization terms}} \right) \quad (8)$$

using which we modify cost function (3) to

$$F(\{\mathbf{r}_i\}, \mathbf{w}) = \sum_i \frac{|\mathcal{Q}|}{|\mathcal{V}_i|} F_i(\mathbf{r}_i, \mathbf{w}) + \frac{C}{2} \|\mathbf{w}\|^2. \quad (9)$$

The β terms of equation (3) may be absorbed into \mathbf{A}_i by augmenting the features by vectors of ones, so no generality is lost in equation (9).

Let us pause to take note of the extra terms in the cost function (9). There is a term regularizing \mathbf{w} towards 0 and another regularizing \mathbf{r}_i towards \mathbf{q}_i . Vector \mathbf{q}_i is a ‘‘center’’ of regularization for the targets \mathbf{r}_i . If C_{r_i} are nonzero we set these to $\tilde{\mathbf{r}}_i$ when training scores are available, otherwise we use $\mathbf{q}_i = \text{Argmin}_{\mathbf{x}} \phi_i(\mathbf{x})$ when only ordering is available (this corresponds to $\mathbf{0}$ for square loss and uniform distribution for KL loss). This allows one to bias the targets towards the training scores when C_{r_i} is high and focus on order otherwise.

Proposition 1. *Let ϕ be s strongly convex with L Lipschitz continuous gradients, and σ_i be the smallest singular value of A_i , then the cost function (9) is jointly convex if*

$$\sum \frac{\sigma_i(C_{w_i}+1/L)}{|\mathcal{V}_i|} + \frac{C}{2} - \frac{4\mathcal{Q}(\sum \frac{1}{|\mathcal{V}_i|})^2}{s \sum \frac{1+C_{r_i}}{|\mathcal{V}_i|}} \geq 0$$

Proof. $\sum_{i=1}^{|\mathcal{Q}|} \frac{1}{|\mathcal{V}_i|} \begin{bmatrix} (1+C_{r_i})H_\phi & -I \\ -I & A_i^\dagger(H_\psi+C_{w_i})A_i + \frac{C}{2}|\mathcal{Q}|I \end{bmatrix}$, is the Hessian of the cost function (9) where ψ is the Legendre conjugate of ϕ and H_ϕ, H_ψ the corresponding diagonal. Recall that $\phi(\cdot)$ and consequently $\psi(\cdot)$ are separable. The smallest eigenvalue of the Hessian may be bounded as the value of the following optimization problem:

$$\min \langle \mathbf{y}, \mathbf{y} \rangle \left(\sum_i \frac{\sigma_i}{|\mathcal{V}_i|} (C_{w_i} + \frac{1}{L}) + \frac{C}{2} \right) - 2 \langle \mathbf{x}, \mathbf{y} \rangle \sum_i \frac{|\mathcal{Q}|}{|\mathcal{V}_i|} + \langle \mathbf{x}, \mathbf{x} \rangle \sum_i \frac{s}{|\mathcal{V}_i|} (1 + C_{r_i}) \quad \text{s.t.} \quad \langle \mathbf{x}, \mathbf{x} \rangle + \langle \mathbf{y}, \mathbf{y} \rangle = 1 \quad (10)$$

where σ_i is the smallest singular value of A_i . Invoking Cauchy-Schwarz inequality and treating the expression as a quadratic function in $\sqrt{\langle \mathbf{x}, \mathbf{x} \rangle}$ we can see that convexity is implied by $\sum \frac{\sigma_i(C_{w_i}+1/L)}{|\mathcal{V}_i|} + \frac{C}{2} - \frac{4(\sum \frac{|\mathcal{Q}|}{|\mathcal{V}_i|})^2}{s \sum \frac{1+C_{r_i}}{|\mathcal{V}_i|}} \geq 0$ \square

Corollary 1. *The cost function (9) is jointly convex if $C \geq \frac{8\mathcal{Q}}{s(1+C_r)} (\sum \frac{1}{|\mathcal{V}_i|})$, if $C_{r_i} = C_r \forall_i$.*

Corollary 1 gives practitioners an easy thumb rule to ensure joint convexity.

These additional regularization terms do not come at an extra computational burden. Estimating \mathbf{r}, \mathbf{w} remain just as easy. We show that the result of the additional terms are that the \mathbf{r}_i updates (5) need to be computed with respect to the *deflected* predicted score $(\nabla\phi)^{-1}(\alpha\mathbf{A}\mathbf{w} + (1-\alpha)\nabla\phi(\mathbf{q}_i))$, as opposed to the predicted score $(\nabla\phi)^{-1}(\mathbf{A}\mathbf{w})$.

Lemma 1. *Let $\alpha_i = \frac{1}{1+C_{\phi_i}}$, then $\text{Argmin}_{\mathbf{r}_i \in \mathcal{R}_{\downarrow_i} \cap \mathcal{S}_i} F_i(\mathbf{r}_i, \mathbf{w}) = \text{Argmin}_{\mathbf{r}_i \in \mathcal{R}_{\downarrow_i} \cap \mathcal{S}_i} D_\phi(\mathbf{r}_i \parallel (\nabla\phi)^{-1}(\alpha_i\mathbf{A}_i\mathbf{w} + (1-\alpha_i)\nabla\phi(\mathbf{q}_i)))$.*

Proof. Use $\mathbb{E}_{\mathbf{x} \sim \pi} [D_\phi(\mathbf{x} \parallel \mathbf{s})] = \mathbb{E}_{\mathbf{x} \sim \pi} [D_\phi(\mathbf{x} \parallel \boldsymbol{\mu})] + D_\phi(\boldsymbol{\mu} \parallel \mathbf{s})$ [4]. \square

3.1.2 Marginal Strong Convexity and Smoothness

Recall our motivations for pursuing joint convexity: (i) initialization independence of the training and (ii) more efficient training algorithms. In light of Proposition 1 and Corollary 1, the reader should be convinced of the former. In this section we explore how joint convexity may be exploited to provide an efficient optimization algorithm for training, as well as guarantees of convergence rates. Previous work on MR [1] come with no guarantees on rates of convergence.

The MR cost function was minimized in [1] using *exact* coordinate-wise minimizations. This can be expensive for the \mathbf{w}, β updates (7) because they are iterative in nature. Further since a single \mathbf{w}, β update is equivalent to solving a generalized linear model (GLM), it is clear that the MR procedure would be slower than solving for a GLM because typically multiple iterations of GLM update are required for convergence.

Here we will replace exact coordinate-wise minimizations over \mathbf{r}, \mathbf{w} by inexact gradient descent updates that satisfy any of the standard ‘‘sufficient descent’’ criteria [5] (for example Armijo’s criteria) used in gradient based methods. Joint convexity will play a crucial role in making this possible.

Joint convexity of $F(\{\mathbf{r}_i\}, \mathbf{w})$ allows us to work with the marginal function

$$G(\mathbf{w}) = \min_{\{\mathbf{r}_i\}} F(\{\mathbf{r}_i\}, \mathbf{w}) \quad (11)$$

without losing convexity. This luxury is not available in MR. The marginal function is guaranteed to be convex when the joint function is convex [23]. Recall convexity is always preserved under pointwise *maximization*, however if the function is *jointly convex* it is also preserved under pointwise minimization as in equation (11).

The gradient $\nabla G(\mathbf{w})$ of the marginal is obtained as

$$\nabla G(\mathbf{w}) = \sum_i \frac{|\mathcal{Q}|}{i} G_i(\mathbf{w}) = \sum_i \frac{|\mathcal{Q}|}{i} \nabla F_i(\{\mathbf{r}_i^*\}, \mathbf{w}) \quad (12)$$

where $\mathbf{r}_i^* = \text{Argmin}_{\mathbf{r}_i \in \mathcal{R}_i} F_i(\mathbf{r}_i, \mathbf{w})$.

Now we can make a few observations: for a choice of a closed form of $\phi(\cdot)$ we know ∇F_i in closed form. Hence the moment we are able to compute \mathbf{r}_i^* we can also compute the gradient of the function $G(\mathbf{w})$ and hence minimize it using any gradient based minimization methods. Also observe that this *gradient compu-*

tation trivially parallelizes because the \mathbf{r}_i s are all independent and can be computed simultaneously. We shall show that \mathbf{r}_i^* can be computed very efficiently in not only finite time but also linear in the number of training points per query. This is covered in Section 3.5.

If in addition to just convexity of the marginal function $G(\mathbf{w})$ we also had strong convexity, not only would it facilitate super-linear convergence of quasi-Newton methods, but it will also guarantee logarithmic regret in the online setting [11]. With these motivations in mind we investigate the conditions for strong convexity of $G(\mathbf{w})$. We do so by examining the Hessian $\nabla^2 G(\mathbf{w})$. Note however that $G(\mathbf{w})$ is not obtained in closed form but by equation (11), which we now need to differentiate twice to find the Hessian.

Differentiating Twice Under the Minimization

Sign: A prominent role is played in the analysis by the ability to differentiate under the minimization sign. We do not know the function $G(\mathbf{w})$ in closed form but are able to compute its Hessian in terms of \mathbf{r}_i^* . Using assumptions of continuous second order differentiability and the shorthand $F_i^* = F_i(\mathbf{r}_i^*, \mathbf{w})$ we obtain

$$\begin{aligned} \nabla^2 G_i(\mathbf{w}) &= \nabla_{\mathbf{w}}^2 F_i^* - \nabla_{\mathbf{w}, \mathbf{r}_i} \nabla F_i^{*\dagger} (\nabla_{\mathbf{r}_i}^2 F_i^*)^{-1} \nabla_{\mathbf{w}, \mathbf{r}_i} \nabla F_i^* = \\ &= \frac{\mathbf{A}_i^\dagger}{|\mathcal{V}_i|} \left[H_\psi + C_{w_i} - \frac{1}{1 + C_{r_i}} (H_\phi)^{-1} \right] \mathbf{A}_i + \frac{C}{|\mathcal{Q}|} I \quad (13) \end{aligned}$$

by differentiation twice under the min operator. Expression (13) will be useful because it allows to determine when is $G(\mathbf{w})$ strongly convex (see Lemma 2) and also because it gives us a way to compute the Hessian that is important for Newton methods that we employ.

Lemma 2. *If ϕ is s strongly convex with L -Lipschitz continuous gradient and σ_i is the principal singular value of \mathbf{A}_i , then $G(\mathbf{w})$ is C strongly convex if $\sum_i \left(\frac{\sigma_i}{L} + \sigma_i C_{w_i} - \frac{\sigma_i}{s(1+C_{r_i})} \right) > 0$.*

Strong convexity and Lipschitz continuity of the gradient ensures that a gradient descent method will have linear rate of convergence [5]. Lemma 2 gives the practitioner a way to choose C_{w_i} and C_{r_i} appropriately.

Can the convergence rates be pushed further? Can we obtain locally quadratic convergence? We answer in the affirmative in the next section.

3.1.3 Lipschitz Continuity of Hessian

In order to enjoy local quadratic convergence, quasi-Newton methods require that the objective function (i) be twice differentiable, (ii) be strongly convex and (iii) have Lipschitz continuous Hessians [5]. The first two have already been established, now we explore

the third. Observe from equation (13) that we only need to be concerned about the sensitivity of the term $[H_\psi + C_{w_i} - \frac{1}{1+C_{\phi_i}}(H_\phi)^{-1}]$ to variations in \mathbf{w} . We make the notation more precise about dependency on \mathbf{w} . Let $\mathbf{r}_i^*(\mathbf{w}) = \text{Argmin}_{\mathbf{r}_i \in \mathcal{R}_i} F_i(\mathbf{r}_i, \mathbf{w})$ and the parenthesis indicate where the Hessians are evaluated in the expression: $[H_\psi(\mathbf{w}) + C_{w_i} - \frac{1}{1+C_{\phi_i}}(H_\phi(\mathbf{r}_i^*(\mathbf{w})))^{-1}]$.

Lemma 3. *Let $\psi(\cdot)$ be the Legendre conjugate of $\phi(\cdot)$ that defines the cost function $G(\mathbf{w})$ in equation (11). Then if $\psi(\cdot)$ has a Lipschitz continuous Hessian then $G(\mathbf{w})$ has a Lipschitz continuous Hessian.*

Proof. $[H_\psi(\mathbf{w}) + C_{w_i} - \frac{1}{1+C_{\phi_i}}(H_\phi(\mathbf{r}_i^*(\mathbf{w})))^{-1}] = [H_\psi(\mathbf{w}) + C_{w_i} - \frac{1}{1+C_{\phi_i}}H_\psi(\nabla\phi(\mathbf{r}_i^*(\mathbf{w})))]$ using Legendre duality. Further, the vector $\nabla\phi(\mathbf{r}_i^*(\mathbf{w}))$ turns out to be the Euclidean projection of the vector $\mathbf{A}_i\mathbf{w}$ on the set \mathcal{R}_i (see Proposition 2). Since projection is a non-expansive operator, $H_\psi(\nabla\phi(\mathbf{r}_i^*(\mathbf{w})))$ is Lipschitz continuous in \mathbf{w} . \square

3.1.4 Summary: Impact on Optimization

Let us take stock of what have we achieved so far. Lemmas 1 through 3 led to quantitative guarantees on rate of convergence in the batch setting. They allow selecting the regularization parameters C_{ϕ_i}, C_{w_i} based on desired convergence performance. The paper [1] could not provide any such quantitative guarantees, because their cost function was not proven to be jointly convex. Note that the nested minimization in the gradient computation trivially parallelizes. We shall see that each parallel task completes in finite time (Section 3.6). *Batch gradient descent on the marginal with (12) evaluated in parallel* converges linearly as a result of strong marginal convexity and smoothness [5]. *Stochastic gradient descent by sampling an index from (12)* also has linear rate of convergence (in an expected sense) [20]. *Quasi-Newton (and truncated Newton) methods with parallel evaluation of gradients* use the gradient computation (12) (and explicit Hessian (13) which has a simple diagonal structure) have superlinear convergence [5].

3.2 Online Algorithm for Learning Permutations

In this section we propose an online model for learning to rank where we have a varying set of items that need to be ordered in each round. The adversary, at round t provides the feature matrix \mathbf{A}_t of d_t items that it has ranked, but that order is not revealed till the learner responds with a “scoring vector” \mathbf{w}_t . The learner is then charged a cost of $G_t(\mathbf{w}_t)$ as defined in (11) according to any twice differentiable σ strongly

convex function ϕ_t with L Lipschitz continuous gradient. The order and the function ϕ_t is then revealed for the learner to use. The objective is to minimize the cumulative loss $\sum_t G_t(\mathbf{w}_t)$.

For the t^{th} gradient update we use the t^{th} term of the gradient (12) with a learning rate of $\frac{1}{\sigma t}$ as

$$\mathbf{w}_{t+1} = \mathbf{w}_t - \frac{1}{\sigma t} F_t(\{\mathbf{r}_t^*\}, \mathbf{w})$$

where $\mathbf{r}_t^* = \text{Argmin}_{\mathbf{r}_t \in \mathcal{R}_t \cap \mathcal{S}_t} F_t(\mathbf{r}_t, \mathbf{w})$ and F_t is defined in (9).

Theorem 1. [11] *The online gradient algorithm applied in an online setting to a s strongly function that has L Lipschitz continuous gradients has regret $\mathcal{O}(\frac{L^2}{\sigma} \log T)$.*

Neither the algorithm nor the bound is new, what is novel though is that the ranking problem of such combinatorial nature can be transformed into a form, without loss in generality, that this algorithm can exploit.

Summary: This concludes what we have to say about the implications joint convexity of the cost function we propose. One can see that it leads to quantitative guarantees on rate of convergence in the batch setting and performance guarantees in the online and the adversarial setting. Now we turn our attention the next topic of this paper: large margins.

3.3 Margins

Performant classification loss functions such as hinge loss [22], logistic loss and exponential loss [9] continue to be active even after training error has fallen to zero. For MR such a margin like property is not only beneficial but also essential because otherwise the cost function is degenerate as may be verified by setting $\mathbf{w}, \beta = \mathbf{0}$. The necessity of this margin property is not mentioned in [1]. Here we take an explicit approach.

By controlling the margin we can also model the notion that errors at the top of the list are more severe than at the bottom. We achieve this by adding linear inequalities and terms. Therefore the properties of strong convexity and Lipschitz continuity of the gradient established in Section 3.1 continue to hold.

We incorporate the margin property in two alternative ways. We augment the cost function (9) by introducing a fixed margin (14) and alternatively a large margin variant (15). In addition to enforcing order in the target vector \mathbf{r}_i it enforces (for the fixed margin formulation) or encourages (for the large margin formulation) a gap between the target values of adjacently ordered items $r_{i,j}, r_{i,j+1}$. In the formulations (14), (15), the components of \mathbf{t}_i denote the gap between the adjacent

targets. In (14) the gaps are pre-specified. It is natural to specify a comparatively higher gap at the top. In (15) the gaps are not specified explicitly, but a reward c_i is awarded per unit gap.

The **fixed margin formulations** is posed in terms of positive pre-prescribed margins $t_{i,j}$ as follows:

$$\begin{aligned} \min_{\mathbf{r}_i, \mathbf{w}} \sum_{i=1}^{|\mathcal{Q}|} F_i(\mathbf{r}_i, \mathbf{w}) \\ r_{i,j+1} - r_{i,j} \geq t_{i,j} \quad \forall j \in [0, d_i - 1], \forall i \in [1, |\mathcal{Q}|] \\ r_{i,0} \geq t_{i,0} \quad \forall i \in [1, |\mathcal{Q}|] \end{aligned} \quad (14)$$

The **large margin formulations** are posed in terms of a vector of *rewards* c_i associated with the vector of gaps $\mathbf{t}_i > \mathbf{0}$ as follows: for every query $q_i \in \mathcal{Q}$, solve:

$$\begin{aligned} \min_{\mathbf{r}_i, \mathbf{w}, \mathbf{t}_i} \sum_{i=1}^{|\mathcal{Q}|} F_i(\mathbf{r}_i, \mathbf{w}) - \langle \mathbf{c}_i, \mathbf{t}_i \rangle \\ r_{i,j+1} - r_{i,j} \geq t_{i,j} \geq 0 \quad \forall j \in [0, d_i - 1], \forall i \in [1, |\mathcal{Q}|] \\ r_{i,0} \geq t_{i,0} \quad \forall i \in [1, |\mathcal{Q}|], \end{aligned} \quad (15)$$

Note that the \mathbf{r}_i optimization is a Bregman projection problem. Furthermore, the \mathbf{r}_i 's are independent and therefore can be projected in parallel. Readers familiar with generalized linear models (GLM) will recognize that the optimization over \mathbf{w} is penalized maximum likelihood parameter estimation for GLMs. Since this procedure is standard, we focus on \mathbf{r} and \mathbf{t} only in the interest of space.

3.4 Bregman Projection on $\mathcal{R}_{\downarrow \mathbf{t}}$

Both the formulations (14) and (15) involve Bregman projections on $\mathcal{R}_{\downarrow \mathbf{t}}$. Elements of $\mathcal{R}_{\downarrow \mathbf{t}} \subset \mathbb{R}^n$ are not only sorted but also have separation between adjacent components, given by the vector \mathbf{t} . In this section we reduce it to a square Euclidean projection on $\text{Argmin}_{\mathbf{y} \in \mathcal{R}_{\downarrow \mathbf{t}}}$, hence removing the need to solve a non-linear optimization problem. It is quite remarkable that this is possible. For the reduction to hold we need additional assumptions of strong convexity and/or Lipschitz continuity. Consider the problem:

$$\min_{\mathbf{r}} D_{\phi}(\mathbf{r} \parallel (\nabla \phi)^{-1}(A\mathbf{w})) \text{ s.t. } \text{Adj-Diff}(\mathbf{r}) \leq \mathbf{t}. \quad (16)$$

If $\mathbf{t} = \mathbf{0}$ this is $\min_{\mathbf{r} \in \mathcal{R}_{\downarrow}} D_{\phi}(\mathbf{r} \parallel (\nabla \phi)^{-1}(A\mathbf{w}))$. When \mathbf{t} is component-wise strictly positive it imposes strict margin between adjacent components of \mathbf{r} .

Proposition 2. *Let $\phi(\cdot)$ be s strongly convex, then*

$$\begin{aligned} (\nabla \phi)^{-1}(\mathbf{z}^*) = \text{Argmin}_{\mathbf{r}} D_{\phi}(\mathbf{r} \parallel (\nabla \phi)^{-1}(A\mathbf{w})) + \langle \mathbf{v}, \mathbf{r} \rangle \\ \text{s.t. } \text{Adj-Diff}(\mathbf{r}) \leq \mathbf{t} \end{aligned} \quad (17)$$

where $\mathbf{z}^* = \text{Argmin}_{\mathbf{z}} \|\mathbf{z} - A\mathbf{w}\| + \langle \mathbf{v}, \mathbf{r} \rangle$ s.t. $\text{Adj-Diff}(\mathbf{z}) \leq \mathbf{t}$.

Proof. For the moment let us ignore the term $\langle \mathbf{v}, \mathbf{r} \rangle$. Let the set of points satisfying the KKT conditions for (16) be $\mathcal{A} = \left\{ \begin{array}{l} \mathbf{r} \\ \boldsymbol{\lambda} \end{array} \middle| \begin{array}{l} \nabla \phi(\mathbf{r}) = A\mathbf{w} - \text{Adj-Diff}(\boldsymbol{\lambda}) \\ \text{Adj-Diff}(\mathbf{r}) \leq \mathbf{t} \end{array} \right\}$, let us denote the KKT points of the optimization problem

$$\min_{\mathbf{z}} \|\mathbf{z} - A\mathbf{w}\| \text{ s.t. } \text{Adj-Diff}(\mathbf{z}) \leq \mathbf{t} \text{ by } \mathcal{B} =$$

$$\left\{ \begin{array}{l} \mathbf{z} \\ \boldsymbol{\lambda} \end{array} \middle| \begin{array}{l} \mathbf{z} = A\mathbf{w} - \text{Adj-Diff}(\boldsymbol{\lambda}) \\ \text{Adj-Diff}(\mathbf{z}) \leq \mathbf{t} \end{array} \right\} = \left\{ \begin{array}{l} \nabla \phi(\mathbf{r}) \\ \boldsymbol{\lambda} \end{array} \middle| \begin{array}{l} \nabla \phi(\mathbf{r}) = A\mathbf{w} - \text{Adj-Diff}(\boldsymbol{\lambda}) \\ \text{Adj-Diff}(\nabla \phi(\mathbf{r})) \leq \mathbf{t} \end{array} \right\}.$$

From $r_{j+1} - r_j \geq t_j$ and strong convexity we have $\nabla \phi(r_{j+1}) - \nabla \phi(r_j) \geq st_j$ thus $\mathcal{A} \subset \mathcal{B}$. Complementary slackness conditions are also verified thus \mathcal{A}, \mathcal{B} are unique minimizers. The term $\langle \mathbf{v}, \mathbf{r} \rangle$ maintains the relation between \mathcal{A} and \mathcal{B} proving that the minima of the two problems coincide. \square

Proposition 3. *Let $\phi(\cdot)$ be strictly convex, $\mathbf{t} \leq \mathbf{0}$ and $\nabla \phi(\cdot)$ $\frac{1}{L}$ Lipschitz continuous, then minimizer \mathbf{z}^* of (17) is*

$$\mathbf{z}^* = \text{Argmin}_{\mathbf{z}} \|\mathbf{z} - A\mathbf{w}\| + \langle \mathbf{v}, \mathbf{r} \rangle \text{ s.t. } \text{Adj-Diff}(\mathbf{z}) \leq L\mathbf{t}.$$

Proof. Define \mathcal{A} and \mathcal{B} as before. From $\nabla \phi(r_{j+1}) - \nabla \phi(r_j) \geq Lt_j$ and Lipschitz continuity we have $r_{j+1} - r_j \geq t_j$ therefore $\mathcal{B} \subset \mathcal{A}$, but \mathcal{A} and \mathcal{B} are unique minimizers. Therefore the proposition holds. \square

The implications: of the propositions are, of course, that, for the optimization over \mathbf{r} , one only needs to implement the square loss variants of (14) and (15) because they are in correspondence with other Bregman divergences as long as the convex function is strongly convex or its gradient is Lipschitz continuous.

The final piece is to show that the reduced quadratic program (QP) is efficiently solvable. This is critical because it is required for the numerical evaluating the gradient (and Hessian) of $G(\mathbf{w})$ where we cannot afford the expense of a generic QP solver. We now show how the QP can be solved in linear time.

3.5 Pool Adjacent Violators Algorithm

The pool adjacent violators algorithm [10] solves

$$\min_{\mathbf{z}} \|\mathbf{z} - A\mathbf{w}\| \text{ s.t. } \text{Adj-Diff}_*(\mathbf{z}) \leq \mathbf{0} \quad (18)$$

called the isotonic regression problem. PAV is essentially a block coordinate ascent of the dual of (18). It runs in *finite time* and a straight-forward implementation scales as $\mathcal{O}(d^2)$ in the dimensions. Subsequently [10] observed that if implemented carefully it remarkably has complexity that is linear in d .

The nonlinear optimization problems (14) and (15) from (18). Fortunately, by a series of non-linear and linear change of variables one can reduce these problems to variations of the isotonic regression problem.

3.6 Decomposing the Margin Formulation

For a fixed \mathbf{w} , a plausible way to optimize (15) is to fix \mathbf{t}_i and optimize \mathbf{r}_i and alternate, keeping \mathbf{w} fixed. One may update \mathbf{w} once \mathbf{t}_i and \mathbf{r}_i converge. This clearly fails because the constraints couple \mathbf{r}_i and \mathbf{t}_i . However, we show that an affine transformation can not only correctly decompose the problem, but also that it separates out the problem out into versions of isotonic regression problems: namely isotonic regression with a lower-bound on the smallest r . Thus it adds another (scalar) constraint to the system $\text{Adj-Diff}(\mathbf{r}) \leq -\mathbf{t}$, where Adj-Diff is the adjacent-difference operator.

Because of the reduction properties shown in Propositions 2 and 3 to estimate \mathbf{r}_i in (15) one only needs to consider the problem of the form:

$$\min_{\mathbf{r}_i, \mathbf{t}_i} \frac{1}{2} \|\mathbf{r}_i - \mathbf{y}_i\|^2 - \langle \mathbf{c}_i, \mathbf{t}_i \rangle \quad \text{s.t.} \quad \text{Adj-Diff}(\mathbf{r}_i) \leq -\mathbf{t}_i, \quad \mathbf{t}_i > 0.$$

Substituting $\mathbf{t}_i = -\text{Adj-Diff}(\mathbf{d}_i)$, $\mathbf{z}_i = \mathbf{r}_i - \mathbf{d}_i$ we obtain

$$\begin{aligned} & \frac{1}{2} \|\mathbf{z}_i + \mathbf{d}_i - \mathbf{y}_i\|^2 + \langle \mathbf{c}_i, \text{Adj-Diff}(\mathbf{d}_i) \rangle \\ & \text{s.t.} \quad \text{Adj-Diff}(\mathbf{z}_i) \leq 0, \quad \text{Adj-Diff}(\mathbf{d}_i) \leq 0. \end{aligned} \quad (19)$$

The variables \mathbf{z}_i and \mathbf{d}_i are completely decoupled, the constraints are the ordering constraints, and if either \mathbf{z}_i or \mathbf{d}_i fixed, the formulation reduces to an isotonic problem in the other (for \mathbf{d}_i some simple algebraic manipulation is necessary to expose the PAV form). Thus, one may alternate over \mathbf{z}_i and \mathbf{d}_i as follows:

$$\mathbf{z}_i^{t+1} = \text{PAV}(\mathbf{y}_i - \mathbf{d}_i^t) \quad (20)$$

$$\mathbf{d}_i^{t+1} = \text{PAV}(\mathbf{y}_i - \mathbf{z}_i^{t+1} - \text{Adj-Diff}^\dagger(\mathbf{c})) \quad (21)$$

and obtain the large margin solution by recovering $\mathbf{r}_i, \mathbf{t}_i$ from converged \mathbf{z}_i and \mathbf{d}_i .

Problem (14) can be decomposed similarly using propositions 2, 3 and the exact same affine transformation $\mathbf{t}_i = -\text{Adj-Diff}(\mathbf{d}_i)$ and $\mathbf{z}_i = \mathbf{r}_i - \mathbf{d}_i$. Here however \mathbf{d}_i is immediately determined, so no iteration over the variables \mathbf{z}_i and \mathbf{d}_i is necessary and solving $\mathbf{z}_i = \text{PAV}(\mathbf{y}_i - \mathbf{d}_i)$ is sufficient to recover the optimal \mathbf{r}_i . *Since this requires a single instance of PAV, it is obvious that this converges in finite time, linear in the number of items.*

proach on the benchmark LETOR 4.0 datasets [18] as well as the OHSUMED dataset [12]. Each of these datasets are pre-partitioned into five-fold validation sets for easy comparison across algorithms. We focus on the variants that use Sqr-loss and KL-divergence because these are strongly convex Bregman divergences. We compare the performance of MEMR against the following strong baselines (i) The MR algorithm as reported in [1] (Recall that the MR algorithm has been shown to outperform many of the current state of the art techniques [1]), (ii) NDCG consistent generalized linear models that also use different Bregman divergences [21] and (iii) max-margin based pairwise learning to rank method RankSVM as implemented by SVMPerf [14] (Note RankSVM as implemented by SVMPerf is a factor of 20 faster than its original implementation in SVMLight). MEMR is implemented in C++ as a minimization method on the function $G(\mathbf{w})$. PAV algorithm is used to compute the gradient, and the Hessian. We tried two strategies (i) quasi-Newton using LBFGS [17] and (ii) Trust region truncated Newton (TRON) [16]. While both were an order of magnitude faster than our baselines the latter gave the fastest convergence. The CPU timings of serial implementations on a 2.8 Ghz Intel Quad core processor are reported in Table 1. We parallelized the LBFGS based implementation. The timings and corresponding speedups are shown in Table 2. We found that overprovisioning of threads (8 threads on a quad-core) was necessary to reach full speedup supported by the hardware.

In our experiments the fixed margin constraints (see equation (14)) were set using different non-increasing functions of the rank. In Figure 2 we show the effect of margins set to different constant values. In Figure 3 we show the effect of margins set by different polynomially decaying functions. The regularization parameter C was selected on the basis of maximum NDCG on

The plot labeled “Sqr-Loss” represents pointwise NDCG consistent Sqr loss proposed by [21]. Plot labeled “Sqr-MR” corresponds to MR [1] with Sqr-loss. Performance of RankSVM is also shown

5 CONCLUSION

In this paper we presented a margin based monotone retargeting framework for learning to rank. Pointwise ranking methods search for optimal parameters of a regression function to fit the training scores that were specified to define the correct ranking order. MEMR on the other hand searches not only for optimal parameters of a regression function but also over all order-

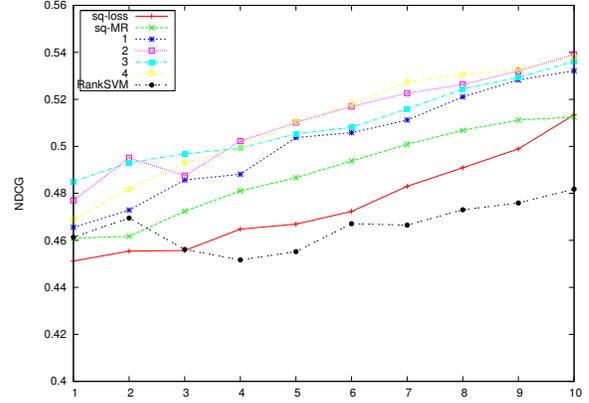

Figure 3: Truncated NDCG@N obtained on MQ2007 using Sqr-loss MEMR with margin between adjacent targets set by function $\frac{C}{\sqrt{r}}$ on the rank associated with the target. Plots shown for values of $C \in \{0.0625e-3, 0.125e-3, 0.25e-3, .5e-3\}$. The baselines are the same as in Figure 2.

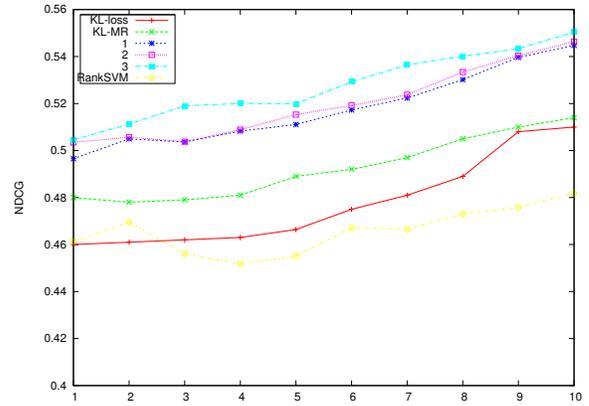

Figure 4: Truncated NDCG@N obtained on MQ2007 using KL-loss MEMR with margin between adjacent targets set by the function $\frac{C}{\sqrt{r}}$ for values of $C \in \{1e-1, 2e-1, 3e-1, 4e-1\}$. The plot labeled “KL-Loss” corresponds KL loss minimizing NDCG consistent GLM [21].

preserving transformations of the training score vectors such that its adjacent components are well separated. The separation property leads to state of the art performance as compared to MR and other max-margin based ranking formulations. Moreover its joint convexity and second order smoothness properties permit efficient algorithms that lead to running times that are a small fraction of competing algorithms, giving almost the best of both worlds: ranking accuracy better than pairwise methods and running times comparable to simple pointwise methods.

Abstract

While many multiagent algorithms are designed for homogeneous systems (i.e. all agents are identical), there are important applications which require an agent to coordinate its actions without knowing a priori how the other agents behave. One method to make this problem feasible is to assume that the other agents draw their latent policy (or type) from a specific set, and that a domain expert could provide a specification of this set, albeit only a partially correct one. Algorithms have been proposed by several researchers to compute posterior beliefs over such policy libraries, which can then be used to determine optimal actions. In this paper, we provide theoretical guidance on two central design parameters of this method: Firstly, it is important that the user choose a posterior which can learn the true distribution of latent types, as otherwise suboptimal actions may be chosen. We analyse convergence properties of two existing posterior formulations and propose a new posterior which can learn correlated distributions. Secondly, since the types are provided by an expert, they may be inaccurate in the sense that they do not predict the agents' observed actions. We provide a novel characterisation of optimality which allows experts to use efficient model checking algorithms to verify optimality of types.

1 INTRODUCTION

Many multiagent algorithms are developed with a homogeneous setting in mind, meaning that all agents use the same algorithm and are a priori aware of this fact. However, there are important applications for which this assumption may not be adequate, such as human-machine interaction, robot search and rescue, and financial markets. In such problems, it is important that an agent be able to effectively coordinate its actions without knowing *a priori* how the other agents

behave. The importance of this problem has been discussed in works such as [Albrecht and Ramamoorthy, 2013, Stone et al., 2010, Bowling and McCracken, 2005].

This problem is hard since the agents may exhibit a large variety of behaviours. General-purpose algorithms for multiagent learning are often impracticable, either because they take too long to produce effective policies or because they rely on prior coordination of behaviours [Albrecht and Ramamoorthy, 2012]. However, it has been recognised (e.g. [Albrecht and Ramamoorthy, 2013, Barrett et al., 2011]) that the complexity of this problem can often be reduced by assuming that there is a latent set of policies for each agent and a latent distribution over these policies, and that a domain expert can provide informed guesses as to what the policies might be. (These guesses could also be generated automatically, e.g. using some machine learning method on a corpus of historical data.)

One algorithm that takes this approach is *Harsanyi-Bellman Ad Hoc Coordination* (HBA) [Albrecht and Ramamoorthy, 2013]. This algorithm maintains a set of user-defined types (by “type”, we mean a policy or programme which specifies the behaviour of an agent) over which it computes posterior beliefs based on the agents' observed actions. The beliefs are then used in a planning procedure to compute expected payoffs for all actions (a procedure combining the concepts of Bayesian Nash equilibrium and Bellman optimality) and the best action is chosen. HBA was implemented as a reinforcement learning procedure and shown to be effective in both simulated and human-machine problems [Albrecht and Ramamoorthy, 2013]. Similar algorithms were studied in [Barrett et al., 2011, Carmel and Markovitch, 1999].

While works such as [Albrecht and Ramamoorthy, 2013, Barrett et al., 2011, Carmel and Markovitch, 1999] demonstrate the practical usefulness of such methods, they provide no theoretical guidance on two central design parameters: Firstly, one may compute the posterior beliefs in various ways, and it is important that the user choose a posterior formulation which is able to accurately approximate the latent distribution of types. This is important as otherwise the expected payoffs may be inaccurate, in which case HBA may

choose suboptimal actions. In this paper, we analyse the convergence conditions of two existing posterior formulations and we propose a new posterior which can learn correlated type distributions. These theoretical insights can be applied by the user to choose appropriate posteriors.

Secondly, since the types are provided by the user (or generated automatically), they may be inaccurate in the sense that their predictions deviate from the agents’ observed actions. This raises the need for a theoretical analysis of how much and what kind of inaccuracy is acceptable for HBA to be able to solve its task, by which we mean that it drives the system into a terminal state. (A different question pertains to payoff maximisation; we focus on task accomplishment as it already includes many practical problems.) We describe a methodology in which we formulate a series of desirable termination guarantees and analyse the conditions under which they are met. Furthermore, we provide a novel characterisation of optimality which is based on the notion of probabilistic bisimulation [Larsen and Skou, 1991]. In addition to concisely defining what constitutes optimal type spaces, this allows the user to apply efficient model checking algorithms to verify optimality in practice.

2 RELATED WORK

Opponent modelling methods such as case-based reasoning [Gilboa and Schmeidler, 2001] and recursive modelling [Gmytrasiewicz and Durfee, 2000] are relevant to the extent that they can complement the user-defined types by creating new types (the opponent models) on the fly. For example, [Albrecht and Ramamoorthy, 2013] used a variant of case-based reasoning and [Barrett et al., 2011] used a tree-based classifier to complement the user-defined types.

Plays and play books [Bowling and McCracken, 2005] are similar in spirit to types and type spaces. However, plays specify the behaviour of an entire team, with additional structure such as applicability and termination conditions, and roles for each agent. In contrast, types specify the action probabilities of a single agent and do not require commitment to conditions and roles.

Plans and plan libraries [Carberry, 2001] are conceptually similar to types and type spaces. However, the focus of plan recognition has been on identifying the goal of an agent (e.g. [Bonchek-Dokow et al., 2009]) and efficient representation of plans (e.g. [Avrahami-Zilberbrand and Kaminka, 2007]), while types are used primarily to compute expected payoffs and can be efficiently represented as programmes [Albrecht and Ramamoorthy, 2013, Barrett et al., 2011].

I-POMDPs [Gmytrasiewicz and Doshi, 2005] and I-DIDs [Doshi et al., 2009] are related to our work since they too assume that agents have a latent type. These methods are designed to handle the full generality of partially observable states and latent types, and they explicitly model nested

beliefs. However, this generality comes at a high computational cost and the solutions are infeasible to compute in many cases. In contrast, we remain in the setting of fully observable states, and we implicitly allow for complex beliefs within the specification of types. This allows our methods to be computationally more tractable.

To the best of our knowledge, none of these related works directly address the theoretical questions considered in this paper. While our results apply to [Albrecht and Ramamoorthy, 2013, Barrett et al., 2011, Carmel and Markovitch, 1999], we believe they could be generalised to account for some of the other related works as well. This includes the methodology described in Section 5.

3 PRELIMINARIES

3.1 MODEL

Our analysis is based on the stochastic Bayesian game [Albrecht and Ramamoorthy, 2013]:

Definition 1. A *stochastic Bayesian game* (SBG) consists of

- discrete state space S with initial state $s^0 \in S$ and terminal states $\bar{S} \subset S$
- players $N = \{1, \dots, n\}$ and for each $i \in N$:
 - set of actions A_i (where $A = A_1 \times \dots \times A_n$)
 - type space Θ_i (where $\Theta = \Theta_1 \times \dots \times \Theta_n$)
 - payoff function $u_i : S \times A \times \Theta_i \rightarrow \mathbb{R}$
 - strategy $\pi_i : \mathbb{H} \times A_i \times \Theta_i \rightarrow [0, 1]$
- state transition function $T : S \times A \times S \rightarrow [0, 1]$
- type distribution $\Delta : \Theta \rightarrow [0, 1]$

where \mathbb{H} contains all *histories* $H^t = \langle s^0, a^0, s^1, a^1, \dots, s^t \rangle$ with $t \geq 0$, $(s^\tau, a^\tau) \in S \times A$ for $0 \leq \tau < t$, and $s^t \in S$.

Definition 2. A SBG starts at time $t = 0$ in state s^0 :

1. In state s^t , the types $\theta_1^t, \dots, \theta_n^t$ are sampled from Θ with probability $\Delta(\theta_1^t, \dots, \theta_n^t)$, and each player i is informed only about its own type θ_i^t .
2. Based on the history H^t , each player i chooses an action $a_i^t \in A_i$ with probability $\pi_i(H^t, a_i^t, \theta_i^t)$, resulting in the joint action $a^t = (a_1^t, \dots, a_n^t)$.
3. The game transitions into a successor state $s^{t+1} \in S$ with probability $T(s^t, a^t, s^{t+1})$, and each player i receives an individual payoff given by $u_i(s^t, a^t, \theta_i^t)$.

This process is repeated until a terminal state $s^t \in \bar{S}$ is reached, after which the game stops.

3.2 ASSUMPTIONS

We make the following general assumptions in our analysis:

Assumption 1. We control player i , by which we mean that we choose the strategies π_i (using HBA). Hence, player i has only one type, θ_i , which is known to us.

We sometimes omit θ_i in u_i and π_i for brevity, and we use j and $-i$ to refer to the other players (e.g. $A_{-i} = \times_{j \neq i} A_j$).

Assumption 2. Given a SBG Γ , we assume that all elements of Γ are known except for the type spaces Θ_j and the type distribution Δ , which are *latent variables*.

Assumption 3. We assume *full observability* of states and actions. That is, we are always informed of the current history H^t before making a decision.

Assumption 4. For any type θ_j and history H^t , there exists a *unique* sequence $(\chi_{a_j})_{a_j \in A_j}$ such that $\pi_j(H^t, a_j, \theta_j) = \chi_{a_j}$ for all $a_j \in A_j$.

We refer to this as *external* randomisation and to the opposite (when there is no unique χ_{a_j}) as *internal* randomisation. Technically, Assumption 4 is implied by the fact that π_j is a function, which means that any input is mapped to exactly one output. However, in practice this can be violated if randomisation is used “inside” a type implementation, hence it is worth stating it explicitly. Nonetheless, it can be shown that under full observability, external randomisation is equivalent to internal randomisation. Hence, Assumption 4 does not limit the types we can represent.

Example 1. Let there be two actions, A and B, and let the expected payoffs for agent i be $E(A) > E(B)$. The agent uses ϵ -greedy action selection [Sutton and Barto, 1998] with $\epsilon > 0$. If agent i randomises *externally*, then the strategy π_i will assign action probabilities $\langle 1 - \epsilon/2, \epsilon/2 \rangle$. If the agent randomises *internally*, then with probability ϵ it will assign probabilities $\langle 0.5, 0.5 \rangle$ and with probability $1 - \epsilon$ it will assign $\langle 1, 0 \rangle$, which is equivalent to external randomisation.

3.3 ALGORITHM

Algorithm 1 gives a formal definition of HBA (based on [Albrecht and Ramamoorthy, 2013]) which is the central algorithm in this analysis. (Section 1 provides an informal description.) Throughout this paper, we will use Θ_j^* and \Pr_j , respectively, to denote the user-defined type space and posterior for player j , where $\Pr_j(\theta_j^* | H^t)$ is the probability that player j has type $\theta_j^* \in \Theta_j^*$ after history H^t . Furthermore, we will use \Pr to denote the *combined* posterior, with $\Pr(\theta_{-i}^* | H^t) = \prod_{j \neq i} \Pr_j(\theta_j^* | H^t)$, and we sometimes refer to this simply as *the posterior*.

Note that the likelihood L in (1) is unspecified at this point. We will consider two variants for L in Section 4. The prior probabilities $P_j(\theta_j^*)$ in (1) can be used to specify prior beliefs about the distribution of types. It is convenient to specify $\Pr_j(\theta_j^* | H^t) = P_j(\theta_j^*)$ for $t = 0$. Finally, note that (2)/(3) define an infinite regress. In practice, this may be implemented using stochastic sampling (e.g. as in [Albrecht and Ramamoorthy, 2013, Barrett et al., 2011]) or by terminating the regress after some finite amount of time. In this analysis, we assume that (2)/(3) are implemented as given.

Algorithm 1 Harsanyi-Bellman Ad Hoc Coordination (HBA) [Albrecht and Ramamoorthy, 2013]

Input: SBG Γ , player i , user-defined type spaces Θ_j^* , history H^t , discount factor $0 \leq \gamma \leq 1$

Output: Action probabilities $\pi_i(H^t, a_i)$

1. For each $j \neq i$ and $\theta_j^* \in \Theta_j^*$, compute posterior probability

$$\Pr_j(\theta_j^* | H^t) = \frac{L(H^t | \theta_j^*) P_j(\theta_j^*)}{\sum_{\hat{\theta}_j^* \in \Theta_j^*} L(H^t | \hat{\theta}_j^*) P_j(\hat{\theta}_j^*)} \quad (1)$$

2. For each $a_i \in A_i$, compute expected payoff $E_{s^t}^{a_i}(H^t)$ with

$$E_s^{a_i}(\hat{H}) = \sum_{\theta_{-i}^* \in \Theta_{-i}^*} \Pr(\theta_{-i}^* | H^t) \sum_{a_{-i} \in A_{-i}} Q_s^{a_i, -i}(\hat{H}) \prod_{j \neq i} \pi_j(\hat{H}, a_j, \theta_j^*) \quad (2)$$

$$Q_s^a(\hat{H}) = \sum_{s' \in S} T(s, a, s') \left[u_i(s, a) + \gamma \max_{a_i} E_{s^t}^{a_i}(\langle \hat{H}, a, s' \rangle) \right] \quad (3)$$

where $\Pr(\theta_{-i}^* | H^t) = \prod_{j \neq i} \Pr_j(\theta_j^* | H^t)$ and $a_{i, -i} \triangleq (a_i, a_{-i})$

3. Distribute $\pi_i(H^t, \cdot)$ uniformly over $\arg \max_{a_i} E_{s^t}^{a_i}(H^t)$

4 LEARNING THE TYPE DISTRIBUTION

This section is concerned with convergence and correctness properties of the posterior. The theorems in this section tell us if and under what conditions HBA will learn the type distribution of the game. As can be seen in Algorithm 1, this is important since the accuracy of the expected payoffs (2) depends crucially on the accuracy of the posterior (1).

However, for this to be a well-posed learning problem, we have to assume that the posterior \Pr can refer to the same elements as the type distribution Δ . Therefore, the results in this section pertain to a weaker form of *ad hoc coordination* [Albrecht and Ramamoorthy, 2013] in which the user knows that the latent type space Θ_j must be a subset of the user-defined type space Θ_j^* . Formally, we assume:

Assumption 5. $\forall j \neq i : \Theta_j \subseteq \Theta_j^*$

Based on this assumption, we simplify the notation in this section by dropping the $*$ in θ_j^* and Θ_j^* . The general case in which Assumption 5 does *not* hold is addressed in Section 5.

We consider two kinds of type distributions:

Definition 3. A type distribution Δ is called *pure* if there is $\theta \in \Theta$ such that $\Delta(\theta) = 1$. A type distribution is called *mixed* if it is not pure.

Pure type distributions can be used to model the fact that each player has a fixed type throughout the game, e.g. as in [Barrett et al., 2011]. Mixed type distributions, on the other hand, can be used to model randomly changing types. This

was shown in [Albrecht and Ramamoorthy, 2013], where a mixed type distribution was used to model defective agents and human behaviour.

4.1 PRODUCT POSTERIOR

We first consider the product posterior:

Definition 4. The *product posterior* is defined as (1) with

$$L(H^t|\theta_j) = \prod_{\tau=0}^{t-1} \pi_j(H^\tau, a_j^\tau, \theta_j) \quad (4)$$

This is the standard posterior formulation used in Bayesian games (e.g. [Kalai and Lehrer, 1993]) and was used in [Albrecht and Ramamoorthy, 2013, Barrett et al., 2011].

Our first theorem states that the product posterior is guaranteed to converge to any pure type distribution:

Theorem 1. Let Γ be a SBG with a pure type distribution Δ . If HBA uses a product posterior, and if the prior probabilities P_j are positive (i.e. $\forall \theta_j^* \in \Theta_j^* : P_j(\theta_j^*) > 0$), then, for $t \rightarrow \infty$: $\Pr(\theta_{-i}|H^t) = \Delta(\theta_{-i})$ for all $\theta_{-i} \in \Theta_{-i}$.

Proof. The proof is not difficult, but tedious. In the interest of space, we give a proof sketch.¹ [Kalai and Lehrer, 1993] studied a model which can be equivalently described as a single-state SBG ($|S| = 1$) with pure Δ and proved that the product posterior converges to the type distribution of the game. Their convergence result can be extended to multi-state SBGs by translating the multi-state SBG Γ into a single-state SBG $\tilde{\Gamma}$ which is equivalent to Γ in the sense that the players behave identically. Essentially, the trick is to remove the states in Γ by introducing a new player whose action choices correspond to the state transitions in Γ . \square

Theorem 1 states that the product posterior will learn any pure type distribution. However, it does not necessarily learn mixed type distributions, as shown in the following example:

Example 2. Consider a SBG with two players. Player 1 is controlled by HBA using a product posterior while player 2 has two types, θ_A and θ_B , which are assigned by a mixed type distribution Δ with $\Delta(\theta_A) = \Delta(\theta_B) = 0.5$. The type θ_A always chooses action A while θ_B always chooses action B. In this case, there will be a time t after which both types have been assigned at least once, and so both actions A and B have been played at least once by player 2. This means that from time t and all subsequent times $\tau \geq t$, we have $\Pr_2(\theta_A|H^\tau) = \Pr_2(\theta_B|H^\tau) = 0$ (since each type plays only one action), so the posterior will never converge to Δ .

4.2 SUM POSTERIOR

We now consider the sum posterior:

¹A full proof of Theorem 1 can be found at: <http://rad.inf.ed.ac.uk/data/publications/2014/uai14proof.pdf>

Definition 5. The *sum posterior* is defined as (1) with

$$L(H^t|\theta_j) = \sum_{\tau=0}^{t-1} \pi_j(H^\tau, a_j^\tau, \theta_j) \quad (5)$$

The sum posterior was introduced in [Albrecht and Ramamoorthy, 2013] to allow HBA to recognise changed types. In other words, the purpose of the sum posterior is to learn mixed type distributions. It is easy to see that a sum posterior would indeed learn the mixed type distribution in Example 2. However, we now give an example to show that without additional requirements the sum posterior does not necessarily learn any (pure or mixed) type distribution:

Example 3. Consider a SBG with two players. Player 1 is controlled by HBA using a sum posterior while player 2 has two types, θ_A and θ_{AB} , which are assigned by a pure type distribution Δ with $\Delta(\theta_A) = 1$. The type θ_A always chooses action A while θ_{AB} chooses actions A and B with equal probability. The product posterior converges to Δ , as predicted by Theorem 1. However, the sum posterior converges to probabilities $(\frac{2}{3}, \frac{1}{3})$, which is incorrect.

Note that this example can readily be modified to use a mixed type distribution, with similar results. Therefore, we conclude that the sum posterior does not necessarily learn any type distribution.

Under what condition is the sum posterior guaranteed to learn the true type distribution? Consider the following two quantities, which can be computed from a given history H^t :

Definition 6. The *average overlap* of player j in H^t is

$$AO_j(H^t) = \frac{1}{t} \sum_{\tau=0}^{t-1} [|\Lambda_j^\tau| \geq 2]_1 \sum_{\theta_j \in \Theta_j} \pi_j(H^\tau, a_j^\tau, \theta_j) |\Theta_j|^{-1} \quad (6)$$

$$\Lambda_j^\tau = \{\theta_j \in \Theta_j \mid \pi_j(H^\tau, a_j^\tau, \theta_j) > 0\}$$

where $[b]_1 = 1$ if b is true, else 0.

Definition 7. The *average stochasticity* of player j in H^t is

$$AS_j(H^t) = \frac{1}{t} \sum_{\tau=0}^{t-1} |\Theta_j|^{-1} \sum_{\theta_j \in \Theta_j} \frac{1 - \pi_j(H^\tau, \hat{a}_j^\tau, \theta_j)}{1 - |A_j|^{-1}} \quad (7)$$

where $\hat{a}_j^\tau \in \arg \max_{a_j} \pi_j(H^\tau, a_j, \theta_j)$.

Both quantities are bounded by 0 and 1. The average overlap describes the similarity of the types, where $AO_j(H^t) = 0$ means that player j 's types (on average) never chose the same action in history H^t , whereas $AO_j(H^t) = 1$ means that they behaved identically. The average stochasticity describes the uncertainty of the types, where $AS_j(H^t) = 0$ means that player j 's types (on average) were fully deterministic in the action choices in history H^t , whereas $AS_j(H^t) = 1$ means that they chose actions randomly with uniform probability.

We can show that, if the average overlap and stochasticity of player j converge to zero as $t \rightarrow \infty$, then the sum posterior is guaranteed to learn any pure or mixed type distribution:

Theorem 2. Let Γ be a SBG with a pure or mixed type distribution Δ . If HBA uses a sum posterior, then, for $t \rightarrow \infty$: If $\text{AO}_j(H^t) = 0$ and $\text{AS}_j(H^t) = 0$ for all players $j \neq i$, then $\Pr(\theta_{-i}|H^t) = \Delta(\theta_{-i})$ for all $\theta_{-i} \in \Theta_{-i}$.

Proof. Throughout this proof, let $t \rightarrow \infty$. The sum posterior is defined as (1) where L is defined as (5). Given the definition of L , both the numerator and the denominator in (1) may be infinite. We invoke L'Hôpital's rule which states that, in such cases, the quotient $\frac{u(t)}{v(t)}$ is equal to the quotient $\frac{u'(t)}{v'(t)}$ of the respective derivatives with respect to t . The derivative of L with respect to t is the average growth per time step, which in general may depend on the history H^t of states and actions. The average growth of L is

$$L'(H^t|\theta_j) = \sum_{a_j \in A_j} F(a_j|H^t) \pi_j(H^t, a_j, \theta_j) \quad (8)$$

where

$$F(a_j|H^t) = \sum_{\theta_j \in \Theta_j} \Delta(\theta_j) \pi_j(H^t, a_j, \theta_j) \quad (9)$$

is the probability of action a_j after history H^t , with $\Delta(\theta_j)$ being the marginal probability that player j is assigned type θ_j . As we will see shortly, we can make an asymptotic growth prediction irrespective of H^t . Given that $\text{AO}_j(H^t) = 0$, we can infer that whenever $\pi_j(H^t, a_j, \theta_j) > 0$ for action a_j and type θ_j , then $\pi_j(H^t, a_j, \theta'_j) = 0$ for all other types $\theta'_j \neq \theta_j$. Therefore, we can write (8) as

$$L'(H^t|\theta_j) = \Delta(\theta_j) \sum_{a_j \in A_j} \pi_j(H^t, a_j, \theta_j)^2 \quad (10)$$

Next, given that $\text{AS}_j(H^t) = 0$, we know that there exists an action a_j such that $\pi_j(H^t, a_j, \theta_j) = 1$, and therefore we can conclude that $L'(H^t|\theta_j) = \Delta(\theta_j)$. This shows that the history H^t is irrelevant to the asymptotic growth rate of L . Finally, since $\sum_{\theta_j \in \Theta_j} \Delta(\theta_j) = 1$, we know that the denominator in (1) will be 1, and we can ultimately conclude that $\Pr_j(\theta_j|H^t) = \Delta(\theta_j)$. \square

Theorem 2 explains why the sum posterior converges to the correct type distribution in Example 2. Since the types θ_A and θ_B always choose different actions and are completely deterministic (i.e. the average overlap and stochasticity are always zero), the sum posterior is guaranteed to converge to the type distribution. On the other hand, in Example 3 the types θ_A and θ_{AB} produce an overlap whenever action A is chosen, and θ_{AB} is completely random. Therefore, the average overlap and stochasticity are always positive, and an incorrect type distribution was learned.

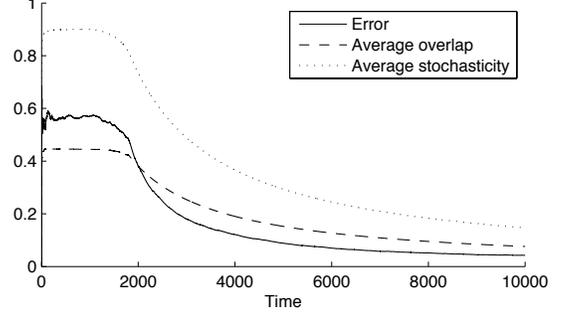

Figure 1: Example run in random SBG with 2 players, 10 actions, and 100 states. Player j has 3 reinforcement learning types with ϵ -greedy action selection (decreasing linearly from $\epsilon = 0.7$ at $t = 1000$, to $\epsilon = 0$ at $t = 2000$). The error at time t is $\sum_{\theta_j} |\Pr_j(\theta_j|H^t) - \Delta(\theta_j)|$ where \Pr_j is the sum posterior.

The assumptions made in Theorem 2, namely that the average overlap and stochasticity converge to zero, require practical justification. First of all, it is important to note that it is only required that these converge to zero *on average* as $t \rightarrow \infty$. This means that in the beginning there may be arbitrary overlap and stochasticity, as long as these go to zero as the game proceeds. In fact, with respect to stochasticity, this is precisely how the exploration-exploitation dilemma [Sutton and Barto, 1998] is solved in practice: In the early stages, the agent randomises deliberately over its actions in order to obtain more information about the environment (*exploration*) while, as the game proceeds, the agent becomes gradually more deterministic in its action choices so as to maximise its payoffs (*exploitation*). Typical mechanisms which implement this are ϵ -greedy and Softmax/Boltzmann exploration [Sutton and Barto, 1998]. Figure 1 demonstrates this in a SBG in which player j has 3 reinforcement learning types. The payoffs for the types were such that the average overlap would eventually go to zero.

Regarding the average overlap converging to zero, we believe that this is a property which should be guaranteed by *design*, for the following reason: If the user-defined type space Θ_j^* is such that there is a constantly high average overlap, then this means that the types $\theta_j^* \in \Theta_j^*$ are in effect very similar. However, types which are very similar are likely to produce very similar trajectories in the planning step of HBA (cf. \hat{H} in (2)) and, therefore, constitute redundancy in both time and space. Therefore, we believe it is advisable to use type spaces which have low average overlap.

4.3 CORRELATED POSTERIOR

An implicit assumption in the definition of (1) is that the type distribution Δ can be represented as a product of n independent factors (one for each player), so that $\Delta(\theta) = \prod_j \Delta_j(\theta_j)$. Therefore, since the sum posterior is in the form of (1), it is in fact only guaranteed to learn *independent* type distributions. This is opposed to *correlated* type distributions, which cannot be represented as a product

of n independent factors. Correlated type distributions can be used to specify constraints on type combinations, such as “player j can only have type θ_j if player k has type θ_k ”. The following example demonstrates how the sum posterior fails to converge to a correlated type distribution:

Example 4. Consider a SBG with 3 players. Player 1 is controlled by HBA using a sum posterior. Players 2 and 3 each have two types, θ_A and θ_B , which are defined as in Example 2. The type distribution Δ chooses types with probabilities $\Delta(\theta_A, \theta_B) = \Delta(\theta_B, \theta_A) = 0.5$ and $\Delta(\theta_A, \theta_A) = \Delta(\theta_B, \theta_B) = 0$. In other words, player 2 can never have the same type as player 3. From the perspective of HBA, each type (and hence action) is chosen with equal probability for both players. Thus, despite the fact that there is zero overlap and stochasticity, the sum posterior will eventually assign probability 0.25 to all constellations of types, which is incorrect. This means that HBA fails to recognise that the other players never choose the same action.

In this section, we propose a new posterior which can learn any correlated type distribution:

Definition 8. The *correlated posterior* is defined as

$$\Pr(\theta_{-i}|H^t) = \eta P(\theta_{-i}) \sum_{\tau=0}^{t-1} \prod_{\theta_j \in \theta_{-i}} \pi_j(H^\tau, a_j^\tau, \theta_j) \quad (11)$$

where P specifies prior probabilities (or beliefs) over Θ_{-i} (analogous to P_j) and η is a normalisation constant.

The correlated posterior is closely related to the sum posterior. In fact, it converges to the true type distribution under the same conditions as the sum posterior:

Theorem 3. Let Γ be a SBG with a *correlated* type distribution Δ . If HBA uses the correlated posterior, then, for $t \rightarrow \infty$: If $\text{AO}_j(H^t) = 0$ and $\text{AS}_j(H^t) = 0$ for all players $j \neq i$, then $\Pr(\theta_{-i}|H^t) = \Delta(\theta_{-i})$ for all $\theta_{-i} \in \Theta_{-i}$.

Proof. Proof is analogous to proof of Theorem 2. \square

It is easy to see that the correlated posterior would learn the correct type distribution in Example 4. Note that, since it is guaranteed to learn any correlated type distribution, it is also guaranteed to learn any independent type distribution. Therefore, the correlated posterior would also learn the correct type distribution in Example 2. This means that the correlated posterior is *complete* in the sense that it covers the entire spectrum of pure/mixed and independent/correlated type distributions. However, this completeness comes at a higher computational complexity. While the sum posterior is in $O(n \max_j |\Theta_j|)$ time and space, the correlated posterior is in $O(\max_j |\Theta_j|^n)$ time and space. In practice, however, the time complexity can be reduced drastically by computing the probabilities $\pi_j(H^\tau, a_j^\tau, \theta_j)$ only once for each j and $\theta_j \in \Theta_j$ (as in the sum posterior), and then reusing them in subsequent computations.

5 INACCURATE TYPE SPACES

Each user-defined type θ_j^* in Θ_j^* is a hypothesis by the user regarding how player j might behave. Therefore, Θ_j^* may be *inaccurate* in the sense that none of the types therein accurately predict the observed behaviour of player j . This is demonstrated in the following example:

Example 5. Consider a SBG with two players and actions L and R. Player 1 is controlled by HBA while player 2 has a single type, θ_{LR} , which chooses L,R,L,R, etc. HBA is provided with $\Theta_j^* = \{\theta_R^*, \theta_{LRR}^*\}$, where θ_R^* always chooses R while θ_{LRR}^* chooses L,R,R,L,R,R etc. Both user-defined types are inaccurate in the sense that they predict player 2’s actions in only $\approx 50\%$ of the game.

Two important theoretical questions in this context are how closely the user-defined type spaces Θ_j^* have to approximate the real type spaces Θ_j in order for HBA to be able to (1) solve the task (i.e. bring the SBG into a terminal state), and (2) achieve maximum payoffs. These questions are closely related to the notions of *flexibility* and *efficiency* [Albrecht and Ramamoorthy, 2013] which, respectively, correspond to the probability of termination and the average payoff per time step. In this section, we are primarily concerned with question 1, and we are concerned with question 2 only in so far as that we want to solve the task in minimal time. (Since reducing the time until termination will increase the average payoff per time step, i.e. increase efficiency.) This focus is formally captured by the following assumption, which we make throughout this section:

Assumption 6. Let player i be controlled by HBA, then $u_i(s, a, \theta_i) = 1$ iff. $s \in \bar{S}$, else 0.

Assumption 6 specifies that we are only interested in reaching a terminal state, since this is the only way to obtain a non-zero payoff. In our analysis, we consider discount factors γ (cf. Algorithm 1) with $\gamma = 1$ and $\gamma < 1$. While all our results hold for both cases, there is an important distinction: If $\gamma = 1$, then the expected payoffs (2) correspond to the actual probability that the following state can lead to (or is) a terminal state (we call this the *success rate*), whereas this is not necessarily the case if $\gamma < 1$. This is since $\gamma < 1$ tends to prefer shorter paths, which means that actions with lower success rates may be preferred if they lead to faster termination. Therefore, if $\gamma = 1$ then HBA is solely interested in termination, and if $\gamma < 1$ then it is interested in *fast* termination, where lower γ prefers faster termination.

5.1 METHODOLOGY OF ANALYSIS

Given a SBG Γ , we define the *ideal process*, X , as the process induced by Γ in which player i is controlled by HBA and in which HBA always knows the current and all future types of all players. Then, given a posterior \Pr and user-defined type spaces Θ_j^* for all $j \neq i$, we define the *user process*, Y , as the process induced by Γ in which player i

is controlled by HBA (same as in X) and in which HBA uses Pr and Θ_j^* in the usual way. Thus, the only difference between X and Y is that X can always predict the player types whereas Y approximates this knowledge through Pr and Θ_j^* . We write $E_{s^t}^{a_i}(H^t|C)$ to denote the expected payoff (as defined by (2)) of action a_i in state s^t after history H^t , in process $C \in \{X, Y\}$.

The idea is that X constitutes the ideal solution in the sense that $E_{s^t}^{a_i}(H^t|X)$ corresponds to the *actual* expected payoff, which means that HBA chooses the truly best-possible actions in X . This is opposed to $E_{s^t}^{a_i}(H^t|Y)$, which is merely the *estimated* expected payoff based on Pr and Θ_j^* , so that HBA may choose suboptimal actions in Y . The methodology of our analysis is to specify what relation Y must have to X to satisfy certain guarantees for termination.

We specify such guarantees in PCTL [Hansson and Jonsson, 1994], a probabilistic modal logic which also allows for the specification of time constraints. PCTL expressions are interpreted over infinite histories in labelled transition systems with atomic propositions (i.e. Kripke structures). In order to interpret PCTL expressions over X and Y , we make the following modifications without loss of generality: Firstly, any terminal state $\bar{s} \in \bar{S}$ is an *absorbing* state, meaning that if a process is in \bar{s} , then the next state will be \bar{s} with probability 1 and all players receive a zero payoff. Secondly, we introduce the atomic proposition `term` and label each terminal state with it, so that `term` is true in s if and only if $s \in \bar{S}$.

We will use the following two PCTL expressions:

$$F_{>p}^{\leq t} \text{term}, F_{>p}^{< \infty} \text{term}$$

where $t \in \mathbb{N}$, $p \in [0, 1]$, and $\succ \in \{>, \geq\}$.

$F_{>p}^{\leq t} \text{term}$ specifies that, given a state s , with a probability of $> p$ a state s' will be reached from s within t time steps such that s' satisfies `term`. The semantics of $F_{>p}^{< \infty} \text{term}$ are similar except that s' will be reached in arbitrary but finite time. We write $s \models_C \phi$ to say that a state s satisfies the PCTL expression ϕ in process $C \in \{X, Y\}$.

5.2 CRITICAL TYPE SPACES

In the following section, we sometimes assume that the user-defined type spaces Θ_j^* are *uncritical*:

Definition 9. The user-defined type spaces Θ_j^* are *critical* if there is $S^c \subseteq S \setminus \bar{S}$ which satisfies:

1. For each $H^t \in \mathbb{H}$ with $s^t \in S^c$, there is $a_i \in A_i$ such that $E_{s^t}^{a_i}(H^t|Y) > 0$ and $E_{s^t}^{a_i}(H^t|X) > 0$
2. There is a positive probability that Y may eventually get into a state $s^c \in S^c$ from the initial state s^0
3. If Y is in a state in S^c , then with probability 1 it will always be in a state in S^c (i.e. it will never leave S^c)

We say Θ_j^* are *uncritical* if they are not critical.

Intuitively, critical type spaces have the potential to lead HBA into a state space in which it *believes* it chooses the right actions to solve the task, while other actions are *actually* required to solve the task. The only effect that its actions have is to induce an infinite cycle, due to a critical inconsistency between the user-defined and true type spaces. The following example demonstrates this:

Example 6. Recall Example 5 and let the task be to choose the same action as player j . Then, Θ_j^* is uncritical because HBA will always solve the task at $t = 1$, regardless of the posterior and despite the fact that Θ_j^* is inaccurate. Now, assume that $\Theta_j^* = \{\theta_{RL}^*\}$ where θ_{RL}^* chooses actions R,L,R,L etc. Then, Θ_j^* is critical since HBA will always choose the opposite action of player j , thinking that it would solve the task, when a different action would actually solve it.

A practical way to ensure that the type spaces Θ_j^* are (eventually) uncritical is to include methods for opponent modelling in each Θ_j^* (e.g. as in [Albrecht and Ramamoorthy, 2013, Barrett et al., 2011]). If the opponent models are guaranteed to learn the correct behaviours, then the type spaces Θ_j^* are guaranteed to become uncritical. In Example 6, any standard modelling method would eventually learn that the true strategy of player j is θ_{LR} . As the model becomes more accurate, the posterior gradually shifts towards it and eventually allows HBA to take the right action.

5.3 TERMINATION GUARANTEES

Our first guarantee states that if X has a positive probability of solving the task, then so does Y :

Property 1. $s^0 \models_X F_{>0}^{< \infty} \text{term} \Rightarrow s^0 \models_Y F_{>0}^{< \infty} \text{term}$

We can show that Property 1 holds if the user-defined type spaces Θ_j^* are uncritical and if Y only chooses actions for player i with positive expected payoff in X .

Let $\mathbb{A}(H^t|C)$ denote the set of actions that process C may choose from in state s^t after history H^t , i.e. $\mathbb{A}(H^t|C) = \arg \max_{a_i} E_{s^t}^{a_i}(H^t|C)$ (cf. step 3 in Algorithm 1).

Theorem 4. Property 1 holds if Θ_j^* are uncritical and

$$\forall H^t \in \mathbb{H} \forall a_i \in \mathbb{A}(H^t|Y) : E_{s^t}^{a_i}(H^t|X) > 0 \quad (12)$$

Proof. Assume $s^0 \models_X F_{>0}^{< \infty} \text{term}$. Then, we know that X chooses actions a_i which *may* lead into a state s' such that $s' \models_X F_{>0}^{< \infty} \text{term}$, and the same holds for all such states s' . Now, given (12) it is tempting to infer the same result for Y , since Y only chooses actions a_i which have positive expected payoff in X and, therefore, could truly lead into a terminal state. However, (12) alone is not sufficient to infer $s' \models_Y F_{>0}^{< \infty} \text{term}$ because of the special case in which Y chooses actions a_i such that $E_{s^t}^{a_i}(H^t|X) > 0$ but without ever reaching a terminal state. This is why we require that the user-defined type spaces Θ_j^* are uncritical, which prevents this special case. Thus, we can infer that $s' \models_Y F_{>0}^{< \infty} \text{term}$, and hence Property 1 holds. \square

The second guarantee states that if X always solves the task, then so does Y :

Property 2. $s^0 \models_X F_{\geq 1}^{<\infty} \text{term} \Rightarrow s^0 \models_Y F_{\geq 1}^{<\infty} \text{term}$

We can show that Property 2 holds if the user-defined type spaces Θ_j^* are uncritical and if Y only chooses actions for player i which lead to states into which X may get as well.

Let $\mu(H^t, s|C)$ be the probability that process C transitions into state s from state s^t after history H^t , i.e. $\mu(H^t, s|C) = \frac{1}{|\mathbb{A}|} \sum_{a_i \in \mathbb{A}} \sum_{a_{-i}} T(s^t, \langle a_i, a_{-i} \rangle, s) \prod_j \pi_j(H^t, a_j, \theta_j^t)$ with $\mathbb{A} \equiv \mathbb{A}(H^t|C)$, and let $\mu(H^t, S'|C) = \sum_{s \in S'} \mu(H^t, s|C)$ for $S' \subseteq S$.

Theorem 5. Property 2 holds if Θ_j^* are uncritical and

$$\forall H^t \in \mathbb{H} \forall s \in S : \mu(H^t, s|Y) > 0 \Rightarrow \mu(H^t, s|X) > 0 \quad (13)$$

Proof. The fact that $s^0 \models_X F_{\geq 1}^{<\infty} \text{term}$ means that, throughout the process, X only transitions into states s with $s \models_X F_{\geq 1}^{<\infty} \text{term}$. As before, it is tempting to infer the same result for Y based on (13), since it only transitions into states which have maximum success rate in X . However, (13) alone is not sufficient since Y may choose actions such that (13) holds true but Y will never reach a terminal state. Nevertheless, since the user-defined type spaces Θ_j^* are uncritical, we know that this special case will not occur, and hence Property 2 holds. \square

We note that, in both Properties 1 and 2, the reverse direction holds true regardless of Theorems 4 and 5. Furthermore, we can combine the requirements of Theorems 4 and 5 to ensure that both properties hold.

The next guarantee subsumes the previous guarantees by stating that X and Y have the same minimum probability of solving the task:

Property 3. $s^0 \models_X F_{\geq p}^{<\infty} \text{term} \Rightarrow s^0 \models_Y F_{\geq p}^{<\infty} \text{term}$

We can show that Property 3 holds if the user-defined type spaces Θ_j^* are uncritical and if Y only chooses actions for player i which X might have chosen as well.

Let $R(a_i, H^t|C)$ be the *success rate* of action a_i , formally $R(a_i, H^t|C) = E_s^{a_i}(H^t|C)$ with $\gamma = 1$ (so that it corresponds to the actual *probability* with which a_i may lead to termination in the future). Define X_{\min} and X_{\max} to be the processes which for each H^t choose actions $a_i \in \mathbb{A}(H^t|X)$ with, respectively, minimal and maximal success rate $R(a_i, H^t|X)$.

Theorem 6. If Θ_j^* are uncritical and

$$\forall H^t \in \mathbb{H} : \mathbb{A}(H^t|Y) \subseteq \mathbb{A}(H^t|X) \quad (14)$$

then

(i) for $\gamma = 1$: Proposition 3 holds in both directions

(ii) for $\gamma < 1$: $s^0 \models_X F_{\geq p}^{<\infty} \text{term} \Rightarrow s^0 \models_Y F_{\geq p'}^{<\infty} \text{term}$

with $p_{\min} \leq q \leq p_{\max}$ for $q \in \{p, p'\}$, where p_{\min} and p_{\max} are the highest probabilities such that $s^0 \models_{X_{\min}} F_{\geq p_{\min}}^{<\infty} \text{term}$ and $s^0 \models_{X_{\max}} F_{\geq p_{\max}}^{<\infty} \text{term}$.

Proof. (i): Since $\gamma = 1$, all actions $a_i \in \mathbb{A}(H^t|X)$ have the same success rate for a given H^t , and given (14) we know that Y 's actions always have the same success rate as X 's actions. Provided that the type spaces Θ_j^* are uncritical, we can conclude that Property 3 must hold, and for the same reasons the reverse direction must hold as well.

(ii): Since $\gamma < 1$, the actions $a_i \in \mathbb{A}(H^t|X)$ may have different success rates. The lowest and highest chances that X solves the task are precisely modelled by X_{\min} and X_{\max} , and given (14) and the fact that Θ_j^* are uncritical, the same holds for Y . Therefore, we can infer the common bound $p_{\min} \leq \{p, p'\} \leq p_{\max}$ as defined in Theorem 6. \square

Properties 1 to 3 are *indefinite* in the sense that they make no restrictions on time requirements. Our fourth and final guarantee subsumes all previous guarantees and states that if there is a probability p such that X terminates *within* t time steps, then so does Y for the same p and t :

Property 4. $s^0 \models_X F_{\geq p}^{\leq t} \text{term} \Rightarrow s^0 \models_Y F_{\geq p}^{\leq t} \text{term}$

We believe that Property 4 is an adequate criterion of optimality for the type spaces Θ_j^* since, if it holds, Θ_j^* must approximate Θ_j in a way which allows HBA to plan (almost) as accurately — in terms of solving the task — as the “ideal” HBA in X which always knows the true types.

What relation must Y have to X to satisfy Property 4? The fact that Y and X are processes over state transition systems means we can draw on methods from the model checking literature to answer this question. Specifically, we will use the concept of *probabilistic bisimulation* [Larsen and Skou, 1991], which we here define in the context of our work:

Definition 10. A *probabilistic bisimulation* between X and Y is an equivalence relation $B \subseteq S \times S$ such that

- (i) $(s^0, s^0) \in B$
- (ii) $s_X \models_X \text{term} \Leftrightarrow s_Y \models_Y \text{term}$ for all $(s_X, s_Y) \in B$
- (iii) $\mu(H_X^t, \hat{S}|X) = \mu(H_Y^t, \hat{S}|Y)$ for any histories H_X^t, H_Y^t with $(s_X^t, s_Y^t) \in B$ and all equivalence classes \hat{S} under B .

Intuitively, a probabilistic bisimulation states that X and Y do (on average) match each other's transitions. Our definition of probabilistic bisimulation is most general in that it does not require that transitions are matched by the same action or that related states satisfy the same atomic propositions other than termination. However, we do note that other definitions exist that make such additional requirements, and our results hold for each of these refinements.

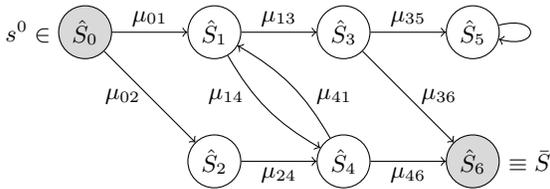

The main contribution of this section is to show that the

optimality criterion expressed by Property 4 holds in *both directions* if there is a probabilistic bisimulation between X and Y . Thus, we offer an alternative formal characterisation of optimality for the user-defined type spaces Θ_j^* :

Theorem 7. Property 4 holds in both directions if there is a probabilistic bisimulation between X and Y .

Proof. First of all, we note that, strictly speaking, the standard definitions of bisimulation (e.g. [Baier, 1996, Larsen and Skou, 1991]) assume the Markov property, which means that the next state of a process depends only on the current state of the process. In contrast, we consider the more general case in which the next state may depend on the history H^t of previous states and joint actions (since the player strategies π_j depend on H^t). However, one can always enforce the Markov property *by design*, i.e. by augmenting the state space S to account for the relevant factors of the past. In fact, we could postulate that the histories as a whole constitute the states of the system, i.e. $S = \mathbb{H}$. Therefore, to simplify the exposition, we assume the Markov property and we write $\mu(s, \hat{S}|C)$ to denote the cumulative probability that C transitions from state s into any state in \hat{S} .

Given the Markov property, the fact that B is an equivalence relation, and $\mu(s_X, \hat{S}|X) = \mu(s_Y, \hat{S}|Y)$ for $(s_X, s_Y) \in B$, we can represent the dynamics of X and Y in a common graph, such as the following one:

The nodes correspond to the equivalence classes under B . A directed edge from \hat{S}_a to \hat{S}_b specifies that there is a positive probability $\mu_{ab} = \mu(s_X, \hat{S}_b|X) = \mu(s_Y, \hat{S}_b|Y)$ that X and Y transition from states $s_X, s_Y \in \hat{S}_a$ to states $s'_X, s'_Y \in \hat{S}_b$. Note that s_X, s_Y and s'_X, s'_Y need not be equal but merely equivalent, i.e. $(s_X, s_Y) \in B$ and $(s'_X, s'_Y) \in B$. There is one node (\hat{S}_0) that contains the initial state s^0 and one node (\hat{S}_6) that contains all terminal states \bar{S} and no other states. This is because once X and Y reach a terminal state they will always stay in it (i.e. $\mu(s, \bar{S}|X) = \mu(s, \bar{S}|Y) = 1$ for $s \in \bar{S}$) and since they are the only states that satisfy term . Thus, the graph starts in \hat{S}_0 and terminates (if at all) in \hat{S}_6 .

Since the graph represents the dynamics of both X and Y , it is easy to see that Property 4 must hold in both directions. In particular, the probabilities that X and Y are in node \hat{S} at time t are identical. One simply needs to add the probabilities of all directed paths of length t which end in \hat{S} (provided that such paths exist), where the probability of a path is the product of the μ_{ab} along the path. Therefore,

X and Y terminate with equal probability, and on average within the same number of time steps. \square

Some remarks to clarify the usefulness of this result: First of all, in contrast to Theorems 4 to 6, Theorem 7 does not explicitly require Θ_j^* to be uncritical. In fact, this is implicit in the definition of probabilistic bisimulation. Moreover, while the other theorems relate Y and X for identical histories H^t , Theorem 7 relates Y and X for *related* histories H_Y^t and H_X^t , making it more generally applicable. Finally, Theorem 7 has an important practical implication: it tells us that we can use efficient methods for model checking (e.g. [Baier, 1996, Larsen and Skou, 1991]) to verify optimality of Θ_j^* . In fact, it can be shown that for Property 4 to hold (albeit not in the other direction) it suffices that Y be a *probabilistic simulation* [Baier, 1996] of X , which is a coarser preorder than probabilistic bisimulation. However, algorithms for checking probabilistic simulation (e.g. [Baier, 1996]) are computationally much more expensive (and fewer) than those for probabilistic bisimulation, hence their practical use is currently limited.

6 CONCLUSION

This paper complements works such as [Albrecht and Ramamoorthy, 2013, Barrett et al., 2011, Carmel and Markovitch, 1999] — with a focus on HBA due to its generality — by providing answers to two important theoretical questions: “Under what conditions does HBA learn the type distribution of the game?” and “How accurate must the user-defined type spaces be for HBA to solve its task?” With respect to the first question, we analyse the convergence properties of two existing posteriors and propose a new posterior which can learn correlated type distributions. This provides the user with formal reasons as to which posterior should be chosen for the problem at hand. With respect to the second question, we describe a methodology in which we analyse the requirements of several termination guarantees, and we provide a novel characterisation of optimality which is based on the notion of probabilistic bisimulation. This gives the user a formal yet practically useful criterion of what constitutes optimal type spaces. The results of this work improve our understanding of how a method such as HBA can be used to effectively solve agent interaction problems in which the behaviour of other agents is not a priori known.

There are several interesting directions for future work. For instance, it is unclear what effect the prior probabilities P_j have on the performance of HBA, and if a criterion for optimal P_j could be derived. Furthermore, since our convergence proofs in Section 4 are asymptotic, it would be interesting to know if useful finite-time error bounds exist. Finally, our analysis in Section 5 is general in the sense that it applies to any posterior. This could be refined by an analysis which commits to a specific posterior.

Abstract

Parallel predictive prefetching is a new framework for accelerating a large class of widely-used Markov chain Monte Carlo (MCMC) algorithms. It speculatively evaluates many potential steps of an MCMC chain in parallel while exploiting fast, iterative approximations to the target density. This can accelerate sampling from target distributions in Bayesian inference problems. Our approach takes advantage of whatever parallel resources are available, but produces results *exactly equivalent* to standard serial execution. In the initial burn-in phase of chain evaluation, we achieve speedup close to linear in the number of available cores.

1 INTRODUCTION

Probabilistic modeling is one of the mainstays of modern machine learning, and Bayesian methods are particularly appealing due to their ability to represent uncertainty in parameter estimates and latent variables. Unfortunately, Bayesian inference can be difficult in the real world. Many problems are not amenable to exact inference, and so require approximate inference in the form of Monte Carlo estimates or variational approximations. These procedures require many evaluations of a target posterior density, and each evaluation can be expensive, especially on large data sets. Our work accelerates Markov chain Monte Carlo (MCMC) but, in contrast to other recent proposals, we arrive at a method in which the stationary distribution is *exactly* the target posterior. This method exploits approximations to the target density to speculatively evaluate many potential future steps of the chain in parallel.

The increasing availability of multi-core machines, and many-core cluster deployments, led to our focus on parallelism. Unfortunately, the execution of MCMC algorithms such as Metropolis-Hastings (MH) is inherently serial. One

can run many independent chains at once, but this does not change the mixing time for any single chain. Since mixing time can be prohibitively large, especially when the target function is high-dimensional and multi-modal, this embarrassingly parallel approach tends not to reduce the time to achieve a useful estimator. Sometimes the target function evaluation can be parallelized, or multiple chains in an ensemble method can be run in parallel, but these strategies are not available in general.

We instead use speculative execution to parallelize a large class of MCMC methods. This approach, sometimes called *prefetching*, has received some attention in the past decade, but does not seem to be widely recognized. Speculative execution is the general technique of optimistically performing computational work that might be eventually useful. To understand speculative execution in the context of MCMC, consider the MH algorithm in Algorithm 1, in which each iteration consists of a proposal that is stochastically accepted or rejected (Metropolis et al., 1953). MH uses randomness in two ways: to generate uniform random variables and to generate proposals. Given a random stream and an initial state, all possible future states of the chain can be thought of as the nodes of a binary tree (Figure 1). Serial execution of MH yields a sequence of states that maps to a single path of nodes through the tree. Starting at the root, each transition stochastically chooses between the current state (left child) and the proposal (right child). This requires evaluating the target density at the root and each subsequent proposal. The main goal of prefetching is to perform these evaluations in parallel. However, only the immediate transition that compares the root of the tree to the first proposal is known *a priori* to be on the true computational path. Prefetching schemes use parallel cores to evaluate these two nodes and also speculatively evaluate additional nodes further down the tree.

An effective prefetching implementation must overcome several challenges. Some involve correctness; for example, care is required in the treatment of pseudo-randomness lest bias be introduced (*i.e.*, each node’s source of randomness must produce exactly the same results as it would in a serial

Algorithm 1 Metropolis–Hastings

Input: initial state θ_0 , number of iterations T , target $\pi(\theta)$, proposal $q(\theta' | \theta)$

Output: samples $\theta_1, \dots, \theta_T$

for $t = 0, \dots, T - 1$ **do**

$\theta' \sim q(\theta' | \theta_t)$

$u \sim \text{Unif}(0, 1)$

if $\frac{\pi(\theta')q(\theta_t | \theta')}{\pi(\theta_t)q(\theta' | \theta_t)} > u$ **then**

$\theta_{t+1} = \theta'$

else

$\theta_{t+1} = \theta_t$

end if

end for

execution). But the key challenge is performance. A naïve scheduling scheme always requires $\approx 2^s$ parallel cores to achieve a speedup of s . Less naïve schemes improve on this speedup using the average proposal acceptance rate: if most proposals are rejected, a prefetching implementation should prefetch more heavily among the right children of the left-most branch, *i.e.*, the path representing a sequence of rejected proposals. Although in practice the optimal acceptance rate is less than 0.5 (Gelman et al., 1996), tiny acceptance rates, which lead to good speedup, cause less effective mixing. If the acceptance rate is set near the 0.234 value of Gelman et al., speedup is still at most logarithmic.

We evaluate a new scheduling approach that uses local information to improve speedup relative to other prefetching schemes. We adaptively adjust speculation based not only on the local average proposal acceptance rate (which changes as evaluation progresses), but also on the actual random deviate used at each state. Even better, we make use of any available fast approximations to the transition operator. Though these approximations are not required, when they are available or learnable, we leverage them to make better scheduling decisions.

We present results using a series of increasingly expensive but more accurate approximations. These decisions are further improved by modeling the error of these approximations, and thus the uncertainty of the scheduling decisions. Performance depends critically on how we model the approximations, and a key insight is in our error model for this setting; much smaller error, and therefore more precise prediction, is obtained by modeling the error of the *difference* between two proposal evaluations, rather than evaluating the errors of the proposals separately. Our current implementation uses approximations that correspond to incremental evaluation of the target distribution, but our framework does not require this. We could use other examples of target density approximation, including exploiting closed form approximations such as Taylor series (Christen and Fox, 2005) and fitting linear or Gaussian Process regressions (Conrad et al., 2014).

Motivated by large-scale Bayesian inference, we present results using incremental approximations that arise from evaluating a subset of factors in a larger product. As we show on inference problems using both real and synthetic data, our system takes advantage of parallelism to speed up the wall-clock time of serial Markov chain evaluation. Unlike prior systems, we achieve near-linear speedup during burn-in on up to 64 cores spread across two or more machines. As evaluation progresses, speedup eventually decreases to logarithmic in the number of cores; we show why this is hard to avoid.

2 RELATED WORK

In this section, we summarize existing parallel strategies for accelerating MCMC, motivated by the computational cost of MCMC. This cost is most often determined by evaluation of the target density relative to mixing. In Metropolis–Hastings, it is incurred when the target is evaluated to determine the acceptance ratio of a proposed move; in slice sampling (Neal, 2003) an expensive target slows both bracket expansion and contraction. We focus on the increasingly common case where the target is expensive and the dominant computational cost. This evaluation can sometimes be parallelized directly, *e.g.*, when the target function is a product of many individually expensive terms. This can arise in Bayesian inference if the target easily decomposes into one likelihood term for each data item. Practically achievable speedup in this setting is limited by the communication and computational costs associated with aggregating the partial evaluations. In general, the target function cannot be parallelized; we divide methods that accelerate MCMC via other sources of parallelism into two classes: ensemble sampling and prefetching.

Other work speeds up MCMC evaluation using approximation. Stochastic variational inference techniques achieve scalable approximate inference via randomized approximations of gradients (Hoffman et al., 2013), while recent developments in MCMC have implemented efficient transition operators that lead to approximate stationary distributions (Welling and Teh, 2011; Korattikara et al., 2014; Bardenet et al., 2014). Recent other work uses a lower bound on the local likelihood factor to simulate from the exact posterior distribution while evaluating only a subset of the data at each iteration (Maclaurin and Adams, 2014). Unlike such prior work, we speed up *exact* evaluation of many existing MCMC algorithms.

2.1 ENSEMBLE SAMPLERS

Ensemble (or *population*) methods for sampling run multiple chains and accelerate mixing by sharing information between the chains. The individual chains can be simu-

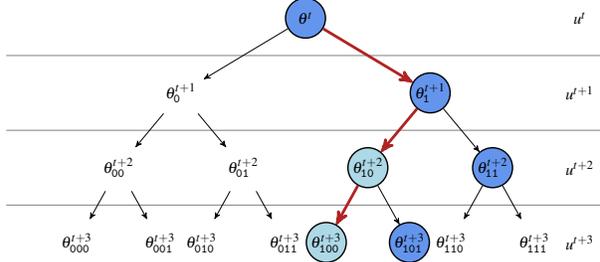

Figure 1: Schematic of a MH simulation superimposed on the binary tree of all possible chains. Each level of the tree represents an iteration, where branching to the right/left indicates accepting/rejecting a proposal. Random variates (on right) are shared across each layer. Thick red arrows highlight one simulated chain starting at the root θ^t ; the first proposal is accepted and the next two are rejected, yielding as output: $\theta_1^{t+1}, \theta_{10}^{t+2}, \theta_{101}^{t+3}$. Dark filled circles indicate states where the target density is evaluated during simulation. Those not on the chain’s path correspond to rejected proposals. Their siblings are pale filled circles on this path; since each is a copy of its parent, the target density does not need to be reevaluated to compute the next transition.

lated in parallel; any information sharing between chains requires communication. Examples include parallel tempering (Swendsen and Wang, 1986), the emcee implementation (Foreman-Mackey et al., 2012) of affine-invariant ensemble sampling (Goodman and Weare, 2010), and a parallel implementation of generalized elliptical slice sampling (Nishihara et al., 2014).

2.2 PREFETCHING

The second class of parallel MCMC algorithms uses parallelism through speculative execution to accelerate individual chains. This idea is called *prefetching* in some of the literature. To the best of our knowledge, prefetching has only been studied in the context of MH-style algorithms where, at each iteration, a single new proposal is drawn from a proposal distribution and stochastically accepted or rejected. The typical body of an MH implementation is a loop containing a single conditional statement and two associated branches. One can then view the possible execution paths as a binary tree, as illustrated in Figure 1. The vanilla version of prefetching speculatively evaluates all paths in this binary tree (Brockwell, 2006). The correct path will be exactly one of these, so with J cores, this approach achieves a speedup of $\log_2 J$ with respect to single core execution, ignoring communication and bookkeeping overheads.

Naïve prefetching can be improved by observing that the two branches are not taken with equal probability. On average, the left-most branch, corresponding to a sequence of rejected proposals, tends to be more probable; the classic

result for the optimal MH acceptance rate is 0.234 (Roberts et al., 1997), so most prefetching scheduling policies have been built around the expectation of rejection. Let $\alpha \leq 0.5$ be the expected probability of accepting a proposal. Byrd et al. (2008) introduced a procedure, called “speculative moves,” that speculatively evaluates only along the “reject” branch of the binary tree; in Figure 1, this corresponds to the left-most branch. In each round of their algorithm, only the first k out of $J - 1$ extra cores perform useful work, where k is the number of rejected proposals before the first accepted proposal, starting from the root of the tree. The expected speedup is then:

$$1 + \mathbb{E}(k) < 1 + \sum_{k=0}^{\infty} k(1 - \alpha)^k \alpha < 1 + \frac{1 - \alpha}{\alpha} = \frac{1}{\alpha}.$$

Note that the first term on the left is due to the core at the root of the tree, which always performs useful computation in the prefetching scheme. When $\alpha = 0.23$, this scheme yields a maximum expected speedup of about 4.3; it achieves an expected speedup of about 4 with 16 cores. If only a few cores are available, this may be a reasonable policy, but if many cores are available, their work is essentially wasted. In contrast, the naïve prefetching policy achieves speedup that grows as the log of the number of cores. Byrd et al. (2010) later considered the special case where the evaluation of the likelihood function occurs on two timescales, slow and fast. They call this method “speculative chains”; it modifies “speculative moves” so that whenever the evaluation of the likelihood function is slow, any available cores are used to speculatively evaluate the subsequent chain, assuming the slow step resulted in an accept.

In work closely related to ours, Strid (2010) extend the naïve prefetching scheme to allocate cores according to the optimal “tree shape” with respect to various assumptions about the probability of rejecting a proposal, *i.e.*, by greedily allocating cores to nodes that maximize the depth of speculative computation expected to be correct (Strid, 2010). Their static prefetching scheme assumes a fixed acceptance rate; versions of this were proposed earlier in the context of simulated annealing (Witte et al., 1991). Their dynamic scheme estimates acceptance probabilities, *e.g.*, at each level of the tree by drawing empirical MH samples (100,000 in the evaluation), or at each branch in the tree by computing $\min\{\beta, r\}$ where β is a constant ($\beta = 1$ in the evaluation) and r is an estimate of the MH ratio based on a fast approximation to the target function. Alternatively, Strid proposes using the approximate target function to identify the single most likely path on which to perform speculative computation. Strid also combines prefetching with other sources of parallelism to obtain a multiplicative effect. To the best of our knowledge, these methods have been developed for MH algorithms and evaluated on up to 64 cores, although usually many fewer.

3 PREDICTIVE PREFETCHING

We propose *predictive prefetching*, an improved scheduling approach that accelerates exact MCMC. Like Strid’s dynamic prefetching procedure, we also exploit inexpensive but approximate target evaluations. However, there are several fundamental differences between our approach and existing prefetching methods. We combine approximate target evaluation with the fact that the random stream used by a MCMC algorithm can be generated in advance and thus incorporated into the estimates of the acceptance probabilities at each branch in the binary tree. Critically, we also model the error of the target density approximation, and thus the uncertainty of whether a proposal will be accepted. In addition, we identify a broad class of MCMC algorithms that could benefit from prefetching, not just MH, and we show how prefetching can exploit a series of approximations, not just a single one.

3.1 MATHEMATICAL SETUP

Consider a transition operator $T(\theta \rightarrow \theta')$ which has $\pi(\theta)$ as its stationary distribution on state space Θ . Simulation of such an operator typically proceeds using an “external” source of pseudo-random numbers that can, without loss of generality, be assumed to be drawn uniformly on the unit hypercube \mathcal{U} . The transition operator is then a deterministic function $T : \Theta \times \mathcal{U} \rightarrow \Theta$. Most practical transition operators – Metropolis–Hastings, slice sampling, *etc.* – are actually compositions of two such functions, however. The first function produces a countable set of candidate points in Θ , here denoted $Q : \Theta \times \mathcal{U}_Q \rightarrow \mathcal{P}(\Theta)$, where $\mathcal{P}(\Theta)$ is the power set of Θ . The second function $R : \mathcal{P}(\Theta) \times \mathcal{U}_R \rightarrow \Theta$ then chooses one of the candidates for the next state in the Markov chain. Here we have used \mathcal{U}_Q and \mathcal{U}_R to indicate the orthogonal parts of \mathcal{U} relevant to each part of the operator. In this setup, the basic Metropolis–Hastings algorithm uses $Q(\cdot)$ to produce a tuple of the current point and a proposed point, while multiple-try MH (Liu et al., 2000) and delayed-rejection MH (Tierney and Mira, 1999; Green and Mira, 2001) create a larger set that includes the current point. In the exponential-shrinkage variant of slice sampling (Neal, 2003), $Q(\cdot)$ produces an infinite sequence of candidates that converges to, but does not include, the current point.

This setup is a somewhat more elaborate treatment than usual, but this is intended to serve two purposes: 1) make it clear that there is a separation between generating a set of possible candidates via $Q(\cdot)$ and selecting among them with $R(\cdot)$, and 2) highlight that both of these functions are deterministic functions, given the pseudo-random variates. Others have pointed out this “deterministic given the randomness” view, and used it to construct alternative approaches to MCMC (Propp and Wilson, 1996; Neal, 2012).

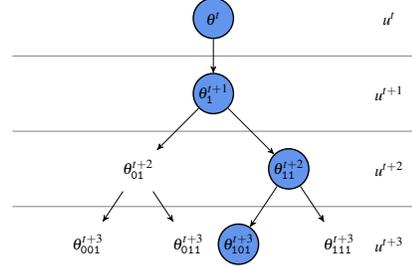

Figure 2: Schematic of the same MH simulation as in Figure 1, this time superimposed on the jobtree. This tree includes only those nodes in the original MH tree where a new state is introduced and thus the target density must be evaluated when comparing such a state to another. The filled circles, corresponding to states where the target density is evaluated in a serial MH execution, are now directly connected by a single path.

We separately consider $Q(\cdot)$ and $R(\cdot)$ because it is generally the case that $Q(\cdot)$ is inexpensive to evaluate and does not require computation of the target density $\pi(\theta)$, while $R(\cdot)$ must compare the target density at the candidate locations and so represents the bulk of the computational burden. Parallel predictive prefetching observes that, since $Q(\cdot)$ is cheap and the pseudo-random variates can be produced in any order, the tree of possible future states of the Markov chain can be constructed before any of the $R(\cdot)$ functions are evaluated, as in Figure 1. The sequence of $R(\cdot)$ evaluations simply chooses a path down this tree. Parallelism can be achieved by speculatively choosing to evaluate $R(\{\theta_i\}, u)$ for some part of the tree that has not yet been reached. If this node in the tree is eventually reached, then we achieve a speedup.

For clarity, we henceforth focus on the straightforward random-walk Metropolis–Hastings operator. In this special case, $Q(\cdot)$ produces a tuple of the current point and a proposal, and the function $R : \Theta \times \Theta \times (0, 1) \rightarrow \Theta$ takes these two points, along with a uniform random variate u in $(0, 1)$, and selects one of the two inputs via:

$$R(\theta, \theta', u) = \begin{cases} \theta' & \text{if } u \frac{q(\theta'|\theta)}{q(\theta|\theta')} < \frac{\pi(\theta')}{\pi(\theta)}, \\ \theta & \text{otherwise} \end{cases}, \quad (1)$$

where $q(\cdot|\cdot)$ is the proposal density corresponding to $Q(\cdot)$. We write the acceptance ratio in this somewhat unusual fashion to highlight the fact that the left-hand side of the inequality does not require evaluation of the target density and is easy to precompute.

3.2 THE JOBTREE

While the MH state tree in Figure 1 effectively represents a simulated chain as a path, it yields an awkward

representation of the computation necessary to produce a chain. Specifically, transitions to right children (when a proposal is accepted) align with this path but transitions to left children (when a proposal is rejected) branch off it. For our prefetching framework, we wanted a better representation of this computation. To this end, we introduced the Metropolis–Hastings *jobtree*, depicted in Figure 2. It contains the same information as the MH state tree but represents only those states where new computation occurs, *i.e.*, where the target density must be evaluated in order to compare such a state to another. Like the original tree, the jobtree is generally binary, except that the root has only one child. It includes the root node and all right children of the MH state tree, corresponding to the current state and all possible subsequent proposals – together, these specify the possible distinct states and at what iteration each would first appear. Paths on the jobtree represent computation in the sense that they map to sequences of states where the target density is evaluated during serial MH simulation; we call any such path a *computation path*.

3.3 EXPLOITING PREDICTIONS

Consider a prefetching framework with J cores that uses one core to compute the immediate transition and the others to precompute transitions for possible future iterations. If each precomputation falls along the actual Markov chain, the framework will achieve the ideal linear speedup proportional to J . If some of them do not fall along the chain, the framework will fail to scale perfectly with the available resources. For instance, recall that the naïve framework that evaluates transitions based on breadth-first search of the prefetching state tree (Figure 1) will achieve speedup proportional to $\log_2 J$. Good speedup thus depends on making good predictions of what path will be taken on the tree, which is in turn determined by our prediction of whether the threshold will be exceeded in Eq. 1.

Let ρ denote a node on the tree, θ_ρ indicate the current state at ρ , and θ'_ρ indicate the proposal. We define

$$r_\rho = u_\rho \frac{q(\theta'_\rho | \theta_\rho)}{q(\theta_\rho | \theta'_\rho)} \quad (2)$$

where u_ρ is the MH threshold variate for node ρ . The Markov chain’s steps are determined by iterations of computing the indicator function $\iota_\rho = \mathbb{I}(r_\rho < \pi(\theta'_\rho)/\pi(\theta_\rho))$, where a proposal is accepted iff $\iota_\rho = 1$. The quantities θ_ρ , θ'_ρ , and r_ρ can be inexpensively computed at any time from the stream of pseudo-random numbers, without examining the expensive target $\pi(\cdot)$. The random variate u_ρ depends only on the depth (iteration) of ρ .

The precomputation schedule should maximize expected speedup, which corresponds to the expected number of precomputations along the true computation path in the job-

tree. To maximize this quantity, the framework needs to anticipate which branches of the jobtree are likely to be taken. The root node and its only child are always evaluated. We associate with each remaining node ρ in the jobtree a predictor ψ_ρ that models the probability that the proposal is accepted, given approximate or partial information. For example, suppose that $\tilde{\pi}(\cdot)$ is an approximation to the target density $\pi(\cdot)$, and assume that in log space, the error of this approximation relative to the target density is normally distributed with some variance σ^2 . Then, we could write the predictor as:

$$\begin{aligned} \psi_\rho &= \Pr\left(\log r_\rho < \log \pi(\theta'_\rho) - \log \pi(\theta_\rho) \mid \tilde{\pi}(\cdot), \sigma^2\right) \quad (3) \\ &= \int_{\log r_\rho}^{\infty} \mathcal{N}\left(z \mid \log \tilde{\pi}(\theta'_\rho) - \log \tilde{\pi}(\theta_\rho), \sigma^2\right) dz. \quad (4) \end{aligned}$$

As more information becomes available in the form of better approximators, the predictor ψ_ρ will change. When $\tilde{\pi}(\cdot) = \pi(\cdot)$, the predictor equals the indicator ι_ρ . We label the edges in the jobtree with *branch probabilities*: the edge from a node ρ to its right child has branch probability equal to the predictor ψ_ρ and the edge to its left child has branch probability $1 - \psi_\rho$. Assuming that the predictions at each node are independent, the probability that a node’s computation is used is the product of the branch probabilities along the path connecting the root to ρ ; we call this quantity the node’s *expected utility*. Those nodes with maximum expected utility should be scheduled for precomputation. (The immediate transition will always be chosen: it has no ancestors and utility 1.)

A predictor is always available – for instance, one can use the recent acceptance probability – but many problems can improve predictions using computation. To model this, we define a sequence of predictors

$$\psi_\rho^{(m)} \approx \psi_\rho, \quad m = 0, 1, 2, \dots, N, \quad (5)$$

where increasing m implies increasing accuracy, and $\psi_\rho^{(N)} = \iota_\rho$. Workers move through this sequence until they perform the exact computation. The predictor sequence affects scheduling decisions: once it becomes sufficiently certain that a worker’s branch will not be taken, that worker and its descendants should be reallocated to more promising branches. Ultimately, every true step of the Markov chain is computed to completion. The approach simulates from the true stationary distribution, not an approximation thereof. The estimators are used only in prefetching.

There are several schemes for producing this estimator sequence, and predictive prefetching applies to any Markov chain Monte Carlo problem for which approximations are available. We focus on the important case where improved estimators are obtained by including more and more of the data in the posterior target distribution.

3.4 LARGE-SCALE BAYESIAN INFERENCE

In Bayesian inference with MCMC, the target density is a (possibly unnormalized) posterior distribution. In most modeling problems, such as those using graphical models, the target density can be decomposed into a product of terms. If the data are conditionally independent given the model parameters, there is a factor for each of the N data:

$$\pi(\theta | \mathbf{x}) \propto \pi_0(\theta) \prod_{n=1}^N \pi(x_n | \theta). \quad (6)$$

Here $\pi_0(\theta)$ is a prior distribution and $\pi(x_n | \theta)$ is the likelihood term associated with the n th datum. The logarithm of the target distribution is a sum of terms

$$\mathcal{L}(\theta) = \log \pi(\theta | \mathbf{x}) = \log \pi_0(\theta) + \sum_{n=1}^N \log \pi(x_n | \theta) + c,$$

where c is an unknown constant that does not depend on θ and can be ignored. Our predictive prefetching algorithm uses this to form predictors ψ_ρ as in Eq. 3; we again reframe ψ_ρ using log probabilities as

$$\psi_\rho \approx \Pr(\log r_\rho < \mathcal{L}(\theta') - \mathcal{L}(\theta)), \quad (7)$$

where r_ρ is the precomputed random MH threshold of Eq. 2. One approach to forming this predictor is to use a normal model for each $\mathcal{L}(\theta)$, as in Korattikara et al. (2014). However, we can achieve a better estimator with lower variance by modeling $\mathcal{L}(\theta)$ and $\mathcal{L}(\theta')$ together, rather than separately. Expanding each log likelihood gives:

$$\mathcal{L}(\theta') - \mathcal{L}(\theta) = \log \pi_0(\theta') - \log \pi_0(\theta) + \sum_{n=1}^N \Delta_n \quad (8)$$

$$\Delta_n = \log \pi(x_n | \theta') - \log \pi(x_n | \theta). \quad (9)$$

In Bayesian posterior sampling, the proposal θ' is usually a perturbation of θ and so we expect $\log \pi(x_n | \theta')$ to be correlated with $\log \pi(x_n | \theta)$. In this case, the differences Δ_n occur on a smaller scale and have a smaller variance compared to the variance due to $\log \pi(x_n | \theta)$ across data terms.

A concrete sequence of estimators is obtained by subsampling the data. Let $\{\Delta_n\}_{n=1}^m$ be a subsample of size $m < N$, without replacement, from $\{\Delta_n\}_{n=1}^N$. This subsample can be used to construct an unbiased estimate of $\mathcal{L}(\theta') - \mathcal{L}(\theta)$. We model the terms of this subsample as i.i.d. from a normal distribution with bounded variance σ^2 , leading to:

$$\mathcal{L}(\theta') - \mathcal{L}(\theta) \sim \mathcal{N}(\hat{\mu}_m, \hat{\sigma}_m^2). \quad (10)$$

The mean estimate $\hat{\mu}_m$ is empirically computable:

$$\hat{\mu}_m = \log \pi_0(\theta') - \log \pi_0(\theta) + \frac{1}{m} \sum_{n=1}^m \Delta_n. \quad (11)$$

The error estimate $\hat{\sigma}_m$ may be derived from s_m/\sqrt{m} , where s_m is the empirical standard deviation of the m subsampled Δ_n terms. To obtain a confidence interval for the sum of N terms, we multiply this estimate by N and the finite population correction $\sqrt{(N-m)/N}$, giving:

$$\hat{\sigma}_m = s_m \sqrt{\frac{N(N-m)}{m}}. \quad (12)$$

We can now form the predictor $\psi_\rho^{(m)}$ by considering the tail probability for $\log r_\rho$:

$$\psi_\rho^{(m)} = \int_{\log r_\rho}^{\infty} \mathcal{N}(z | \hat{\mu}_m, \hat{\sigma}_m^2) dz \quad (13)$$

$$= \frac{1}{2} \left[1 + \operatorname{erf} \left(\frac{\log \hat{\mu}_m - \log r_\rho}{\sqrt{2} \hat{\sigma}_m} \right) \right]. \quad (14)$$

3.5 SYSTEM

Our system is fully parallel and runs on network clusters of computers, each of which may comprise multiple cores. We do not perform any affinity scheduling, so all cores are treated identically whether they co-reside on the same machine or not. Our system does not use shared memory; rather, cores communicate via message passing. Note that we assign one thread to each core. To date, the largest installation on which we have run is a shared cluster of 5 machines with a total of 160 cores, on which we have used in parallel at least 64 cores spanning a minimum of 2 machines.

Our system executes predictive prefetching as follows. A master node manages the jobtree and distributes a different node in the jobtree to each worker. When a worker receives a message to compute on node ρ , it first computes the corresponding proposal θ_ρ (which may consume values from the random sequence). It asynchronously transmits the proposal and the new point in the random sequence back to the master. It then starts evaluating the target density, producing progressively improved approximations to the target that it periodically reports back to the master. Meanwhile, the master uses estimates of $\mathcal{L}(\theta'_\rho) - \mathcal{L}(\theta_\rho)$ values, the appropriate r_ρ constants, and an adaptive estimate of the current acceptance probability to calculate the predictor $\psi_\rho^{(m)}$ for each node in the evaluation tree. To assign a worker to a node, the master stochastically traverses down the jobtree from the root, following branches according to their branch probabilities, until it finds a node that is inactive, *i.e.*, no other worker is currently working on it. In this way, the master stochastically assigns workers to those nodes with highest expected utility. During computation, expected utilities change. When the master notices that the expected utility of a worker's node falls below that of other inactive nodes, the master tells the worker to abandon its work. If the abandoned proposal becomes likely again, a worker will pick it up where the earlier worker left off.

J	Burn-in					
	$i_1 = 9575$		$i_2 = 24000$	$i_3 = 50000$		
1	16674	—	41978	—	87500	—
16	2730	$6.1\times$	8678	$4.3\times$	20318	$4.3\times$
32	1731	$9.6\times$	7539	$5.6\times$	19046	$4.6\times$
64	989	$16.8\times$	5894	$7.1\times$	15146	$5.8\times$

Table 1: Cumulative time (in seconds) and speedup for evaluating the Gaussian mixture model with different numbers of workers J .

In our implementation, the target posteriors $\log \pi(\theta | \mathbf{x})$ and $\log \pi(\theta' | \mathbf{x})$ are evaluated by separate workers. Our normal model for the MH ratio based on a subsample of size m depends on the empirical mean and standard deviation of the differences Δ_n , but we use an approximation to avoid the extra communication required to keep track of all these differences. The worker for θ calculates

$$G_m(\theta) = \log \pi_0(\theta) + \frac{N}{m} \sum_{n=1}^m \log \pi(x_n | \theta) \quad (15)$$

rather than the difference mean $\hat{\mu}_m$ from Eq. 11. The master can then compute $\hat{\mu}_m = G_m(\theta') - G_m(\theta)$, but the empirical standard deviation of differences, s_m in Eq. 12, must be estimated. We set

$$s_m = \sqrt{S_m(\theta)^2 + S_m(\theta')^2 - 2\tilde{c}S_m(\theta)S_m(\theta')}, \quad (16)$$

where $S_m(\theta)$ denotes the empirical standard deviation of the $m \log \pi(x_n | \theta)$ terms, and \tilde{c} approximates the correlation between $\log \pi(x_n | \theta)$ and $\log \pi(x_n | \theta')$. We empirically observe this correlation to be very high; in all experiments we set $\tilde{c} = 0.9999$. Note that this approximation only affects the quality of our speculative predictions; it does not affect the actual decision to accept or reject the proposal θ' .

Our implementation requires at least two cores, one master and one worker. Note that when there is only one worker, it is always performing useful computation for the immediate transition at the root, leaving the master with essentially nothing to do besides some bookkeeping.

4 EXPERIMENTS

Our evaluation focuses on MH for large-scale Bayesian inference using the approximations described above (though our framework can use any approximation scheme for the target distribution). Our implementation is written in C++ and Python, and uses MPI for communication between the master and worker cores.¹ We evaluate our implementation on up to 64 cores in a multicore cluster environment in which machines are connected by 10GB ethernet and each

¹<https://github.com/elaine84/fetching>

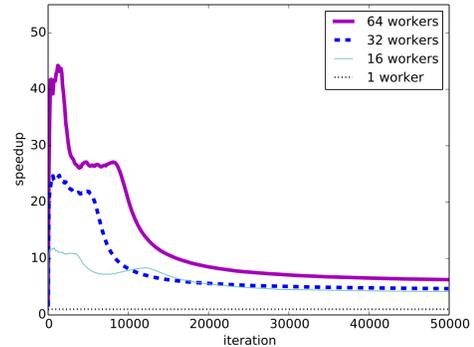

Figure 3: Cumulative speedup relative to our baseline, as a function of the number of MH iterations, for the mixture of Gaussians problem. The different curves correspond to different numbers of workers.

machine has 32 cores (four 8-core Intel Xeon E7-8837 processors). We report speedups relative to serial computation with one worker.

We evaluate our system on both synthetic and real Bayesian inference problems. First, we consider the posterior density of the eight-component mixture of eight-dimensional Gaussians used by Nishihara et al. (2014), where the likelihood involves 10^6 samples drawn from this model. Next, we consider the posterior density of a Bayesian Lasso regression (Park and Casella, 2008) that models molecular photovoltaic activity. The likelihood involves a dataset of 1.8×10^6 molecules described by 56-dimensional real-valued cheminformatic features (Olivares-Amaya et al., 2011; Amador-Bedolla et al., 2013); each response is real-valued and corresponds to a lengthy density functional theory calculation (Hachmann et al., 2011, 2014).

In our experiments, we use a spherical Gaussian for the proposal distribution. A simple adaptive scheme sets the scale of this distribution, improving convergence relative to standard MH. Our approach falls under the provably convergent adaptive algorithms studied by Andrieu and Moulines (2006); we easily incorporated them into our framework.

We expect predictive prefetching to perform best when the densities at a proposal and corresponding current point are significantly different, which is common in the initial burn-in phase of chain evaluation. In this phase, early estimates based on small subsamples effectively predict whether the proposal is accepted or rejected. When the density at the proposal is very close to that at the current point – for example, as the proposal distribution approaches the target distribution – the outcome is inherently difficult to predict; early estimates will be uncertain or even wrong. Incorrect estimates could destroy speedup (no precomputations would be useful). We hope to do better than this worst case, and to at least achieve logarithmic speedup.

	mean	standard deviation	min	max
n_{eff}	3405	7253	50	26000
\hat{R}	1.005	0.006	1.000	1.020

Table 2: Convergence statistics after burn-in (over iterations i_2 – i_3) for the Gaussian mixture model, computed over the 64 dimensions of the model.

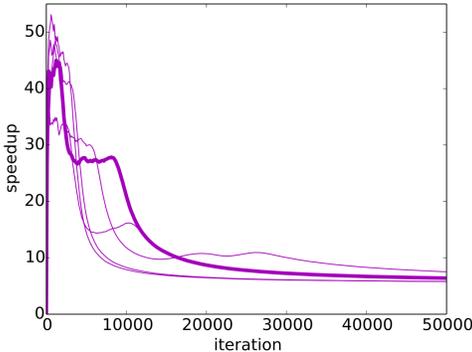

Figure 4: Cumulative speedup relative to our baseline, as a function of the number of MH iterations, for the mixture of Gaussians problem. The different curves correspond to different initial conditions; all curves are for 64 workers.

In our experiments, we divide the evaluation of the target function into 100 batches. Thus, for the mixture problem, each subsample contains 10^4 data items.

Table 1 shows the results for the Gaussian mixture model. We run the model with the same initial conditions and pseudorandom sequences with varying numbers of worker threads. All experiments produce identical chains. We evaluate the cumulative time and speedup obtained at three different iteration counts. The first, $i_1 = 9575$ iterations, are burn-in. After i_1 iterations, all dimensions of samples achieve the Gelman-Rubin statistic $\hat{R} < 1.05$, computed using two independent chains, where the first $i_1/2$ samples have been discarded (Gelman and Rubin, 1992). We then run the model further to i_3 iterations. Iterations $i_2 = 24000$ through $i_3 = 50000$ are used to compute an effective number of samples n_{eff} . (Table 2 shows convergence statistics after i_3 iterations.) The results are as we hoped. The initial burn-in phase obtains better-than-logarithmic speedup (though not perfect linear speedup). With 64 workers, the chain achieves burn-in $16.8\times$ faster than with one worker. After burn-in, efficiency drops as expected, but we still achieve logarithmic speedup (rather than sub-logarithmic). At 50000 iterations, speedup for each number of workers J rounds to $\log_2 J$.

Figure 3 explains these results by graphing cumulative speedup over the whole range of iterations. The initial

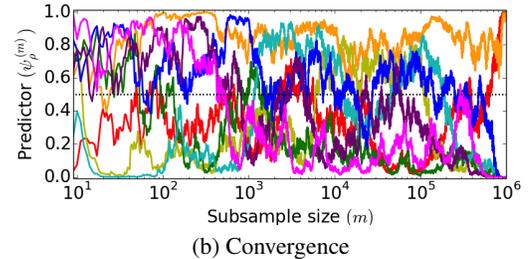

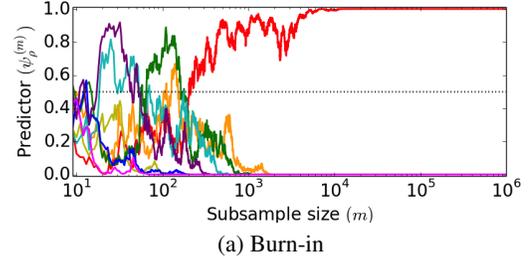

Figure 5: Example predictor trajectories for the mixture of Gaussians. We show the predictor $\psi_\rho^{(m)}$ as a function of subsample size m . Different colors indicate different proposals. Burn-in is much easier to predict than convergence.

speedup is close to linear – we briefly achieve more than $40\times$ speedup at $J = 64$ workers. As burn-in proceeds, cumulative speedup falls off to logarithmic in J . Figure 4 shows cumulative speedup for the Gaussian mixture model with several different initial conditions. We see a range of variation due to differences in the adaptive scheme during burn-in. The overall pattern is stable, however: good speedup during burn-in followed by logarithmic speedup later. Also note that speedup does not necessarily decrease steadily, or even monotonically. At some initial conditions, the chain enters an easier-to-predict region before truly burning in; while in such a region, speedup is maintained. Our system takes advantage of these regions effectively.

Figure 5 shows how our predictors behave both during and after burn-in. During burn-in, estimates are effective, and the predictor converges quite quickly to the correct indicator. After burn-in, the new proposal’s target density is close to the old proposal’s, and the estimates are similarly hard to distinguish. Sometimes the random variate r_ρ is small enough for the predictor to converge quickly to 1; more often, the predictor varies widely over time, and does not converge to 0 or 1 until almost all data are evaluated. This behavior makes logarithmic speedup a best case. Luckily, the predictor is more typically uncertain (with an intermediate value) than wrong (with an extreme value that eventually flips to the opposite value): incorrect predictors could lead to sublogarithmic speedup.

Figure 6 shows that good speedups are achievable for real problems. The speedup distribution for the Bayesian Lasso problem for molecular photovoltaic activity appears similar

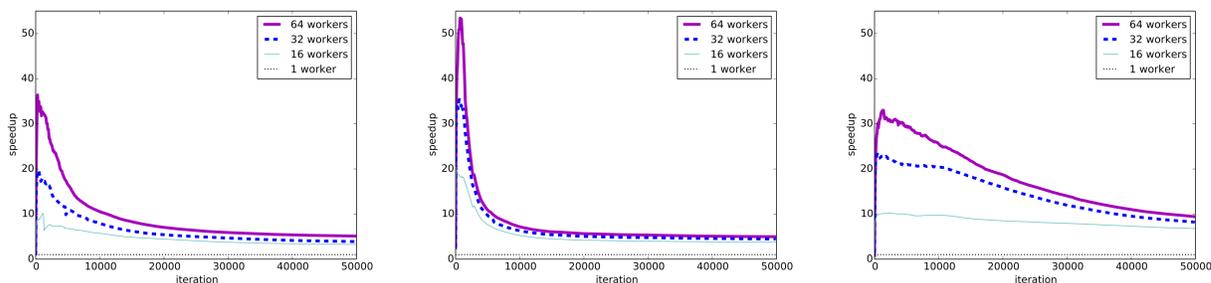

Figure 6: Cumulative speedup relative to our baseline, as a function of the number of MH iterations, for the Bayesian Lasso problem. Different curves indicate different numbers of workers. Each figure corresponds to a different initial condition.

to that of the mixture of Gaussians. There are differences, however: Lasso evaluation did not converge by 50000 iterations according to standard convergence statistics. On several initial conditions, the chain started taking small steps, and therefore dropped to logarithmic speedup, before achieving convergence. Overall performance might be improved by detecting this case and switching some speculative resources over to other initial conditions, an idea we leave for future work.

5 CONCLUSIONS

We presented parallel predictive prefetching, a general framework for accelerating many widely used MCMC algorithms that are inherently serial and often slow to converge. Our approach applies to MCMC algorithms whose transition operator can be decomposed into two functions, one that produces a countable set of candidate proposal states and a second that selects the best candidate. Predictive prefetching uses speculative computation to exploit the common setting in which (1) generating candidates is computationally fast compared to the evaluation required to select the best candidate, and (2) this evaluation can be approximated quickly. Our first focus has been on the MH algorithm, in which predictive prefetching exploits a sequence of increasingly accurate predictors for the decision to accept or reject a proposed state. Our second focus has been on large-scale Bayesian inference, for which we identified an effective predictive model that estimates the likelihood from a subset of data. The key insight is that we model the uncertainty of these predictions with respect to the difference between the likelihood of each datum evaluated at the proposal and current state. As these evaluations are highly correlated, the variance of the differences is much smaller than the variance of the states evaluated separately, leading to significantly higher confidence in our predictions. This allows us to justify more aggressive use of parallel resources, leading to greater speedup with respect to serial execution or more naïve prefetching schemes.

The best speedup that is realistically achievable for this

problem is sublinear in the number of cores but better than logarithmic, and our results achieve this. Our approach generalizes both to schemes that learn an approximation to the target density and to other MCMC algorithms with more complex structure, such as slice sampling and more sophisticated adaptive techniques.

Abstract

We introduce a new convex formulation for stable principal component pursuit (SPCP) to decompose noisy signals into low-rank and sparse representations. For numerical solutions of our SPCP formulation, we first develop a convex variational framework and then accelerate it with quasi-Newton methods. We show, via synthetic and real data experiments, that our approach offers advantages over the classical SPCP formulations in scalability and practical parameter selection.

1 INTRODUCTION

Linear superposition is a useful model for many applications, including nonlinear mixing problems. Surprisingly, we can perfectly distinguish multiple elements in a given signal using convex optimization as long as they are concise and look sufficiently different from one another. Popular examples include robust principal component analysis (RPCA) where we decompose a signal into low rank and sparse components and *stable principal component pursuit (SPCP)*, where we also seek an explicit noise component within the RPCA decomposition. Applications include alignment of occluded images (Peng et al., 2012), scene triangulation (Zhang et al., 2011), model selection (Chandrasekaran et al., 2012), face recognition, and document indexing (Candès et al., 2011).

The SPCP formulation can be mathematically stated as follows. Given a noisy matrix $Y \in \mathbb{R}^{m \times n}$, we decompose it as a sum of a low-rank matrix L and a

sparse matrix S via the following convex program

$$\begin{aligned} & \underset{L, S}{\text{minimize}} \quad \|L\|_* + \lambda_{\text{sum}} \|S\|_1 \\ & \text{subject to} \quad \|L + S - Y\|_F \leq \varepsilon, \end{aligned} \quad (\text{SPCP}_{\text{sum}})$$

where the 1-norm $\|\cdot\|_1$ and nuclear norm $\|\cdot\|_*$ are given by $\|S\|_1 = \sum_{i,j} |s_{i,j}|$, $\|L\|_* = \sum_i \sigma_i(L)$, where $\sigma(L)$ is the vector of singular values of L . In (SPCP_{sum}), the parameter $\lambda_{\text{sum}} > 0$ controls the relative importance of the low-rank term L vs. the sparse term S , and the parameter ε accounts for the unknown perturbations $Y - (L + S)$ in the data not explained by L and S .

When $\varepsilon = 0$, (SPCP_{sum}) is the “robust PCA” problem as analyzed by Candès et al. (2011); Chandrasekaran et al. (2009), and it has perfect recovery guarantees under stylized incoherence assumptions. There is even theoretical guidance for selecting a minimax optimal regularization parameter λ_{sum} (Candès et al., 2011). Unfortunately, many practical problems only approximately satisfy the idealized assumptions, and hence, we typically tune RPCA via cross-validation techniques. SPCP further complicates the practical tuning due to the additional parameter ε .

To cope with practical tuning issues of SPCP, we propose the following new variant called “max-SPCP”:

$$\begin{aligned} & \underset{L, S}{\text{minimize}} \quad \max(\|L\|_*, \lambda_{\text{max}} \|S\|_1) \\ & \text{subject to} \quad \|L + S - Y\|_F \leq \varepsilon, \end{aligned} \quad (\text{SPCP}_{\text{max}})$$

where $\lambda_{\text{max}} > 0$ acts similar to λ_{sum} . Our work shows that this new formulation offers both modeling and computational advantages over (SPCP_{sum}).

Cross-validation with (SPCP_{max}) to estimate $(\lambda_{\text{max}}, \varepsilon)$ is significantly easier than estimating $(\lambda_{\text{sum}}, \varepsilon)$ in (SPCP_{sum}). For example, given an *oracle* that provides an ideal separation $Y \simeq L_{\text{oracle}} + S_{\text{oracle}}$, we can use $\varepsilon = \|L_{\text{oracle}} + S_{\text{oracle}} - Y\|_F$ in both cases. However, while we can estimate $\lambda_{\text{max}} = \|L_{\text{oracle}}\|_* / \|S_{\text{oracle}}\|_1$, it is not clear how to choose λ_{sum} from data. Such cross

be non-convergent (Chen et al., 2013). Interestingly, there are only a handful of methods that can handle this case. Those using smoothing techniques no longer promote exactly sparse and/or exactly low-rank solutions (Aybat et al., 2013). Those using dual decomposition techniques require high iteration counts. Because each step requires a partial singular value decomposition (SVD) of a large matrix, it is critical that the methods only take a few iterations.

As a rough comparison, we start with related solvers that solve (SPCP_{sum}) for $\varepsilon = 0$. Wright et al. (2009a) solves an instance of (SPCP_{sum}) with $\varepsilon = 0$ and a 800×800 system in 8 hours. By switching to the (Lag-SPCP) formulation, Ganesh et al. (2009) uses the accelerated proximal gradient method (Beck & Teboulle, 2009) to solve a 1000×1000 matrix in under one hour. This is improved further in Lin et al. (2010) which again solves (SPCP_{sum}) with $\varepsilon = 0$ using the augmented Lagrangian and ADMM methods and solves a 1500×1500 system in about a minute. As a prelude to our results, our method can solve some systems of this size in about 10 seconds (c.f., Fig. 1).

In the case of (SPCP_{sum}) with $\varepsilon > 0$, Tao & Yuan (2011) propose the alternating splitting augmented Lagrangian method (ASALM), which exploits separability of the objective in the splitting scheme, and can solve a 1500×1500 system in about five minutes.

The partially smooth proximal gradient (PSPG) approach of Aybat et al. (2013) smooths just the nuclear norm term and then applies the well-known FISTA algorithm (Beck & Teboulle, 2009). Aybat et al. (2013) show that the proximity step can be solved efficiently in closed-form, and the dominant cost at every iteration is that of the partial SVD. They include some examples on video, lopsided matrices: 25000×300 or so, in about 1 minute). solving 1500×1500 formulations in under half a minute.

The nonsmooth adaptive Lagrangian (NSA) algorithm of Aybat & Iyengar (2014) is a variant of the ADMM for (SPCP_{sum}), and makes use of the insight of Aybat et al. (2013). The ADMM variant is interesting in that it splits the variable L , rather than the sum $L + S$ or residual $L + S - Y$. Their experiments solve a 1500×1500 synthetic problems in between 16 and 50 seconds (depending on accuracy).

Shen et al. (2014) develop a method exploiting low-rank matrix factorization scheme, maintaining $L = UV^T$. This technique has also been effectively used in practice for matrix completion (Aravkin et al., 2013b; Lee et al., 2010; Recht & Ré, 2011), but lacks a full convergence theory in either context. The method of (Shen et al., 2014) was an order of magnitude faster than ASALM, but encountered difficulties in some ex-

periments where the sparse component dominated the low rank component in some sense. Mansour & Vetro (2014) attack the (SPCP_{sum}) formulation using a factorized approach, together with alternating solves between (U, V) and S . Non-convex techniques also include hard thresholding approaches, e.g. the approach of Kyriillidis & Cevher (2014). While the factorization technique may potentially speed up some of the methods presented here, we leave this to future work, and only work with convex formulations.

4 VARIATIONAL FRAMEWORK

Both of the formulations of interest (SPCP_{sum}) and (SPCP_{max}) can be written as follows:

$$\min \phi(L, S) \quad \text{s.t.} \quad \rho(L + S - Y) \leq \varepsilon. \quad (4.1)$$

Classic formulations assume ρ to be the Frobenius norm; however, this restriction is not necessary, and we consider ρ to be smooth and convex. In particular, ρ can be taken to be the robust Huber penalty (Huber, 2004). Even more importantly, this formulation allows pre-composition of a smooth convex penalty with an arbitrary linear operator \mathcal{A} , which extends the proposed approach to a much more general class of problems. Note that a simple operator is already embedded in both formulations of interest:

$$L + S = \begin{bmatrix} I & I \end{bmatrix} \begin{bmatrix} L \\ S \end{bmatrix}. \quad (4.2)$$

Projection onto a set of observed indices Ω is also a simple linear operator that can be included in ρ . Operators may include different transforms (e.g., Fourier) applied to either L or S .

The main formulations of interest differ only in the functional $\phi(L, S)$. For (SPCP_{sum}), we have

$$\phi_{\text{sum}}(L, S) = \|L\|_* + \lambda_{\text{sum}} \|S\|_1,$$

while for (SPCP_{max}),

$$\phi_{\text{max}}(L, S) = \max(\|L\|_*, \lambda_{\text{max}} \|S\|_1).$$

The problem class (4.1) falls into the class of problems studied by van den Berg & Friedlander (2008, 2011) for $\rho(\cdot) = \|\cdot\|^2$ and by Aravkin et al. (2013a) for arbitrary convex ρ . Making use of this framework, we can define a value function

$$v(\tau) = \min_{L, S} \rho(\mathcal{A}(L, S) - Y) \quad \text{s.t.} \quad \phi(L, S) \leq \tau, \quad (4.3)$$

and use Newton’s method to find a solution to $v(\tau) = \varepsilon$. The approach is agnostic to the linear operator \mathcal{A} (it can be of the simple form (4.2); include restriction in the missing data case, etc.).

For both formulations of interest, ϕ is a norm defined on a product space $\mathbb{R}^{n \times m} \times \mathbb{R}^{n \times m}$, since we can write

$$\phi_{\text{sum}}(L, S) = \left\| \left\| \lambda_{\text{sum}} \begin{bmatrix} \|L\|_* \\ \|S\|_1 \end{bmatrix} \right\|_1 \right\|, \quad (4.4)$$

$$\phi_{\text{max}}(L, S) = \left\| \left\| \lambda_{\text{max}} \begin{bmatrix} \|L\|_* \\ \|S\|_1 \end{bmatrix} \right\|_\infty \right\|. \quad (4.5)$$

In particular, both $\phi_{\text{sum}}(L, S)$ and $\phi_{\text{max}}(L, S)$ are *gauges*. For a convex set C containing the origin, the gauge $\gamma(x | C)$ is defined by

$$\gamma(x | C) = \inf_{\lambda} \{\lambda : x \in \lambda C\}. \quad (4.6)$$

For any norm $\|\cdot\|$, the set defining it as a gauge is simply the unit ball $\mathbb{B}_{\|\cdot\|} = \{x : \|x\| \leq 1\}$. We introduce gauges for two reasons. First, they are more general (a gauge is a norm only if C is bounded with nonempty interior and symmetric about the origin). For example, gauges trivially allow inclusion of non-negativity constraints. Second, definition (4.6) and the explicit set C simplify the exposition of the following results.

In order to implement Newton's method for (4.3), the optimization problem to evaluate $v(\tau)$ must be solved (fully or approximately) to obtain (\bar{L}, \bar{S}) . Then the τ parameter for the next (4.3) problem is updated via

$$\tau^{k+1} = \tau^k - \frac{v(\tau) - \tau}{v'(\tau)}. \quad (4.7)$$

Given (\bar{L}, \bar{S}) , $v'(\tau)$ can be written in closed form using (Aravkin et al., 2013a, Theorem 5.2), which simplifies to

$$v'(\tau) = -\phi^\circ(\mathcal{A}^T \nabla \rho(\mathcal{A}(\bar{L}, \bar{S}) - Y)), \quad (4.8)$$

with ϕ° denoting the polar gauge to ϕ . The polar gauge is precisely $\gamma(x | C^\circ)$, with

$$C^\circ = \{v : \langle v, x \rangle \leq 1 \quad \forall x \in C\}. \quad (4.9)$$

In the simplest case, where \mathcal{A} is given by (4.2), and ρ is the least squares penalty, the formula (4.8) becomes

$$v'(\tau) = -\phi^\circ \left(\begin{bmatrix} \bar{L} + \bar{S} - Y \\ \bar{L} + \bar{S} - Y \end{bmatrix} \right).$$

The main computational challenge in the approach outlined in (4.3)-(4.8) is to design a fast solver to evaluate $v(\tau)$. Section 6 does just this.

The key to RPCA is that the regularization functional ϕ is a gauge over the product space used to decompose Y into summands L and S . This makes it straightforward to compute polar results for both ϕ_{sum} and ϕ_{max} .

Theorem 4.1 (Max-Sum Duality for Gauges on Product Spaces). *Let γ_1 and γ_2 be gauges on \mathbb{R}^{n_1} and \mathbb{R}^{n_2} , and consider the function*

$$g(x, y) = \max\{\gamma_1(x), \gamma_2(y)\}.$$

Then g is a gauge, and its polar is given by

$$g^\circ(z_1, z_2) = \gamma_1^\circ(z_1) + \gamma_2^\circ(z_2).$$

Proof. Let C_1 and C_2 denote the canonical sets corresponding to gauges γ_1 and γ_2 . It immediately follows that g is a gauge for the set $C = C_1 \times C_2$, since

$$\begin{aligned} \inf\{\lambda \geq 0 | (x, y) \in \lambda C\} &= \inf\{\lambda | x \in \lambda C_1 \text{ and } y \in \lambda C_2\} \\ &= \max\{\gamma_1(x), \gamma_2(y)\}. \end{aligned}$$

By (Rockafellar, 1970, Corollary 15.1.2), the polar of the gauge of C is the support function of C , which is given by

$$\begin{aligned} \sup_{x \in C_1, y \in C_2} \langle (x, y), (z_1, z_2) \rangle &= \sup_{x \in C_1} \langle x, z_1 \rangle + \sup_{y \in C_2} \langle y, z_2 \rangle \\ &= \gamma_1^\circ(z_1) + \gamma_2^\circ(z_2). \end{aligned}$$

□

This theorem allows us to easily compute the polars for ϕ_{sum} and ϕ_{max} in terms of the polars of $\|\cdot\|_*$ and $\|\cdot\|_1$, which are the dual norms, the spectral norm and infinity norm, respectively.

Corollary 4.2 (Explicit variational formulae for (SPCP_{sum}) and (SPCP_{max})). *We have*

$$\begin{aligned} \phi_{\text{sum}}^\circ(Z_1, Z_2) &= \max \left\{ \|Z_1\|_2, \frac{1}{\lambda_{\text{sum}}} \|Z_2\|_\infty \right\} \\ \phi_{\text{max}}^\circ(Z_1, Z_2) &= \|Z_1\|_2 + \frac{1}{\lambda_{\text{max}}} \|Z_2\|_\infty, \end{aligned} \quad (4.10)$$

where $\|X\|_2$ denotes the spectral norm (largest eigenvalue of $X^T X$).

This result was also obtained by (van den Berg & Friedlander, 2011, Section 9), but is stated only for norms. Theorem 4.1 applies to gauges, and in particular now allows asymmetric gauges, so non-negativity constraints can be easily modeled.

We now have closed form solutions for $v'(\tau)$ in (4.8) for both formulations of interest. The remaining challenge is to design a fast solver for (4.3) for formulations (SPCP_{sum}) and (SPCP_{max}). We focus on this challenge in the remaining sections of the paper. We also discuss the advantage of (SPCP_{max}) from this computational perspective.

5 PROJECTIONS

In this section, we consider the computational issues of projecting onto the set defined by $\phi(L, S) \leq \tau$. For $\phi_{\text{max}}(L, S) = \max(\|L\|_*, \lambda_{\text{max}} \|S\|_1)$ this is straightforward since the set is just the product set of the

nuclear norm and ℓ_1 norm balls, and efficient projectors onto these are known. In particular, projecting an $m \times n$ matrix (without loss of generality let $m \leq n$) onto the nuclear norm ball takes $\mathcal{O}(m^2n)$ operations, and projecting it onto the ℓ_1 -ball can be done on $\mathcal{O}(mn)$ operations using fast median-finding algorithms (Brucker, 1984; Duchi et al., 2008).

For $\phi_{\text{sum}}(L, S) = \|L\|_* + \lambda_{\text{sum}}\|S\|_1$, the projection is no longer straightforward. Nonetheless, the following lemma shows this projection can be efficiently implemented.

Proposition 5.1. (van den Berg & Friedlander, 2011, Section 5.2) *Projection onto the scaled ℓ_1 -ball, that is, $\{x \in \mathbb{R}^d \mid \sum_{i=1}^d \alpha_i |x_i| \leq 1\}$ for some $\alpha_i > 0$, can be done in $\mathcal{O}(d \log(d))$ time.*

The proof of the proposition follows by noting that the solution can be written in a form depending only on a single scalar parameter, and this scalar can be found by sorting $(|x_i|/\alpha_i)$ followed by appropriate summations. We conjecture that fast median-finding ideas could reduce this to $\mathcal{O}(d)$ in theory, the same as the optimal complexity for the ℓ_1 -ball.

Armed with the above proposition, we state an important lemma below. For our purposes, we may think of S as a vector in \mathbb{R}^{mn} rather than a matrix in $\mathbb{R}^{m \times n}$.

Lemma 5.2. (van den Berg & Friedlander, 2011, Section 9.2) *Let $L = U\Sigma V^T$ and $\Sigma = \text{diag}(\sigma)$, and let $(S_i)_{i=1}^{mn}$ be any ordering of the elements of S . Then the projection of (L, S) onto the ϕ_{sum} ball is $(U \text{diag}(\hat{\sigma})V^T, \hat{S})$, where $(\hat{\sigma}, \hat{S})$ is the projection onto the scaled ℓ_1 -ball $\{(\sigma, S) \mid \sum_{j=1}^{\min(m,n)} |\sigma_j| + \sum_{i=1}^{mn} \lambda_{\text{sum}} |S_i| \leq 1\}$.*

Sketch of proof. We need to solve

$$\min_{\{(L', S') \mid \phi_{\text{sum}}(L', S') \leq 1\}} \frac{1}{2} \|L' - L\|_F^2 + \frac{1}{2} \|S' - S\|_F^2.$$

Alternatively, solve

$$\min_{S'} \min_{\{L' \mid \|L'\|_* \leq 1 - \lambda_{\text{sum}} \|S'\|_1\}} \frac{1}{2} \|L' - L\|_F^2 + \frac{1}{2} \|S' - S\|_F^2.$$

The inner minimization is equivalent to projecting onto the nuclear norm ball, and this is well-known to be soft-thresholding of the singular values. Since it depends only on the singular values, recombining the two minimization terms gives exactly a joint projection onto a scaled ℓ_1 -ball. \square

Remark 5.1. *All the references to the ℓ_1 -ball can be replaced by the intersection of the ℓ_1 -ball and the non-negative cone, and the projection is still efficient. As noted in Section 4, imposing non-negativity constraints*

is covered by the gauge results of Theorem 4.1 and Corollary 4.2. Therefore, both the variational and efficient computational framework can be applied to this interesting case.

6 SOLVING THE SUB-PROBLEM VIA PROJECTED QUASI-NEWTON METHODS

In order to accelerate the approach, we can use quasi-Newton (QN) methods since the objective has a simple structure.¹ The main challenge here is that for the $\|L\|_*$ term, it is tricky to deal with a weighted quadratic term (whereas for $\|S\|_1$, we can obtain a low-rank Hessian and solve it efficiently via coordinate descent).

We wish to solve (**flip-SPCP**_{max}). Let $X = (L, S)$ be the full variable, so we can write the objective function as $f(X) = \frac{1}{2} \|\mathcal{A}(X) - Y\|_F^2$. To simplify the exposition, we take $\mathcal{A} = (I, I)$ to be the $mn \times 2mn$ matrix, but the presented approach applies to general linear operators (including terms like \mathcal{P}_Ω). The matrix structure of L and S is not important here, so we can think of them as $mn \times 1$ vectors instead of $m \times n$ matrices.

The gradient is $\nabla f(X) = \mathcal{A}^T(\mathcal{A}(X) - Y)$. For convenience, we use $r(X) = \mathcal{A}(X) - Y$ and

$$\nabla f(X) = \begin{pmatrix} \nabla_L f(X) \\ \nabla_S f(X) \end{pmatrix} = \mathcal{A}^T \begin{pmatrix} r(X) \\ r(X) \end{pmatrix}, \quad r_k \equiv r(X_k).$$

The Hessian is $\mathcal{A}^T \mathcal{A} = \begin{pmatrix} I & I \\ I & I \end{pmatrix}$. We cannot simultaneously project (L, S) onto their constraints with this Hessian scaling (doing so would solve the original problem!), since the Hessian removes separability. Instead, we use (L_k, S_k) to approximate the cross-terms.

The true function is a quadratic, so the following

¹ We use “quasi-Newton” to mean an approximation to a Newton method and it should not be confused with methods like BFGS

quadratic expansion around $X_k = (L_k, S_k)$ is exact:

$$\begin{aligned}
f(L, S) &= f(X_k) + \left\langle \begin{pmatrix} \nabla_L f(X_k) \\ \nabla_S f(X_k) \end{pmatrix}, \begin{pmatrix} L - L_k \\ S - S_k \end{pmatrix} \right\rangle \\
&\quad + \left\langle \begin{pmatrix} L - L_k \\ S - S_k \end{pmatrix}, \nabla^2 f \begin{pmatrix} L - L_k \\ S - S_k \end{pmatrix} \right\rangle \\
&= f(X_k) + \left\langle \begin{pmatrix} r_k \\ r_k \end{pmatrix}, \begin{pmatrix} L - L_k \\ S - S_k \end{pmatrix} \right\rangle \\
&\quad + \left\langle \begin{pmatrix} L - L_k \\ S - S_k \end{pmatrix}, \begin{pmatrix} 1 & 1 \\ 1 & 1 \end{pmatrix} \begin{pmatrix} L - L_k \\ S - S_k \end{pmatrix} \right\rangle \\
&= f(X_k) + \left\langle \begin{pmatrix} r_k \\ r_k \end{pmatrix}, \begin{pmatrix} L - L_k \\ S - S_k \end{pmatrix} \right\rangle \\
&\quad + \left\langle \begin{pmatrix} \mathbf{L} - L_k \\ \mathbf{S} - S_k \end{pmatrix}, \begin{pmatrix} L - L_k + \mathbf{S} - S_k \\ \mathbf{L} - L_k + S - S_k \end{pmatrix} \right\rangle
\end{aligned}$$

The coupling of the second order terms, shown in bold, prevents direct 1-step minimization of f , subject to the nuclear and 1-norm constraints. The FISTA (Beck & Teboulle, 2009) and spectral gradient methods (SPG) (Wright et al., 2009b) replace the Hessian $\begin{pmatrix} I & I \\ I & I \end{pmatrix}$ with the upper bound $2 \begin{pmatrix} I & 0 \\ 0 & I \end{pmatrix}$, which solves the coupling issue, but potentially lose too much second order information. After comparing FISTA and SPG, we use the SPG method for solving (flip-SPCP_{sum}). However, for (flip-SPCP_{max}) (and for (Lag-SPCP)), which has no constraints but rather non-smooth terms, which can be treated like constraints using proximity operators), the constraints are uncoupled and we can take a “middle road” approach, replacing

$$\left\langle \begin{pmatrix} \mathbf{L} - L_k \\ \mathbf{S} - S_k \end{pmatrix}, \begin{pmatrix} L - L_k + \mathbf{S} - S_k \\ \mathbf{L} - L_k + S - S_k \end{pmatrix} \right\rangle$$

with

$$\left\langle \begin{pmatrix} L - L_k \\ S - S_k \end{pmatrix}, \begin{pmatrix} L - L_k + \mathbf{S}_k - \mathbf{S}_{k-1} \\ \mathbf{L}_{k+1} - \mathbf{L}_k + S - S_k \end{pmatrix} \right\rangle.$$

The first term is decoupled, allowing us to update L_k , and then this is plugged into the second term in a Gauss-Seidel fashion. In practice, we also scale this second-order term with a number slightly greater than 1 but less than 2 (e.g., 1.25) which leads to more robust behavior. We expect this “quasi-Newton” trick to do well when $S_{k+1} - S_k$ is similar to $S_k - S_{k-1}$.

7 NUMERICAL RESULTS

The numerical experiments are done with the algorithms suggested in this paper as well as code from PSPG (Aybat et al., 2013), NSA (Aybat & Iyengar, 2014), and ASALM (Tao & Yuan, 2011)². We modi-

²PSPG, NSA and ASALM available from the experiment package at <http://www2.ie.psu.edu/aybat/codes.html>

fied the other software as needed for testing purposes. PSPG, NSA and ASALM all solve (SPCP_{sum}), but ASALM has another variant which solves (Lag-SPCP) so we test this as well. All three programs also use versions of PROPACK from Becker & Candès (2008); Larsen (1998) to compute partial SVDs. Since the cost of a single iteration may vary among the solvers, we measure error as a function of time, not iterations. When a reference solution (L^*, S^*) is available, we measure the (relative) error of a trial solution (L, S) as $\|L - L^*\|_F / \|L^*\|_F + \|S - S^*\|_F / \|S^*\|_F$. The benchmark is designed so the time required to calculate this error at each iteration does not factor into the reported times. Since picking stopping conditions is solver dependent, we show plots of error vs time, rather than list tables. All tests are done in Matlab and the dominant computational time was due to matrix multiplications for all algorithms; all code was run in the same quad-core 1.6 GHz i7 computer.

For our implementations of the (flip-SPCP_{max}), (flip-SPCP_{sum}) and (Lag-SPCP), we use a randomized SVD (Halko et al., 2011). Since the number of singular values needed is not known in advance, the partial SVD may be called several times (the same is true for PSPG, NSA and ASALM). Our code limits the number of singular values on the first two iterations in order to speed up calculation without affecting convergence. Unfortunately, the delicate projection involved in (flip-SPCP_{sum}) makes incorporating a partial SVD to this setting more challenging, so we use Matlab’s dense SVD routine.

7.1 Synthetic test with exponential noise

We first provide a test with generated data. The observations $Y \in \mathbb{R}^{m \times n}$ with $m = 400$ and $n = 500$ were created by first sampling a rank 20 matrix Y_0 with random singular vectors (i.e., from the Haar measure) and singular values drawn from a uniform distribution with mean 0.1, and then adding exponential random noise (with mean equal to one tenth the median absolute value of the entries of Y_0). This exponential noise, which has a longer tail than Gaussian noise, is expected to be captured partly by the S term and partly by the $\|L + S - Y\|_F$ term.

Given Y , the reference solution (L^*, S^*) was generated by solving (Lag-SPCP) to very high accuracy; the values $\lambda_L = 0.25$ and $\lambda_S = 10^{-2}$ were picked by hand tuning (λ_L, λ_S) to find a value such that both L^* and S^* are non-zero. The advantage to solving (Lag-SPCP) is that knowledge of $(L^*, S^*, \lambda_L, \lambda_S)$ allows us to generate the parameters for all the other variants, and hence we can test different problem formulations.

With these parameters, L^* was rank 17 with nuclear

norm 6.754, S^* had 54 non-zero entries (most of them positive) with ℓ_1 norm 0.045, the normalized residual was $\|L^* + S^* - Y\|_F / \|Y\|_F = 0.385$, and $\varepsilon = 1.1086$, $\lambda_{\text{sum}} = 0.04$, $\lambda_{\text{max}} = 150.0593$, $\tau_{\text{sum}} = 6.7558$ and $\tau_{\text{max}} = 6.7540$.

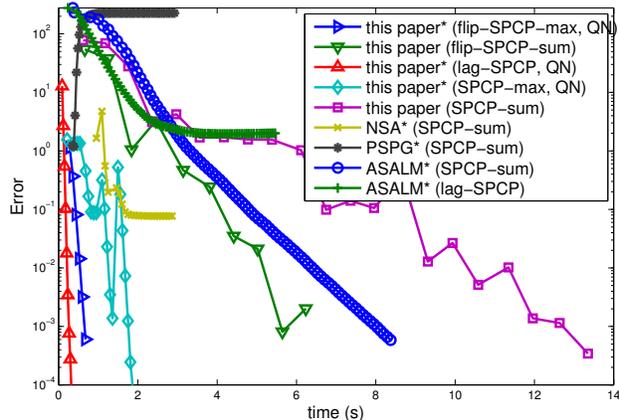

Figure 1: The exponential noise test. The asterisk in the legend means the method uses a fast SVD.

Results are shown in Fig. 1. Our methods for (**flip-SPCP_{max}**) and (**Lag-SPCP**) are extremely fast, because the simple nature of these formulations allows the quasi-Newton acceleration scheme of Section 6. In turn, since our method for solving (**SPCP_{max}**) uses the variational framework of Section 4 to solve a sequence of (**flip-SPCP_{max}**) problems, it is also competitive (shown in cyan in Figure 1). The jumps are due to re-starting the sub-problem solver with a new value of τ , generated according to (4.7).

Our proximal gradient method for (**flip-SPCP_{sum}**), which makes use of the projection in Lemma 5.2, converges more slowly, since it is not easy to accelerate with the quasi-Newton scheme due to variable coupling, and it does not make use of fast SVDs. Our solver for (**SPCP_{sum}**), which depends on a sequence of problems (**flip-SPCP_{sum}**), converges slowly.

The ASALM performs reasonably well, which was unexpected since it was shown to be worse than NSA and PSPG in Aybat et al. (2013); Aybat & Iyengar (2014). The PSPG solver converges to the wrong answer, most likely due to a bad choice of the smoothing parameter μ ; we tried choosing several different values other than the default but did not see improvement for this test (for other tests, not shown, tweaking μ helped significantly). The NSA solver reaches moderate error quickly but stalls before finding a highly accurate solution.

7.2 Synthetic test from Aybat & Iyengar (2014)

We show some tests from the test setup of Aybat & Iyengar (2014) in the $m = n = 1500$ case. The default setting of $\lambda_{\text{sum}} = 1/\sqrt{\max(m, n)}$ was used, and then the NSA solver was run to high accuracy to obtain a reference solution (L^*, S^*) . From the knowledge of $(L^*, S^*, \lambda_{\text{sum}})$, one can generate $\lambda_{\text{max}}, \tau_{\text{sum}}, \tau_{\text{max}}, \varepsilon$, but not λ_S and λ_L , and hence we did not test the solvers for (**Lag-SPCP**) in this experiment. The data was generated as $Y = L_0 + S_0 + Z_0$, where L_0 was sampled by multiplication of $m \times r$ and $r \times n$ normal Gaussian matrices, S_0 had p randomly chosen entries uniformly distributed within $[-100, 100]$, and Z_0 was white noise chosen to give a SNR of 45 dB. We show three tests that vary the rank from $\{0.05, 0.1\} \cdot \min(m, n)$ and the sparsity ranging from $p = \{0.05, 0.1\} \cdot mn$. Unlike Aybat & Iyengar (2014), who report error in terms of a true noiseless signal (L_0, S_0) , we report the optimization error relative to (L^*, S^*) .

For the first test (with $r = 75$ and $p = 0.05 \times mn$), L^* had rank 786 and nuclear norm 111363.9; S^* had 75.49% of its elements nonzero and ℓ_1 norm 5720399.4, and $\|L^* + S^* - Y^*\|_F / \|Y^*\|_F = 1.5 \cdot 10^{-4}$. The other parameters were $\varepsilon = 3.5068$, $\lambda_{\text{sum}} = 0.0258$, $\lambda_{\text{max}} = 0.0195$, $\tau_{\text{sum}} = 2.5906 \cdot 10^5$ and $\tau_{\text{max}} = 1.1136 \cdot 10^5$. An interesting feature of this test is that while L_0 is low-rank, L^* is nearly low-rank but with a small tail of significant singular values until number 786. We expect methods to converge quickly to low-accuracy where only a low-rank approximation is needed, and then slow down as they try to find a larger rank highly-accurate solution.

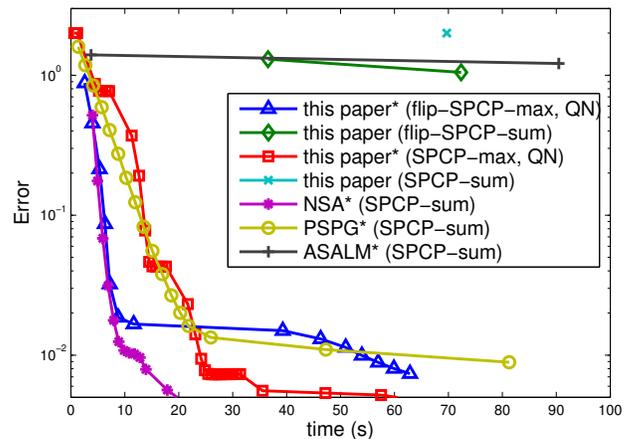

Figure 2: The 1500 \times 1500 synthetic noise test.

The results are shown in Fig. 2. Errors barely dip below 0.01 (for comparison, an error of 2 is achieved

by setting $L = S = 0$). The NSA and PSPG solvers do quite well. In contrast to the previous test, ASALM does poorly. Our methods for ($\text{flip-SPCP}_{\text{sum}}$), and hence (SPCP_{sum}), are not competitive, since they use dense SVDs. We imposed a time-limit of about one minute, so these methods only manage a single iteration or two. Our quasi-Newton method for ($\text{flip-SPCP}_{\text{max}}$) does well initially, then takes a long time due to a long partial SVD computation. Interestingly, (SPCP_{max}) does better than pure ($\text{flip-SPCP}_{\text{max}}$). One possible explanation is that it chooses a fortuitous sequence of τ values, for which the corresponding ($\text{flip-SPCP}_{\text{max}}$) subproblems become increasingly hard, and therefore benefit from the warm-start of the solution of the easier previous problem. This is consistent with empirical observations regarding continuation techniques, see e.g., (van den Berg & Friedlander, 2008; Wright et al., 2009b).

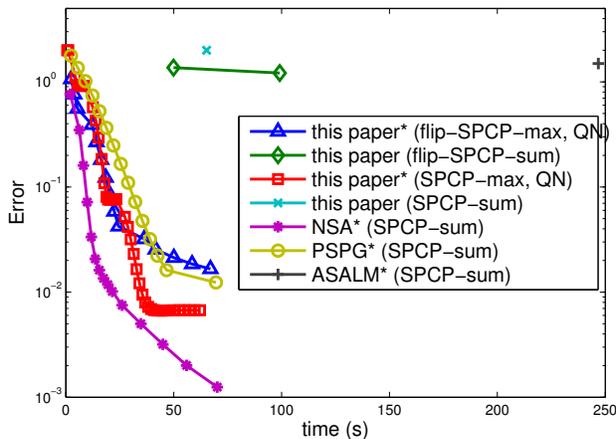

Figure 3: Second 1500×1500 synthetic noise test.

Figure 3 is the same test but with $r = 150$ and $p = 0.1 \cdot mn$, and the conclusions are largely similar.

7.3 Cloud removal

Figure 4 shows 15 images of size 300×300 from the MODIS satellite,³ after some transformations to turn images from different spectral bands into one grayscale images. Each image is a photo of the same rural location but at different points in time over the course of a few months. The background changes slowly and the variability is due to changes in vegetation, snow cover, and different reflectance. There are also outlying sources of error, mainly due to clouds (e.g., major clouds in frames 5 and 7, smaller clouds in frames 9, 11 and 12), as well as artifacts of the CCD camera on

³Publicly available at <http://ladsweb.nascom.nasa.gov/>

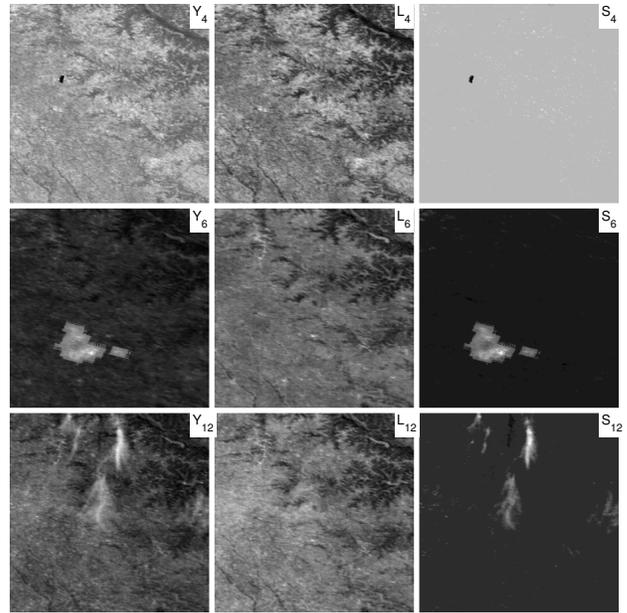

Figure 5: Showing frames 4, 5 and 12. Leftmost column is original data, middle column is low-rank term of the solution, and right column is sparse term of the solution. Data have been processed slightly to enhance contrast for viewing.

the satellite (frame 4 and 6) and issues stitching together photos of the same scene (the lines in frames 8 and 10).

There are hundreds of applications for clean satellite imagery, so removing the outlying error is of great practical importance. Because of slow changing background and sparse errors, we can model the problem using the robust PCA approach. We use the ($\text{flip-SPCP}_{\text{max}}$) version due to its speed, and pick parameters ($\lambda_{\text{max}}, \tau_{\text{max}}$) by using a Nelder-Mead simplex search. For an error metric to use in the parameter tuning, we remove frame 1 from the data set (call it y_1) and set Y to be frames 2–15. From this training data Y , the algorithm generates L and S . Since L is a $300^2 \times 14$ matrix, it has far from full column span. Thus our error is the distance of y_1 from the span of L , i.e., $\|y_1 - \mathcal{P}_{\text{span}(L)}(y_1)\|_2$.

Our method takes about 11 iterations and 5 seconds, and uses a dense SVD instead of the randomized method due to the high aspect ratio of the matrix. Some results of the obtained (L, S) outputs are in Fig. 5, where one can see that some of the anomalies in the original data frames Y are picked up by the S term and removed from the L term. Frame 4 has what appears to be a camera pixel error; frame 6 has another artificial error (that is, caused by the camera and not the scene); and frame 12 has cloud cover.

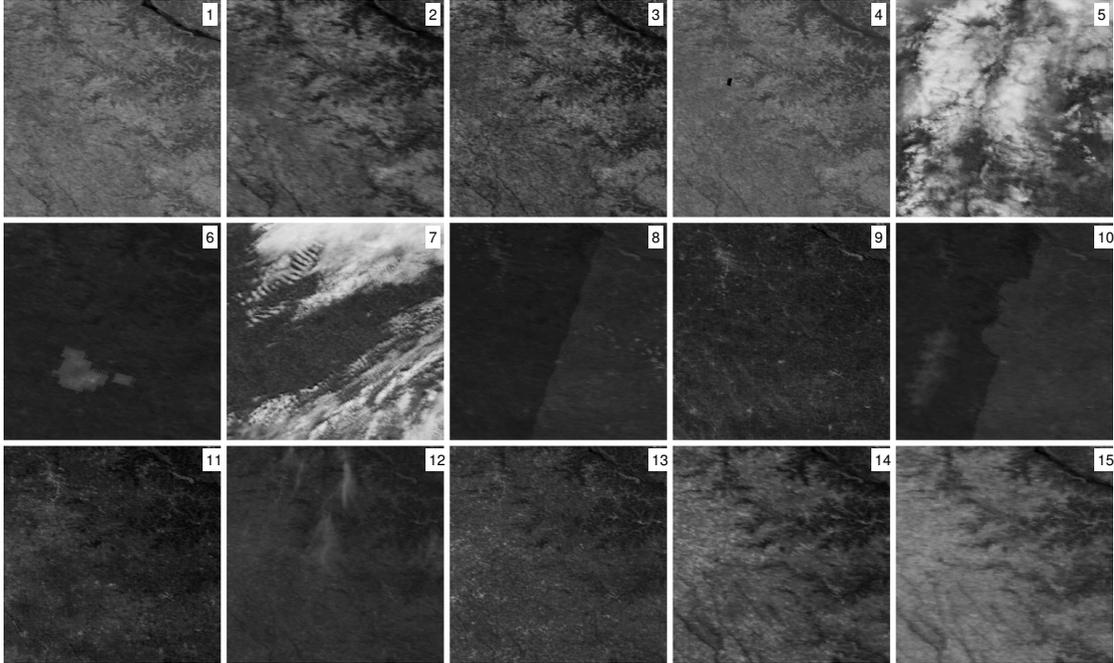

Figure 4: Satellite photos of the same location on different days

8 CONCLUSIONS

In this paper, we reviewed several formulations and algorithms for the RPCA problem. We introduced a new denoising formulation (SPCP_{\max}) to the ones previously considered, and discussed modeling and algorithmic advantages of denoising formulations (SPCP_{\max}) and (SPCP_{sum}) compared to flipped versions (flip-SPCP_{\max}) and ($\text{flip-SPCP}_{\text{sum}}$). In particular, we showed that these formulations can be linked using a variational framework, which can be exploited to solve denoising formulations using a sequence of flipped problems. For (flip-SPCP_{\max}), we proposed a quasi-Newton acceleration that is competitive with state of the art, and used this innovation to design a fast method for (SPCP_{\max}) through the variational framework. The new methods were compared against prior art on synthetic examples, and applied to a real world cloud removal application application using publicly available MODIS satellite data.

Abstract

Real world systems typically feature a variety of different dependency types and topologies that complicate model selection for probabilistic graphical models. We introduce the *ensemble-of-forests* model, a generalization of the *ensemble-of-trees* model of Meilă and Jaakkola (2006). Our model enables structure learning of Markov random fields (MRF) with multiple connected components and arbitrary potentials. We present two approximate inference techniques for this model and demonstrate their performance on synthetic data. Our results suggest that the ensemble-of-forests approach can accurately recover sparse, possibly disconnected MRF topologies, even in presence of non-Gaussian dependencies and/or low sample size. We applied the ensemble-of-forests model to learn the structure of perturbed signaling networks of immune cells and found that these frequently exhibit non-Gaussian dependencies with disconnected MRF topologies. In summary, we expect that the ensemble-of-forests model will enable MRF structure learning in other high dimensional real world settings that are governed by non-trivial dependencies.

1 INTRODUCTION

This work presents the ensemble-of-forests model for approximate structure learning in Markov random fields (MRF). As opposed to most existing MRF structure learners that either work with specific types of potentials (e.g. discrete, Gaussian) or assume connected MRF topology (Lin et al., 2009), our approach is applicable for MRFs with arbitrary potentials and topology, including disconnected topologies, and is therefore suited to accommodate a wide range of real world settings.

Markov random fields (MRF) are undirected probabilistic graphical models specifying conditional independence relations among a set of random variables. Learning MRFs involves parameter inference and model selection, i.e. learning the underlying graph structure. For general MRFs, exact parameter inference is difficult due to the necessity to evaluate the intractable partition sum and therefore is addressed by approximate inference approaches. Structure learning is an even more difficult task. The naive method of enumerating all possible topologies is prohibitively expensive and, thus, alternative approaches have been proposed based on independence tests or approximate score-based methods Koller and Friedman (2009).

Currently, the prevalent approach to model continuous random variables is to assume Gaussianity. Under this hypothesis, the Gaussian Markov random field (GMRF) structure can be directly read from the inverse covariance matrix (Koller and Friedman, 2009): zero entries exactly correspond to conditional independence statements of the Markov random field. Sparse inverse covariance selection constitutes a convex relaxation of the structure learning task for GMRFs that can be solved efficiently (Banerjee et al., 2006; Friedman et al., 2008).

Random variables of real world systems typically exhibit unusual dependency types (Trivedi and Zimmer, 2005; Berkes et al., 2008) that are not appropriately captured by the Gaussian potentials of GMRFs. *Copula* potentials constitute a more general and expressive alternative to deal with non-Gaussian dependency types. Copulas are multivariate distributions that encode the dependencies among random variables. Copula models are very flexible, as they enable researchers to independently specify the marginal distributions of random variables and their dependency structure. Liu et al. (2009) define MRFs with semi-parametric Gaussian copula potentials. Approximate structure learning in this model is tractable because the dependency type is Gaussian and, thus, parameter inference is easy and model selection can also be efficiently approximated by resorting to sparse inverse covariance estimation. However, in MRFs with general copula potentials, even

parameter estimation is difficult because of the intractable partition sum. This situation entails that structure learning is also difficult.

The intractability of exact inference for MRFs with general copula potentials has motivated alternative approaches based on approximate inference. Meilä and Jaakkola (2006) introduced the *ensemble-of-trees* (ET) model that enables approximate inference for both parameter estimation and structure learning of general MRFs. A Markov network is represented as a mixture model whose components are tree-structured distributions defined over all possible spanning trees of the underlying graph. Despite the super-exponential number of such trees, the model remains tractable by defining conveniently decomposable priors over the structure and parameters of tree-distributions. Recently, Kirshner (2008) presented a tree-averaged density model based on tree structured MRFs with copula potentials. The tasks of parameter estimation and structure learning are jointly expressed as a single (non-convex) objective, which is optimized via Expectation-Maximization. Lin et al. (2009) utilize the ET model for structure learning of GMRFs and empirically demonstrate superior performance compared to sparse inverse covariance selection for limited sample size. Above considerations render copula MRFs as attractive models because they are more general than GMRFs and efficient learning approaches exist for them.

Real world systems with many random variables are frequently best represented by MRFs that decompose into several connected components. In biology, for instance, a specific stimulus might activate competing, independent signaling pathways each including its own MRF component (Johnstone et al., 2008). However, the ET structure learning approach is not able to recover disconnected topologies since it is averaging over ensembles of spanning trees. It is desirable to generalize the ET approach in order to overcome this limitation and, thereby, still benefit from the expressiveness of copula MRFs in these real world settings.

The main contribution of this work is the generalization of the ET model to the *ensemble-of-forests* (EF) model that explicitly accounts for graph topologies with multiple connected components. In the proposed model, a Markov network is represented as a mixture of forests, i.e. collections of tree-structured MRFs. An implementation of the exact model is intractable, as the averaging over all possible forests results in a hard combinatorial problem. Instead, we present approximate formulations of the structure learning task. The rest of this paper is organized as follows. In Sections 2 – 3 we formally introduce the methods that we build upon. Then, in Sections 4 – 6 we describe the *ensemble-of-forests* model and present benchmark results on synthetic datasets. In Sections 7 – 8 we apply our method to plant microarray and immune cell perturbation data. Finally, Section 9 concludes with a short discussion.

2 COPULA MODELS

This section reviews the application of copulas to describe general multivariate distributions and/or potentials in MRFs. Copulas are multivariate continuous distributions defined on the unit hypercube, $C : [0, 1]^d \rightarrow [0, 1]$, with uniform univariate marginals. Let X_1, \dots, X_d be real random variables with joint cumulative distribution function (cdf) $F(\mathbf{x})$ and marginally distributed as $F_1(x_1), \dots, F_d(x_d)$ respectively. Then, the random variables $U_1 = F_1(x_1), \dots, U_d = F_d(x_d)$ are uniformly distributed on $[0, 1]$. This property forms the basis for Sklar’s theorem, according to which any joint distribution $F(x_1, \dots, x_d)$ with continuous marginals can be uniquely expressed as

$$F(x_1, \dots, x_d) = C(F_1(x_1), \dots, F_d(x_d)). \quad (1)$$

The converse is also true: arbitrary univariate marginals $\{F_i\}$ can be combined using a copula function C to uniquely construct a valid joint distribution with marginals $\{F_i\}$. The copula function C exclusively encodes the dependencies among random variables.

Furthermore, copula density functions $c(\mathbf{u}) = \frac{\partial^d C(\mathbf{u})}{\partial u_1 \dots \partial u_d}$ can be expressed in terms of probability density functions as

$$c(u_1, \dots, u_d) = \frac{f(x_1, \dots, x_d)}{\prod_{i=1}^d f_i(x_i)}. \quad (2)$$

A large number of copula functions have been proposed in the literature (Nelsen, 1999), especially for the bivariate case. Commonly used examples are the Clayton, Gumbel, Frank, Gaussian and Student’s t parametric copula families. In Figure 1, we present contour plots of six distributions with standard Gaussian marginals but different types of dependencies between the marginals. In each case, the dependency structure is specified via a different copula function.

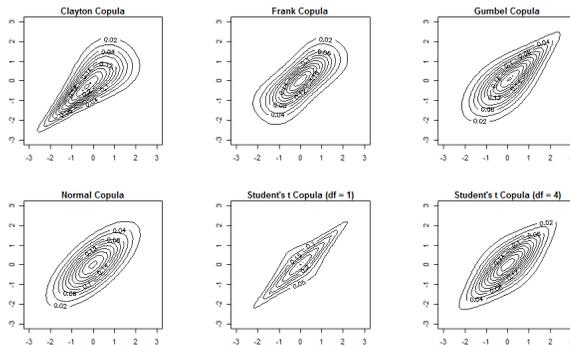

Figure 1: Contour plots of six joint distributions defined using standard Gaussian marginals and different dependency structures specified by different copulas.

Bivariate copulas are typically used to model strong extreme-value dependencies in financial data (Embrechts et al., 2003; Trivedi and Zimmer, 2005). Recently, the probabilistic graphical model framework has been successfully employed for the construction of copula-based high-dimensional models. A review on this topic can be found in (Elidan, 2013).

3 ENSEMBLE-OF-TREES MODELS

Here we introduce the ensemble-of-trees (ET) method for approximate parameter inference and structure learning of MRFs. This method forms the basis for the ensemble-of-forests method, the main conceptual contribution of this paper. From here on, we adopt the following notation: we consider a Markov network encoded by a graph $\mathcal{G} = (\mathcal{V}, \mathcal{E})$, where \mathcal{V} is the set of nodes corresponding to random variables $\mathcal{X} = \{X_1, \dots, X_d\}$ and \mathcal{E} is the set of edges.

The ensemble-of-trees model of Meilä and Jaakkola (2006) is an approximate inference approach to carry out structure learning for MRFs with “inconvenient” potentials. It constitutes a mixture model over all possible spanning trees of the complete graph over the nodeset \mathcal{V} . A prior distribution over spanning tree structures T is defined as

$$p_\beta(T) = \frac{1}{Z_\beta} \prod_{e_{uv} \in T} \beta_{uv} \quad (3)$$

where each parameter $\beta_{uv} = \beta_{vu} \geq 0$, for all $u \neq v$, $u, v \in \mathcal{V}$ can be interpreted as a weight for edge e_{uv} , directly proportional to the probability of appearance of that edge.

$Z_\beta = \sum_T \prod_{e_{uv} \in T} \beta_{uv}$ is a normalizing constant, ensuring that the prior constitutes a valid probability distribution. It turns out that Z_β can be efficiently computed. Defining the matrix $\mathbf{Q}(\beta)$ as the first $d - 1$ rows and columns of the Laplacian matrix

$$L_{uv} = \begin{cases} -\beta_{uv} & \text{if } u \neq v, \\ \sum_k \beta_{uk} & \text{if } u = v \end{cases} \quad (4)$$

Meilä and Jaakkola (2006) generalize Kirchhoff’s Matrix-Tree theorem for binary weights and show that

$$Z_\beta = \sum_T \prod_{e_{uv} \in T} \beta_{uv} = |\mathbf{Q}(\beta)|. \quad (5)$$

This result makes the averaging over all possible (d^{d-2}) spanning tree structures computationally tractable.

Assuming a prior tree structure T , the conditional distribution of a data sample \mathbf{x} can be expressed as

$$p(\mathbf{x}|T, \boldsymbol{\theta}) = \prod_{v \in \mathcal{V}} \theta_v(x_v) \prod_{e_{uv} \in T} \frac{\theta_{uv}(x_u, x_v)}{\theta_u(x_u)\theta_v(x_v)} \quad (6)$$

where the parameter vector $\boldsymbol{\theta}$ consists of univariate $\theta_v(x_v)$ and bivariate $\theta_{uv}(x_u, x_v)$ marginal densities defined, respectively, over the nodes and the edges of the tree (Meilä and Jaakkola, 2006). These distributions are assumed invariant for all tree structures.

Finally, after introducing the notation $w_{uv}(\mathbf{x}) = \frac{\theta_{uv}(x_u, x_v)}{\theta_u(x_u)\theta_v(x_v)}$, $w_0(\mathbf{x}) = \prod_{v \in \mathcal{V}} \theta_v(x_v)$ and applying twice the generalized Matrix-Tree theorem we have

$$\begin{aligned} p_\beta(\mathbf{x}) &= \sum_T p_\beta(T) p(\mathbf{x}|T, \boldsymbol{\theta}) \\ &= \frac{w_0(\mathbf{x})}{Z_\beta} \sum_T \prod_{e_{uv} \in T} \beta_{uv} w_{uv}(\mathbf{x}) \\ &= w_0(\mathbf{x}) \frac{|\mathbf{Q}(\beta \otimes \mathbf{w}(\mathbf{x}))|}{|\mathbf{Q}(\beta)|} \quad (7) \end{aligned}$$

where the symbol \otimes denotes element-wise multiplication.

The structure learning task in the ET model can be approximated by an empirical estimation of β , as in (Lin et al., 2009), where β is used to approximate the MRF adjacency matrix: non-zero entries β_{uv} correspond to edges in the graph. In our model, we adopt this interpretation of β .

3.1 ET MODELS WITH DISCONNECTED SUPPORT GRAPH

A mixture model over spanning trees is based on the implicit assumption that the *support graph* of the model is connected. The support graph is a graph that contains exactly the edges corresponding to positive entries in β . The case of disconnected support graphs is considered by Meilä and Jaakkola (2006) only for *a priori* defined connected components. That is, certain patterns of zero entries in the parameter set β predefine a partitioning of nodes into different connected components and these assignments to components cannot be changed e.g. during the course of a structure learning procedure. In this case, each connected component can be treated independently from all others. Assuming k connected components that partition \mathcal{V} into $\{V^1, \dots, V^k\}$ and introducing the notation

$$\beta_{V^i} = \{\beta_{uv}, u \neq v, u, v \in V^i\}$$

equation (7) is generalized as

$$p_\beta(\mathbf{x}) = w_0(\mathbf{x}) \frac{\prod_{i=1}^k |\mathbf{Q}(\beta_{V^i} \otimes \mathbf{w}_{V^i}(\mathbf{x}))|}{\prod_{i=1}^k |\mathbf{Q}(\beta_{V^i})|} \quad (8)$$

4 ENSEMBLE-OF-FORESTS MODELS

Here we introduce the main contribution of our work, that is the *ensemble-of-forests* (EF) model. This model constitutes an approximate inference approach for structure

learning of MRFs with multiple connected components that are not known *a priori*. We assume a nodeset \mathcal{V} of size d and a partition thereof $\mathbf{V} = \{V^1, \dots, V^k\}$. Then, a *maximal forest* or *forest* of size k is a collection of spanning trees $\{T^i\}_{i=1, \dots, k}$, one for each V^i . Extending the ensemble-of-trees model, we introduce a mixture model over all possible forests up to a certain size, i.e. allowing for disconnected structures with a maximal number of k connected components. The limiting cases are $k = 1$, corresponding to the ET model, and $k = d$, corresponding to a model that allows for any possible arrangement of connected components.

The prior probability of a collection of spanning trees $\mathcal{F} := \{T^1, \dots, T^k\}$ is defined as

$$p_{\beta}(\mathcal{F}) = \frac{1}{Z_{\beta}} \prod_{T^i \in \mathcal{F}} \prod_{e_{uv} \in T^i} \beta_{uv} \quad (9)$$

where $\beta_{uv} = \beta_{vu} \geq 0$, for all $u \neq v$, $u, v \in \mathcal{V}$. Now, in order to normalize over all possible forests that consist of at most k connected components, the partition function is computed via

$$\begin{aligned} Z_{\beta} &= \sum_{\mathbf{V} \in \text{part}(\mathcal{V})} \sum_{\mathcal{F} \in f(\mathbf{V})} \prod_{T^i \in \mathcal{F}} \prod_{e_{uv} \in T^i} \beta_{uv} \\ &= \sum_{\mathbf{V} \in \text{part}(\mathcal{V})} \prod_{V^i \in \mathbf{V}} |\mathbf{Q}(\beta_{V^i})| \quad (10) \end{aligned}$$

where the outer summation $\sum_{\mathbf{V} \in \text{part}(\mathcal{V})}$ is performed over all possible partitions of \mathcal{V} into k subsets and the inner summation $\sum_{\mathcal{F} \in f(\mathbf{V})}$ is performed over all maximal forests defined on a specific node partition \mathbf{V} . Partitions where some of the subsets V^i are empty are allowed and correspond to graphs with less than k connected components. For example, the partition $\{\mathcal{V}, \emptyset, \dots, \emptyset\}$ represents a fully connected graph. In order to treat such partitions without changing our notation, we define $\mathbf{Q}(\beta_{\emptyset}) = 1$.

Ignoring the constant term $w_0(\mathbf{x})$, the negative log-likelihood of the model given a dataset $\mathcal{D} = \{x^{(1)}, \dots, x^{(N)}\}$ is written as

$$\begin{aligned} \mathcal{L}(\mathcal{D}; \beta) &= N \log \sum_{\mathbf{V} \in \text{part}(\mathcal{V})} \prod_{V^i \in \mathbf{V}} |\mathbf{Q}(\beta_{V^i})| \\ &\quad - \sum_{j=1}^N \log \sum_{\mathbf{V} \in \text{part}(\mathcal{V})} \prod_{V^i \in \mathbf{V}} |\mathbf{Q}(\beta \mathbf{w}_{V^i}^{(j)})| \quad (11) \end{aligned}$$

where $\beta \mathbf{w}_{V^i}^{(j)}$ is a shorthand for $\beta_{V^i} \otimes \mathbf{w}_{V^i}(\mathbf{x}^{(j)})$.

5 LEARNING IN THE EF MODEL

In this section, we describe two approaches for structure learning of Markov networks based on the EF model,

namely the *EF-cuts* and *EF- λ* methods. Additionally, we describe common features of the two methods, such as the choice of MRF potentials and the optimization algorithm used for minimizing the learning objective.

5.1 SELECTION OF EDGE POTENTIALS

The first step in learning the EF model is concerned with the choice of the edge potentials $w_{uv}(\mathbf{x})$. Here, we consider continuous distributions as edge potentials. Although we do not explicitly consider discrete distributions in the following, we want to emphasize that learning in the EF model easily extends to this class of potentials. In order to keep our model as generic as possible, we have chosen to use copula-based potentials. Note from Equation (2) that the potentials $w_{uv}(\mathbf{x})$ exactly correspond to bivariate copula densities. In our analysis, we have used the bivariate Clayton, Frank, Gumbel, Gaussian and Student's t copula as candidate parametric families. These copulas have one single parameter to be estimated.

In order to fit a single-parameter copula family to data, we follow a two-step procedure. As a first step, the marginal cdf for each random variable is estimated in a non-parametric approach (Kojadinovic and Yan, 2010) and the obtained estimators, known as pseudo-observations, are plugged into the copula function. Subsequently, the dependence parameter is computed by maximizing the pseudo-likelihood

$$\log L(\theta) = \sum_{i=1}^n \log c(\hat{\mathbf{u}}_i; \theta) \quad (12)$$

where $\hat{\mathbf{U}}_i$ is the vector of estimators for the marginals and n is the sample size. The best-fitting copula for each variable pair is selected via cross-validation, where the cross-validation score is based on the pseudo-likelihood of the left-out samples.

5.2 THE EF-cuts HEURISTIC

Graphs with two connected components constitute an important subclass of disconnected networks. Even when restricting ourselves to a maximum of two connected components, it is computationally prohibitive to use the exact ensemble-of-forests model of Equation (11) for sets of random variables of non-trivial size due to the super-exponential number of possible node partitions $\text{part}(\mathcal{V})$. Therefore, we resort to heuristic approaches for choosing partitions that are most likely to allow us to recover the true graph structure. For a given parameter configuration β , we aim to identify a number of high scoring partitions of the nodeset and then average over these partitions only.

Our heuristic is based on the intuition that edges e_{uv} with small β_{uv} are assigned a low prior probability and, therefore, are expected to be most likely not present in the true

MRF. Therefore, we would like to prioritize partitions generated by dropping these low-weight edges. Following that intuition, we derive a scoring system based on systematic enumeration of minimum cuts.

A *cut* of a graph $\mathcal{G} = (\mathcal{V}, \mathcal{E})$ is a partition of \mathcal{V} into subsets $A, B = \mathcal{V} - A$. The weight of a cut is the sum of the weights of all edges crossing the cut. Starting with the minimum-weight cut, we want to enumerate a ranked set of graph cuts of increasing weight. An efficient algorithm (Vazirani and Yannakakis, 1992) exists for this task. In our case, edge weights correspond to the structural parameters β . Let (A, B) denote a cut and let \mathcal{C} denote the set of M minimum-weight cuts in the graph. Since we are only considering graphs with at most two connected components, a forest \mathcal{F} consists of two spanning trees T_A, T_B . To simplify our notation, we include the case of connected graphs as a special case where $A = \mathcal{V}$ and $B = \emptyset$. This is a special cut of zero weight and is always included in \mathcal{C} . We perform structure learning by minimizing the negative log-likelihood of the model with respect to β . The respective objective is derived from Equation (11) by setting $k = 2$ and only considering partitions that belong to the set \mathcal{C} . The optimization problem can be formulated as

$$\begin{aligned} \min_{\beta} N \log \sum_{(A,B) \in \mathcal{C}} |\mathbf{Q}(\beta_A)| |\mathbf{Q}(\beta_B)| \\ - \sum_{j=1}^N \log \sum_{(A,B) \in \mathcal{C}} |\mathbf{Q}(\beta \mathbf{w}_A^{(j)})| |\mathbf{Q}(\beta \mathbf{w}_B^{(j)})| \\ \text{s.t. } \beta_{uv} \geq 0 \quad u, v \in \mathcal{V}, \quad u \neq v. \end{aligned} \quad (13)$$

Let us denote \mathcal{C}' the set of partitions where nodes u, v belong to the same connected component. The set of partitions where u, v belong to different components has no contribution to the gradient $(\nabla_{\beta} f)_{uv}$. Without loss of generality, we will assume that if nodes u, v belong to the same partition set, then this is set A and the other set is $B = \mathcal{V} - A$. Then the gradient of the objective (13) follows as

$$\begin{aligned} (\nabla_{\beta} f)_{uv} = N \frac{\sum_{(A,B) \in \mathcal{C}'} M_{uv}(\beta_A) |\mathbf{Q}(\beta_A)| |\mathbf{Q}(\beta_B)|}{\sum_{(A,B) \in \mathcal{C}'} |\mathbf{Q}(\beta_A)| |\mathbf{Q}(\beta_B)|} \\ - \sum_{j=1}^N w_{uv}^{(j)} \frac{\sum_{(A,B) \in \mathcal{C}'} M_{uv}(\beta_A) |\mathbf{Q}(\beta \mathbf{w}_A^{(j)})| |\mathbf{Q}(\beta \mathbf{w}_B^{(j)})|}{\sum_{(A,B) \in \mathcal{C}'} |\mathbf{Q}(\beta \mathbf{w}_A^{(j)})| |\mathbf{Q}(\beta \mathbf{w}_B^{(j)})|} \end{aligned} \quad (14)$$

where M is defined as in (Meilă and Jaakkola, 2006)

$$M_{uv} = \begin{cases} Q_{uu}^{-1} + Q_{vv}^{-1} - 2Q_{uv}^{-1} & \text{if } u \neq v, u \neq w, v \neq w, \\ Q_{uu}^{-1} & \text{if } u \neq v, v = w, \\ Q_{vv}^{-1} & \text{if } u \neq v, u = w, \\ 0 & \text{if } u = v. \end{cases} \quad (15)$$

With w we denote the index of the row and column that are removed from the Laplacian matrix of Equation (4) in order to obtain Q .

The min-cut heuristic is a feasible approximation to structure learning of MRFs with disconnected topologies. However, it is practically restricted to graph structures with at most two connected components. Furthermore, the approach does not scale with increasing node or sample size due to the complicated objective and gradient functions. These considerations limit its applicability to real world scenarios.

5.3 THE EF- λ HEURISTIC

In the following, we introduce the EF- λ heuristic that scales well with dimensionality and number of connected components of the underlying MRF. The starting point is again equation (11), but now we drop the summation $\sum_{\mathbf{V} \in \text{part}(\mathcal{V})}$ over possible node partitions. Instead, we only consider a single partition \mathbf{V} . Additionally, we impose an L_1 penalty term on the structural parameters β to encourage sparse solutions. The new optimization task is expressed as

$$\begin{aligned} \min_{\beta} N \sum_{V^i \in \mathbf{V}} \log |\mathbf{Q}(\beta_{V^i})| - \sum_{j=1}^N \sum_{V^i \in \mathbf{V}} \log |\mathbf{Q}(\beta \mathbf{w}_{V^i}^{(j)})| + \lambda \|\beta\|_1 \\ \text{s.t. } \beta_{uv} \geq 0 \quad u, v \in \mathcal{V}, \quad u \neq v. \end{aligned} \quad (16)$$

An iterative optimization procedure is employed to minimize the objective (16). At each iteration step, summation is performed over maximal forests defined for the single node partition \mathbf{V} that is induced by the current iterate β . The number of connected components does not need to be fixed. The penalty term has the critical role of controlling sparsity and, thus, allowing structures with multiple connected components to be considered.

A similar L_1 -regularized approach cannot be employed for the ET model, because the ET objective is not defined for all sparsity patterns in β . Therefore, there is effectively no sparsity induction by an L_1 penalty in ET. Furthermore, for some iterative optimization procedures, numerical instabilities might occur if β is temporarily set to an invalid value.

The gradient of the objective for the EF- λ takes a simple form. Considering the non-negativity of β , the L_1 -norm $\|\beta\|_1$ is equal to $\sum_{u,v \in \mathcal{V}, u \neq v} \beta_{uv}$. Thus, the objective is differentiable at all points. Assuming that β induces a par-

tioning of \mathcal{V} into $\{V^1, \dots, V^k\}$, the gradient of the objective can be expressed as

$$(\nabla_{\beta} f)_{uv} = NM_{uv}(\beta_{V^i}) - \sum_{j=1}^N w_{uv}^{(j)} M_{uv}(\beta \mathbf{w}_{V^i}^{(j)}) + \lambda \quad (17)$$

for $u, v \in V^i$ and is equal to 0 otherwise.

The choice of the regularization parameter λ is an important aspect of the EF- λ approach. We optimize the EF- λ objective using different penalty parameters $\lambda = \exp(-\rho)$, where ρ takes values in the interval $[3, 6]$ with a step of 0.1. The optimal λ is selected so as to minimize the extended Bayesian Information Criterion (eBIC) (Foygel and Drton, 2010) defined as

$$eBIC = 2\mathcal{L} + |E| \log n + 4|E|\gamma \log d \quad (18)$$

where \mathcal{L} is the negative log-likelihood of the model, $|E|$ is the number of non-zero predicted β entries, n is the sample size, d is the number of nodes and γ is an additional penalty term imposed on more complex structures. The classical Bayesian Information Criterion is obtained as a subcase for $\gamma = 0$. We performed simulations with different values of γ in the interval $[0, 1]$ and resulted in using $\gamma = 0.5$.

5.4 OPTIMIZATION OF THE LEARNING OBJECTIVE

The objectives (13) and (16) to fit the EF model are non-convex functions. Therefore, there is no guarantee of convergence to a global optimum and the initial point for optimization has to be carefully chosen. Lin et al. (2009) initialize β with an upper-bound obtained by optimizing a convex sub-expression of the full objective. Our preliminary experiments confirmed that this method yielded significantly better optima than random initializations. Therefore, we adopted this choice for initialization. As for the main optimization task, we have used the Spectral Projected Gradient (SPG) algorithm (Varadhan and Gilbert, 2009), a gradient-based method that allows for simple box constraints.

6 BENCHMARK ON SIMULATED DATA

In this section, we evaluate the empirical performance of our proposed EF approximations via comparison to the ET (Lin et al., 2009) and glasso (Friedman et al., 2008) algorithms on synthetic Gaussian and non-Gaussian data. We use the glasso implementation from the R-package huge (Zhao et al., 2012). The glasso regularization term is obtained via Stability Approach to Regularization Selection (StARS) (Liu et al., 2010), a criterion based on variability of the graphs estimated by overlapping subsamplings. We employ this criterion, since it achieves the best

performance in our simulations. For the ET and EF approaches we use Gaussian copula or Student’s t-copula potentials and optimize the corresponding objective via SPG. For the EF-cuts method, we consider the first 50 minimum-weight cuts.

6.1 RESULTS ON GAUSSIAN MRF DATA

We first aim at confirming that the EF model achieves comparable performance to state-of-the-art methods for MRF structure learning. To this end, we generated Gaussian MRF data following the procedure described in (Lin et al., 2009). The off-diagonal entries of the precision matrix $\Omega = \Sigma^{-1}$ are sampled from $\pm(0.1 + 0.2|n|)$, where n is drawn from $\mathcal{N} \sim (0, 1)$. The diagonal entries are selected via Gershgorin’s circle theorem to ensure that the matrix is positive definite. Given $\Omega = \Sigma^{-1}$, data can be easily sampled from a multivariate Gaussian distribution $\mathcal{N} \sim (\mathbf{0}, \Sigma)$.

We first generate random connected graphs of $d = 25$ nodes with an average of 2 neighbours/node. For a given graph, we draw 500 samples from the corresponding GMRF distribution and then compare the ability of different methods to retrieve the graph structure when a different sample size is available. Performance metrics for this setting, obtained from 100 repetitions, are reported in Figure 2A, while the average runtime for each method is given in Table 1. We can see that the EF- λ and EF-cuts approaches have similar accuracy as the ET, as the corresponding Hamming distances to the ground truth (i.e. number of misclassified edges) are on the same level. Notably, the number of false positive edges predicted by the EF- λ method is zero in most cases. Thus, precision is always very close to one. As a trade-off, recall is limited, especially for lower sample sizes. When 500 samples are available, recall reaches levels comparable to the baseline methods. The EF-cuts method performs very similar to the ET, while exhibiting a much higher runtime. The reported runtimes for EF- λ and glasso correspond to a complete run with 32 λ -values. The runtime for glasso is not dependent on the sample size and is mostly consumed for choosing the optimal λ . On the other hand, the runtime for EF- λ increases with sample size. However, we argue that the added runtime constitutes a reasonable trade-off for achieving superior structure learning performance.

Table 1: Average runtime (in seconds) for the experiments presented in Figure 2. For EF- λ and glasso the reported runtime corresponds to a complete run with 32 λ -values and choice of the optimal λ .

Sample Size:	25	50	100	250	500
ET	6	9	13	28	57
EF- λ	32	39	56	110	188
EF-cuts	1166	2088	3512	8151	14435
glasso	31	31	31	31	31

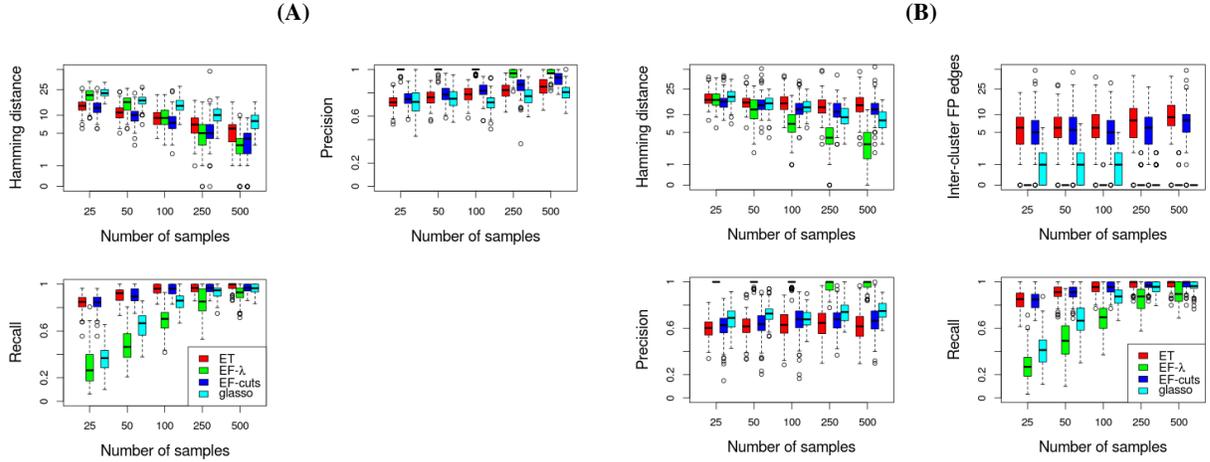

Figure 2: Comparison of the EF- λ , EF-cuts, ET and glasso algorithms on recovering the structure of (A) connected (B) disconnected sparse GMRFs from different sample sizes. Simulated graphs comprise 25 nodes with 2 neighbours/node on average. The boxplots contain results from 100 repetitions.

In a next step, we evaluated the performance of the EF model in a situation where the data is drawn from a Gaussian MRF with multiple connected components. Therefore, we generated data from GMRFs with no restriction on the number of connected components. Again, each graph comprises $d = 25$ nodes with an average of 2 neighbours/node. Performance metrics for this setting, obtained from 100 repetitions, are reported in **Figure 2B**. We can observe that the EF- λ approach outperforms the other three in terms of accuracy, as it achieves the lowest Hamming distance. As in the one-component setting, the number of false positive edges predicted by this method is zero in most cases. Thus, there are no inter-cluster false positive edges (i.e. edges that are falsely predicted to connect nodes belonging to different clusters) and precision is always very close to one. The recall achieved is inferior to the other methods. However, as the sample size grows, recall also reaches competitive levels. Again in this setting, the EF-cuts approach performs very similar to the original ET method.

We have seen that the EF-cuts method performs very similar to the original ET method, but exhibits much higher runtimes. On the other hand, the EF- λ heuristic performs very well for both connected and disconnected MRFs and is additionally faster and more generic than the the EF-cuts. Thus, we only include EF- λ in the next simulations and refer to it as simply EF.

6.2 RESULTS ON NON-GAUSSIAN MRF DATA

Here we explore the ability to learn the structure of MRFs with non-Gaussian potentials. The EF, as well as the ET approach, are applicable for arbitrary potentials and are, therefore, expected to well adapt to this situation.

We now perform simulations for a Markov network whose data dependencies are no longer Gaussian. More specifi-

cally, we generate random graphs consisting of 25 nodes that are organized in small cliques of size 3 or 4. For each clique we draw data samples of pseudo-observations (Kojadinovic and Yan, 2010) from a Student’s t-copula with 1 degree of freedom. The dependencies among random variables in each clique are clearly non-Gaussian. Subsequently, we apply the Gaussian quantile function to the pseudo-observations of each random variable and, thereby, we obtain data that is marginally normally distributed. In this setting, we compare the EF approach to the ET, glasso and, additionally, to the non-paranormal model (npn) of Liu et al. (2009). The latter utilizes Gaussian copulas for structure learning. Its implementation is also available via the R-package *huge*.

The results of 100 simulations are summarized in the boxplots of **Figure 3**. The Hamming distances produced by the EF approach are considerably smaller than those produced by competing approaches. Moreover, no false positive edges are predicted by the EF method. Precision and also recall are very high. In contrast, the glasso and non-paranormal methods, that assume Gaussian dependency structures, achieve limited recall. The ET method produces higher Hamming distances and also low precision, since it introduces false positive edges that connect the cliques. Note that the Hamming distance for this method is almost equal to the number of inter-cluster false positive edges. In such a setting, the EF approach performs significantly better than all alternative methods since it naturally deals with t-copula dependencies and disconnected MRF topologies.

6.3 A HIGH-DIMENSIONAL SETTING WITH VERY LOW SAMPLE SIZE

Here, we explore structure learning on the basis of an extremely low number of samples from a comparably high dimensional MRF. This situation commonly arises in many

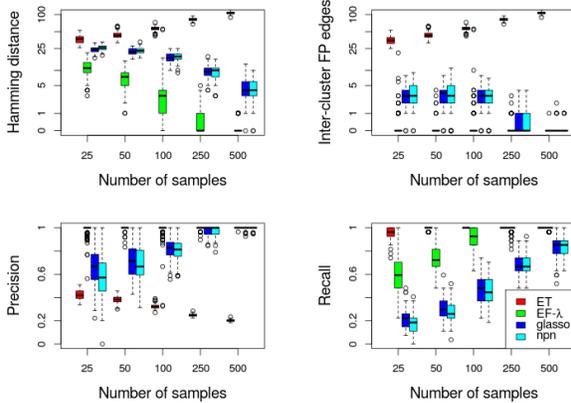

Figure 3: Comparison of the EF, ET, glasso and non-paranormal algorithms on recovering the structure of sparse MRFs with Student’s t -copula ($df = 1$) potentials. Simulated graphs comprise 25 nodes organized in small cliques of size 3 or 4. The boxplots contain results from 100 repetitions.

real world applications, as for instance in biology where typically only few observations are available. In this situation, we do not expect to comprehensively recover the underlying MRF structure. Instead, we aim to maximize the number of recovered true MRF edges at high precision, i.e. without accumulating false positive relationships. Therefore, we generate 50 data samples from an 80-dimensional GMRF, where each node has on average 3 neighbours. The ROC curves in **Figure 4** compare the performance of the EF and glasso approaches. We can see that, for very low sample sizes, the EF method recovers almost a double number of edges at a tolerance level of 1% FDR. In **Table 2** we present the average runtime for EF and glasso when run with a single λ value.

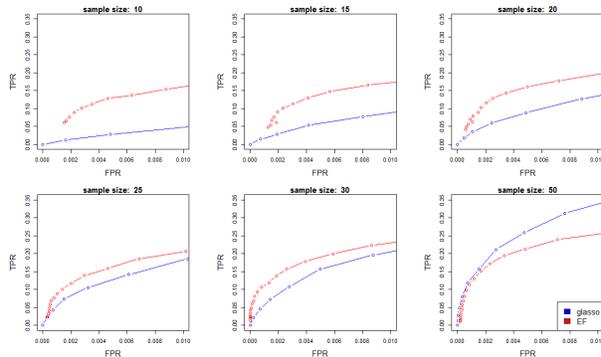

Figure 4: Comparison of the EF and glasso algorithms in a high-dimensional setting (80-node graph) with very low sample size. ROC curves for different numbers of available data replicates are presented, averaged over 100 repetitions. The curves are truncated at a tolerance level of 1% FDR.

Table 2: Average runtime (in seconds) for the simulations presented in **Figure 4**. Runtime is averaged over repetitions and λ values.

Sample Size:	10	15	20	25	30	50
EF- λ	107	153	163	182	185	248
glasso	< 1	< 1	< 1	< 1	< 1	< 1

7 RESULTS ON MICROARRAY DATA

Here we demonstrate the performance of the EF approach on a microarray dataset (Wille et al., 2004) from the isoprenoid biosynthesis pathways in *Arabidopsis thaliana*. Expression levels of 39 genes (variables) are quantified under $n = 118$ conditions (observations). EF is evaluated via comparison to glasso (Friedman et al., 2008), the state-of-the-art algorithm for learning the structure of continuous MRFs. For the EF analysis, we used the Gaussian, Gumbel, Clayton, Frank and Student’s t copula as candidate parametric families. A summary of the copula selection results is presented in **Table 4**, where we can observe that a variety of different dependency types is present.

For both methods, a decreasing sequence of 40 λ -values was used. The optimal regularization parameter λ for EF was obtained via eBIC (Foygel and Drton, 2010), resulting in a sparse MRF whose graph structure is depicted in **Figure 5A**. On the contrary, the use of information criteria (eBIC, StARS (Liu et al., 2010)) for glasso yielded very dense networks, as depicted in **Figure 5B**. In order to additionally compare both approaches with respect to results at similar sparsity levels, we also selected the glasso graph with the smallest Hamming distance with respect to the graph learned via EF. To evaluate the performance of the algorithms, we used a 5-fold cross validation setting and evaluated the best-fitting model on the basis of the average per-sample held-out log-likelihood. Results are shown in **Table 3** and demonstrate that the MRF learned via EF has better cross validation performance. Besides the performance advantage, we note that the sparse structure of EF model selection enables straightforward interpretation and further hypothesis generation by domain experts.

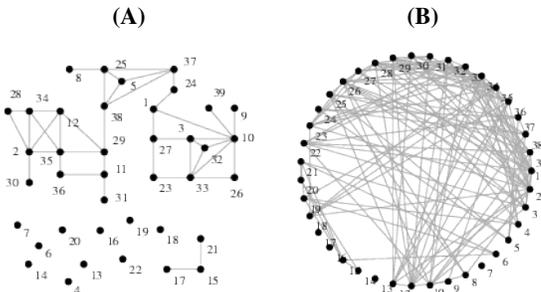

Figure 5: Optimal MRF graph structure recovered via (A) EF, (B) glasso for the microarray data. The numbering scheme legend is provided as Supplementary Material.

Table 3: Average per-sample held-out log-likelihood for the microarray data.

	Log-likelihood	Std. error
EF- λ	9.694	0.526
glasso (StARS)	8.522	0.418
glasso (sparse)	8.995	0.455

8 RESULTS ON IMMUNE CELL PERTURBATION DATA

Finally we apply the EF model to study the occurrence of MRFs with multiple connected components in a proteomics setting. Specifically, we analyze mass cytometry data from human peripheral blood mononuclear cells (PBMC), essentially representing all immune cells residing in the blood stream (Bodenmiller et al., 2012). Mass cytometry allows for proteomic profiling of molecular signaling events at single-cell resolution. The considered publicly available dataset recapitulates the response of PBMC populations to various molecular stimuli under several different pharmacological interventions. Signaling response has been measured by quantifying 14 phosphorylation sites (variables). For each intervention and cell type, 96 conditions were considered, where a condition consisted of an intervention strength setting and a specific stimulus.

Here we present results for interventions with the drug dasatinib. Again we observe the occurrence of a variety of non-Gaussian dependencies in this real world dataset (Table 4). We evaluate the performance of EF by comparing it to glasso, as we did for the microarray data. The average held-out log-likelihood per dataset is reported in the boxplots of Figure 6A. Different PBMC datasets are grouped together according to the stimulus used in each experiment. We can see that EF achieves constantly superior performance. Furthermore, in Figure 6B, separate histograms of the number of connected components for each stimulus are presented. For specific stimuli, MRF topologies with multiple components are common, reflecting the molecular impact of the intervention on the respective cellular signaling event. The EF approach is able to adapt to and recover underlying disconnected topologies even in the presence of unusual dependencies and, thus, we expect this approach to enable the probabilistic characterization of cellular signaling events and, thus, to enable molecular insights of possibly pathologically altered responses and to generate hypotheses for clinical interventions.

9 DISCUSSION

We have introduced the ensemble-of-forests model to approximate structure learning for MRFs with arbitrary potentials and connected components. Additionally, we have

Table 4: Frequencies of selected copula families during the analysis of plant microarray and PBMC mass cytometry data.

	Gumbel	Frank	Clayton	Gaussian	t (df=1)
Micro.	0.28	0.06	0.13	0.51	0.02
PBMC	0.20	0.06	0.35	0.23	0.16

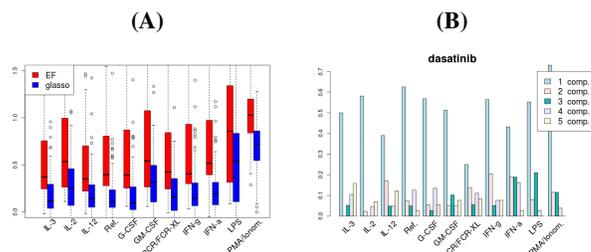

Figure 6: (A) Comparison of the EF and glasso algorithms. Boxplots of average held-out log-likelihood for different cell-type / stimulus combinations. (B) Histograms of the number of MRF connected components predicted by EF when applied to PBMC mass cytometry data. Separate histograms are given for each stimulus, indicated on the x-axis. Frequencies on the y-axis are normalized to sum up to 1 for each stimulus.

presented two approximate inference techniques for this model and compared their structure learning performance with state-of-the-art methods on a comprehensive set of synthetic data.

ET and EF models are appealing structure learning approaches when unusual MRF potentials are to be expected. Indeed, our simulation results confirm that the EF method can accurately reconstruct non-Gaussian dependencies that are a priori accounted for.

Disconnected dependency structures frequently arise in real world applications. However, the ET model is conceptually not able to handle such cases. We have extended the ET to the EF model to the end of accommodating multiple-component situations. Our simulation results confirm that we are able to faithfully recover MRF topologies with one as well as with multiple connected components. The study of the plant microarray and PBMC mass cytometry data furthermore confirms the ubiquitous occurrence of the multiple-component situation in cell biology and further emphasizes the need for structure learning approaches that are able to deal with this situation.

We also assessed how the EF model performs for limited sample size, again a typical case for real world applications. Our approach seems ideal for low-sample situations, where we aim to maximize the number of recovered true MRF edges at high precision.

In summary, we expect the EF model to enable MRF structure learning for many real world applications since this approach naturally deals with low sample size, unusual dependency types and disconnected dependency topologies.

Abstract

The BDI architecture, where agents are modelled based on their beliefs, desires and intentions, provides a practical approach to develop large scale systems. However, it is not well suited to model complex Supervisory Control And Data Acquisition (SCADA) systems pervaded by uncertainty. In this paper we address this issue by extending the operational semantics of CAN(PLAN) into CAN(PLAN)+. We start by modelling the beliefs of an agent as a set of epistemic states where each state, possibly using a different representation, models part of the agent’s beliefs. These epistemic states are stratified to make them commensurable and to reason about the uncertain beliefs of the agent. The syntax and semantics of a BDI agent are extended accordingly and we identify fragments with computationally efficient semantics. Finally, we examine how primitive actions are affected by uncertainty and we define an appropriate form of lookahead planning.

1 INTRODUCTION

SCADA (Supervisory Control And Data Acquisition) systems are known for their large scale processes in a wide variety of domains, including production processes [Zhi et al., 2000] and energy and transportation systems [Boyer, 2009]. One way of modelling such systems is by means of the BDI architecture [Bratman, 1987] which allows us to decompose a complex system into a set of autonomous and interacting agents, where an agent is defined by its (B)eliefs, (D)esires and (I)ntentions. Agent-based programming languages based on the BDI framework have been proposed [Ingrand et al., 1992, Rao, 1996, Dastani, 2008] and have been used to some extent to model SCADA systems (e.g. [McArthur et al., 2007]).

However, current BDI implementations are not well-suited to model the next generation of complex SCADA systems.

The reason for this is two-fold. On the one hand, current BDI implementations are not able to deal with uncertainty associated with the beliefs of an agent (e.g. due to noisy sensing) or the uncertain effects of actions (e.g. due to actuator malfunctions). This limits the ability of a BDI agent to react in a satisfactory way in an uncertain environment. On the other hand, and closely related, is that most BDI implementations do not provide any mechanisms for lookahead planning to guide (part of) the BDI execution in this uncertain setting.

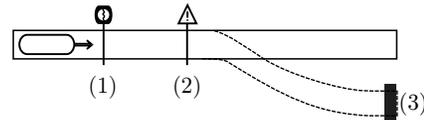

Figure 1: Scenario for a train agent with an unreliable signal (1), a dangerous junction (2) and a goal station (3).

To illustrate these issues, consider the running example in Figure 1. A train agent is moving along a track with a signal (1). The signal, which is green or orange, informs the agent if it violates the safe distance (with uncertainty due to e.g. mist, conflicting signals ...). Once the agent has passed the signal, the agent decides on how to approach the junction (2). The speed of the train is not known exactly, yet the agent needs to decide whether it wants to keep speeding (as it is running late) or slow down (resp. 75% and 50% chance of reaching the junction in time). Once at the junction, the action to take the junction only has a 30% chance of succeeding when speeding (e.g. due to derailment). Otherwise, the junction can safely be taken. For simplicity, the station is reached on time only when the junction is safely taken. Clearly, an agent should be able to reason about the uncertainty and be able to plan ahead, e.g. foresee that slowing down is the best action.

Not a lot of work in the literature on BDI tackled the problem of representing, and reasoning about, uncertain information. A notable exception is the recent work in [Chen et al., 2013], which incorporates uncertain perceptions in the epistemic state of an agent after which

it is mapped to a classical belief base, thus ignoring the other information. The work on graded BDI systems [Casali et al., 2005, Casali et al., 2011] similarly discusses how uncertainty can pervade the beliefs, desires and intentions. However, the graded BDI framework is mainly of theoretical interest and has not led to actual implementations, contrary to how AgentSpeak and CAN have helped to advance the state-of-the-art in BDI implementations.

Planning in a BDI agent, where the agent reflects on its actions before executing them, has been considered in numerous works. While the BDI model does not prevent planning, most BDI implementations resort to simple plan selection strategies to avoid the computational cost associated with declarative planning. This prevents them from acting optimally when needed, e.g. when important resources are consumed during the execution of plans. A formal approach to planning in BDI, called CANPLAN, was presented in [Sardiña et al., 2006]. CANPLAN is based on the Conceptual Agent Notation (CAN) [Winikoff et al., 2002], a high-level agent language in the spirit of BDI [Rao and Georgeff, 1991]. It is closely related to AgentSpeak [Rao, 1996] but allows for declarative goals alongside procedural steps (i.e. we can state *what* we want to achieve, not just *how* to achieve it). CANPLAN extends this work by introducing a *Plan*(\cdot) action, making planning on-demand an integral part of the BDI framework. Nevertheless, none of the approaches to BDI address the issues that arise when dealing with actions with uncertain effects, or uncertain beliefs in general.

In this paper we propose the CAN+ and CANPLAN+ frameworks, which extend CAN and CANPLAN to provide formal approaches for dealing with uncertain beliefs and (planning for) actions with uncertain effects. The beliefs of an agent are modelled as a set of epistemic states, with each *local* epistemic state representing a distinct part of the beliefs held by the agent. Each epistemic state can deal with a different form of uncertainty (e.g. possibilities or infinitesimal probabilities) and includes its own revision strategy. Such a set of local epistemic states will be called a *Global Uncertain Belief set* (GUB) and allows the agent to reason about different forms of uncertainty in a uniform way, as long as these can be expressed using epistemic states that are equivalent to Definition 1. This is achieved in two steps. Firstly, a stratification of each local epistemic state allows for commensurability, along with the ability to reason about the uncertain beliefs. In other words: it enables an agent to reason about those beliefs it currently does not assume to be true (in the sense of beliefs in classical logics). Nevertheless, an agent commonly still considers some outcomes to be more plausible than others. The agent thus gains the ability to reflect on its own uncertainty. Secondly, an agent will be able to revise a GUB directly, with the GUB ensuring that only the information relevant to a specific local epistemic state is used to revise it. This idea of

a GUB will be introduced in the CAN framework to obtain CAN+. CANPLAN+ further extends upon it by adding the ability to execute and plan for non-deterministic actions, all while dealing with uncertain beliefs.

The remainder of this paper is organised as follows. Some preliminary notions are discussed in Section 2. We explore how we can efficiently model and reason about uncertain beliefs in Section 3, where we introduce the idea of epistemic states and how they can be applied in a BDI setting. In Section 4 we extend CAN to enable us to deal with uncertain beliefs, while uncertain actions and planning under uncertainty are addressed in Section 5. Related work is discussed in Section 6 and conclusions are drawn in Section 7.

2 PRELIMINARIES

An agent in the BDI framework is defined by its beliefs, desires and intentions. The beliefs encode the agent’s understanding of the environment, the desires are those goals that an agent would like to accomplish and the intentions those desires that the agent has chosen to act upon.

CAN, and its extension CANPLAN, formalise the behaviour of a classical BDI agent, which is defined by a belief base \mathcal{B} and a plan library Π . The belief base of an agent is a set of formulas over some logical language that supports entailment (i.e. $\mathcal{B} \models b$, b a belief), belief addition and belief deletion (resp. $\mathcal{B} \cup \{b\}$ and $\mathcal{B} \setminus \{b\}$). The plan library is a set of plans of the form $e : \psi \leftarrow P$ where e is an event, ψ is the context and P is a plan body. Events can either be external (i.e. from the environment in which the agent is operating) or internal (i.e. sub-goals that the agent itself tries to accomplish). The plan body P is *applicable* to handle the event e when $\mathcal{B} \models \psi$, i.e. the context evaluates to true. The event and context differ in that the context is lazily evaluated; it is checked right before the execution of the plan body. The language used in the plan body P is defined in Backus-Naur Form (BNF) as:

$$P ::= nil \mid +b \mid -b \mid act \mid ?\phi \mid !e \mid P_1; P_2 \mid P_1 \parallel P_2 \mid P_1 \triangleright P_2 \mid (|\Delta|) \mid Goal(\phi_s, P, \phi_f) \mid Plan(P)$$

with *nil* an empty or completed program, $+b$ and $-b$ belief addition and deletion, *act* a primitive action, $?\phi$ a test for ϕ in the belief base, and $!e$ a subgoal, i.e. an (internal) event. Actions, tests and subgoals can fail, e.g. when the preconditions are not met. Composition is possible through $P_1; P_2$ for sequencing, $P_1 \parallel P_2$ for parallelism (i.e. a non-deterministic ordering) and $P_1 \triangleright P_2$ to execute P_2 only on failure of P_1 . $(|\Delta|)$ is used to denote a set of guarded plans, with Δ of the form $\psi_1 : P_1, \dots, \psi_n : P_n$, which intuitively states that the plan body P_i is *guarded* by the context ψ_i , i.e. the context needs to be true to execute the plan body. The plan form $Goal(\phi_s, P, \phi_f)$ is a distinguishing feature of CAN that allows to model both declarative and procedural goals. It states that we should achieve the (declarative)

goal ϕ_s using the (procedural) plan P , where the goal fails if ϕ_f becomes true during the execution. CANPLAN furthermore introduces the $Plan(P)$ construct, which is used for offline lookahead planning. This construct will be discussed in more detail in Section 5.

The operational semantics of CANPLAN are defined in terms of configurations. A basic configuration is a tuple $\langle \mathcal{B}, \mathcal{A}, P \rangle$ with \mathcal{B} a belief base, \mathcal{A} the sequence of primitive actions that have been executed so far and P the remainder of the plan body to be executed (i.e. the current intention). An agent (configuration) is a tuple $\langle \mathcal{N}, \mathcal{D}, \Pi, \mathcal{B}, \mathcal{A}, \Gamma \rangle$ with \mathcal{N} the name of the agent, \mathcal{D} the action description library, Π the plan library, Γ the set of current intentions of the agent and \mathcal{B} and \mathcal{A} as before. For each action act the action description library contains a rule of the form $act : \psi \leftarrow \phi^-; \phi^+$. We have that ψ is the precondition, while ϕ^- and ϕ^+ denote respectively a delete and add set of belief atoms, i.e. propositional atoms.

A *transition relation* \longrightarrow on (both types of) configurations is defined by a set of derivation rules. A transition $C \longrightarrow C'$ denotes a single step execution from C yielding C' . We write $C \longrightarrow$ to state there exists a C' such that $C \longrightarrow C'$ and $C \not\longrightarrow$ otherwise. We use $\xrightarrow{*}$ to denote the transitive closure over \longrightarrow . A *derivation rule* consists of a (possibly empty) set of premises p_i and a single transition conclusion c . Such a derivation rule is denoted as

$$\frac{p_1 \quad p_2 \quad \dots \quad p_n}{c} l$$

with l a label attached to the derivation rule for easy reference. Transitions over basic configurations (resp. agent configurations) define what it means to execute a single intention (resp. the agent as a whole). For example, the transition for belief addition and a primitive action are:

$$\frac{\langle \mathcal{B}, \mathcal{A}, +b \rangle \longrightarrow \langle \mathcal{B} \cup \{b\}, \mathcal{A}, nil \rangle +b}{(a : \psi \leftarrow \phi^-; \phi^+) \in \mathcal{D} \quad a\theta = act \quad \mathcal{B} \models \psi\theta} \frac{}{\langle \mathcal{B}, \mathcal{A}, act \rangle \longrightarrow \langle (\mathcal{B} \setminus \phi^- \theta) \cup \phi^+ \theta, \mathcal{A} \cdot act, nil \rangle} act$$

where the latter states that when the unified precondition $\psi\theta$ is true in the belief base \mathcal{B} , the effect of the action is the application of the add and delete atom lists to the belief base. We refer the reader to [Sardiña and Padgham, 2011] for a full overview of the semantics of CANPLAN.

Finally, a *preorder* \leq_A defined on any set A is a reflexive and transitive relation over $A \times A$. We say that \leq_A is *total* iff for all $a, b \in A$ we have that either $a \leq_A b$ or $b \leq_A a$. A strict order $<_A$ and an indifference relation $=_A$ can conventionally be induced from \leq_A .

3 MODELLING AND REASONING ABOUT UNCERTAIN BELIEFS

As discussed in Section 2, a belief base in CAN is defined over a logic for which operations are available to add,

delete and entail beliefs. This classical setting allows for an easy approach to belief revision. However in this paper we are concerned with the modelling of, and reasoning over, uncertain information. To deal with uncertainty we will need more elaborate ways to both represent the beliefs and to revise the beliefs when new information becomes available. To this end, we will use epistemic states instead of a belief base as in CAN.

3.1 MODELLING UNCERTAIN BELIEFS AS EPISTEMIC STATES

To define epistemic states, we first start by considering a finite set \mathcal{At} of propositional atoms. For a set of atoms $A \subseteq \mathcal{At}$ we define the set of literals that can be constructed using the atoms in A as $lit(A) = \{a \mid a \in A\} \cup \{\neg a \mid a \in A\}$. A proposition ϕ is defined in BNF as $\phi ::= a \mid \neg a \mid (\phi_1 \wedge \phi_2) \mid (\phi_1 \vee \phi_2)$, i.e. all propositions are in Negation Normal Form (NNF). This does not affect the expressiveness of our language as arbitrary formulas can be efficiently converted into NNF. It will, however, make the definition of our semantics easier. We will denote this language as \mathcal{L} . Now we introduce the concept of an epistemic state:

Definition 1. (from [Ma and Liu, 2011]) *Let Ω be a set of possible worlds. An epistemic state is a mapping $\Phi : \Omega \rightarrow \mathbb{Z} \cup \{-\infty, +\infty\}$.*

An epistemic state will be used to represent the mental state of an agent, where the value $\Phi(\omega)$ associated with a possible world ω , called the *weight* of ω , is understood as the degree of belief in the possible world ω . Throughout the paper we will denote epistemic states using capital Greek letters. For $\omega, \omega' \in \Omega$ and $\Phi(\omega) > \Phi(\omega')$ the intuition is that ω is more plausible than ω' . Two epistemic states Φ and Ψ are *semantically equivalent* iff $\exists k \in \mathbb{Z} \cdot \forall \omega \in \Omega : \Phi(\omega) = \Psi(\omega) + k$, i.e. the value associated with the possible worlds only has a relative meaning. In the remainder of this paper we assume that epistemic states have $2^{\mathcal{At}}$ as their domain with $A \subseteq \mathcal{At}$. The *strength* of preference on a propositional formula ϕ is defined as $\Phi(\phi) - \Phi(\neg\phi)$ with $\Phi(\phi) = \max_{\omega \models \phi} (\Phi(\omega))$. We use \max_{Φ} to denote $\max_{\omega \in \Omega} (\Phi(\omega)) - \min_{\omega \in \Omega} (\Phi(\omega)) + 1$, i.e. the weight stronger than any of the strengths associated with information in Φ , and $\min_{\Phi} = 1 - \max_{\Phi}$.¹ The values \max_{Φ} and \min_{Φ} are only needed in Section 4 when considering belief additions and deletions as in CAN.

Before we provide an example, it is important to clarify that the definition of an epistemic state from Definition 1 allows for the construction of a general framework. Indeed, this definition does not impose any restrictions on the values associated with the possible worlds, other than that they are weights. As such, it is the

¹These values only change when the epistemic state is revised and can be computed as a by-product of revision.

most general way in which we can talk about an epistemic state, regardless of the actual representation. Other representations for epistemic states, which attach more specific meaning to the values, have been shown to be equivalent to the one from Definition 1. For example, Definition 1 induces an Ordinal Conditional Function (OCF) [Spohn, 1988]², which in turn can be transformed into other representations, e.g. those based on infinitesimal probabilities [Darwiche and Goldszmidt, 1994] and possibility theory [Dubois and Prade, 1995]. The representation from Definition 1 can thus be *instantiated* using any of the other representations to best suit the nature of the uncertainty. After developing all main concepts, we will show in Section 4 that this will allow us to work with these different forms of uncertainty in a uniform way.

We now give an example of such an epistemic state.

Example 1. Consider a signal that can be (o)range or (g)reen (but never both on). When the signal is orange it usually indicates that the agent is about to violate the safe distance (sd). The agent believes that the light is green and that there is still a safe distance with the train in front. Even when the signal would turn out not to be green, the agent still believes that there would be a safe distance with the train in front of it. An epistemic state Φ could be:

$$\begin{aligned} \Phi(\{o, g, sd\}) &= -\infty & \Phi(\{\neg o, g, sd\}) &= 10 \\ \Phi(\{o, g, \neg sd\}) &= -\infty & \Phi(\{\neg o, g, \neg sd\}) &= -2 \\ \Phi(\{o, \neg g, sd\}) &= 7 & \Phi(\{\neg o, \neg g, sd\}) &= 7 \\ \Phi(\{o, \neg g, \neg sd\}) &= 6 & \Phi(\{\neg o, \neg g, \neg sd\}) &= -2 \end{aligned}$$

where $\max_{\Phi} = +\infty$ and $\min_{\Phi} = -\infty$. The weight associated with e.g. $\{o, g, sd\}$ means that we strongly disbelieve this possible world, while the weight associated with $\{\neg o, g, sd\}$ implies that we believe this possible world to be more plausible than any of the other possible worlds.

The belief set, i.e. the sentences that an agent is committed to believe, is commonly defined as the set that has all the most plausible worlds as its models.

Definition 2. (from [Ma and Liu, 2011]) Let Φ be an epistemic state. The belief set of Φ , denoted as $Bel(\Phi)$, is defined as $Bel(\Phi) = \phi$ with ϕ any propositional formula such that $Mod(\phi) = \min(\Omega, \leq_{\Phi})$. Here $Mod(\phi)$ is the set of models of ϕ and \leq_{Φ} is a total preorder relation over Ω such that $\omega \leq_{\Phi} \omega'$ iff $\Phi(\omega) \geq \Phi(\omega')$.

The model of the belief set thus only contains those possible worlds with the highest weight. In this paper we extend on this idea by also taking the other possible worlds into account. These other possible worlds constitute the uncertain information, i.e. they define the preferences the agent has over the outcomes that are currently not believed to be true.

²Compared to OCFs, the representation from Definition 1 avoids the normalisation step.

To clearly identify these preferences, irrespective of the actual values of these weights in different representations of the epistemic states, we consider a stratification of the set of possible worlds. The highest stratum (containing those possible worlds with the strongest associated belief) corresponds to the set of models of the belief set, i.e. that what the agent believes to be true. The other strata constitute the uncertain information, with information in a higher stratum believed/preferred over information in a lower stratum.

Definition 3. Let Φ be an epistemic state. The stratification λ of the domain Ω from Φ induced by the total preorder relation \leq_{Φ} is defined as:

$$\lambda(\omega) = \begin{cases} 1 & \omega \in \min(\Omega, \leq_{\Phi}) \\ n+1 & \omega \in \min(\Omega \setminus \{\omega \mid \lambda(\omega) \leq n\}, \leq_{\Phi}) \end{cases}$$

In Example 1 we obtain $\lambda(\{\neg o, g, sd\}) = 1$, $\lambda(\{o, \neg g, sd\}) = \lambda(\{\neg o, \neg g, sd\}) = 2$, etc. This idea of a stratification readily corresponds with the more common notion of a stratification over propositional formulas as any subset of possible worlds can trivially be represented by a single propositional formula.

Notice that the models of the belief set (see Definition 2) correspond to those possible worlds ω for which $\lambda(\omega) = 1$, i.e. information on all the other strata is ignored. Instead of simply ignoring this information, we want to make it possible for a BDI agent to reason about the preferences expressed throughout the stratification. To this end we extend the language \mathcal{L} with the connectives \geq and $>$. The intuition of $a \geq b$ (resp. $a > b$) is that the agent believes a to be at least as plausible as b (resp. a is strictly more plausible than b). These new connectives are taken to have the lowest precedence. The resulting language \mathcal{L}_{\geq} , or the *context language*, can be defined in BNF as:

$$\phi ::= a \mid \neg a \mid \phi_1 \wedge \phi_2 \mid \phi_1 \vee \phi_2 \mid \phi_1 \geq \phi_2 \mid \phi_1 > \phi_2$$

where formulas with connectives such as \rightarrow and \leftrightarrow can easily be transformed into logically equivalent statements in the language \mathcal{L}_{\geq} . Notice that this definition is the equivalent of NNF for propositional formulas. Any proposition using the connectives \neg , \wedge , \vee , \geq and $>$ can be turned into an equivalent formula in \mathcal{L}_{\geq} in the usual way and by rewriting $\neg(\psi_1 \geq \psi_2)$ as $(\psi_2 > \psi_1)$ and $\neg(\psi_1 > \psi_2)$ as $(\psi_2 \geq \psi_1)$. We assume that this has been done when needed throughout paper.

By extending the mapping λ we can define the semantics of \mathcal{L}_{\geq} over arbitrary formulas. We have:

$$\lambda(\phi) = \begin{cases} \min \{\lambda(\omega) \mid \omega \models \phi\} & \text{if } \phi \in \mathcal{L} \\ \lambda(\text{pare}(\phi)) & \text{otherwise} \end{cases}$$

with $\min(\emptyset) = \infty$. Before defining the function *pare*, we point out that λ is closely related to a possibility measure [Dubois et al., 1994] for propositional

formulas $\phi, \psi \in \mathcal{L}$. We readily establish some interesting properties such as $\lambda(\phi \vee \psi) = \min(\lambda(\phi), \lambda(\psi))$, $\lambda(\phi \wedge \psi) \geq \max(\lambda(\phi), \lambda(\psi))$, $\lambda(\top) = 1$, $\lambda(\perp) = \infty$ and $\min(\lambda(\phi), \lambda(\neg\phi)) = 1$.

When ϕ is not a propositional statement (i.e. $\phi \notin \mathcal{L}$), we need to pare down the formula until the formula is a classical propositional statement. This is done by:

$$\begin{aligned} \text{pare}(\phi \wedge \psi) &= \text{check}(\phi) \wedge \text{check}(\psi) \\ \text{pare}(\phi \vee \psi) &= \text{check}(\phi) \vee \text{check}(\psi) \\ \text{pare}(\phi \geq \psi) &= \begin{cases} \top & \text{if } \lambda(\neg\phi) \geq \lambda(\neg\psi) \\ \perp & \text{otherwise} \end{cases} \\ \text{check}(\phi) &= \begin{cases} \phi & \text{if } \phi \in \mathcal{L} \\ \text{pare}(\phi) & \text{otherwise} \end{cases} \end{aligned}$$

with $\text{pare}(\phi > \psi)$ equivalently defined as $\text{pare}(\phi \geq \psi)$. The intuition of paring down is straightforward: for each operand of the operators \wedge and \vee we verify whether it is an expression in the language \mathcal{L} (for which the λ -value can readily be determined). Otherwise, we need to further pare it down. When the operator is \geq or $>$, we define it as a plausibility ordering with an expression such as $\phi > \psi$ read as “ ϕ is more plausible than ψ ” or, alternatively, “we have less reason to believe $\neg\phi$ than $\neg\psi$ ”.³ Such an expression can always be evaluated to true or false, i.e. \top or \perp .

Finally, we can define when a formula ϕ is entailed.

Definition 4. Let Φ be an epistemic state and ϕ a formula in \mathcal{L}_{\geq} . We say that ϕ is entailed by Φ , written as $\Phi \models \phi$, if and only if $\lambda(\phi) < \lambda(\neg\phi)$.

Example 2. Consider λ of Φ from Example 1. We have:

$$\begin{aligned} \lambda(g \wedge sd) = 1 \quad \lambda(o \wedge sd) = 2 \quad \lambda(g \wedge \neg g) = \infty \\ \lambda((o \vee g) > \neg sd) = 1 \quad \lambda(g \geq o) = 1 \quad \lambda(o \geq g) = \infty \end{aligned}$$

For example, $\lambda(g \wedge sd) = 1$ since $\lambda\{\neg o, g, sd\} = 1$ and $\{\neg o, g, sd\} \models g \wedge sd$. An expression such as $(o \vee g) > \neg sd$, which is also believed to be true, states that the agent does not care about the colour of the light as long as the agent is not violating the safe distance.

Note that in Definition 4 it is insufficient to state that a formula is entailed when $\lambda(\psi) = 1$. Indeed, for $a \in \mathcal{At}$ we can have that $\lambda(a) = \lambda(\neg a) = 1$, which occurs when we are ignorant about the value of a . As such, we need to ensure that both expressions are mapped onto strictly distinct strata. This notion of entailment (assuming $\psi \in \mathcal{L}$) corresponds exactly to those formulas that can be derived from the belief base $Bel(\Phi)$.

Proposition 1. Let $\phi \in \mathcal{L}$ be a propositional formula, Φ an epistemic state with domain Ω and λ the stratification of Ω . We have that $\Phi \models \phi$ iff for all $\omega \in \Omega$ such that $\lambda(\omega) = 1$ we have that $\omega \models \phi$, i.e. $Bel(\Phi) \models \phi$.

³In terms of possibilistic theory: we want $N(\phi) \geq N(\psi)$, i.e. we want $\Pi(\neg\phi) \leq \Pi(\neg\psi)$ (with λ a reversed order).

3.2 SEMANTICS BASED ON LITERAL MAPPING

While the semantics we presented thus far allows us to reason about the uncertain information, they are computationally expensive for evaluating a context because they rely on an exponential structure. A tractable way to evaluate contexts can be obtained by restricting ourselves to a fragment of the language \mathcal{L}_{\geq} , allowing us to determine the truth of a context based on the λ -value associated with the constituent literals.

Example 3. Consider the stratification λ of Φ from Example 1. We have $\lambda(o) = 2$, $\lambda(\neg o) = 1$, $\lambda(g) = 1$, $\lambda(\neg g) = 2$, $\lambda(sd) = 1$ and $\lambda(\neg sd) = 3$.

Due to the way we defined λ over arbitrary formulas, we know that $\lambda(\phi \vee \psi)$ is decomposable, while $\lambda(\phi \wedge \psi)$ is not. Indeed, recall that we only have that $\lambda(\phi \wedge \psi) \geq \max(\lambda(\phi), \lambda(\psi))$. Therefore, we cannot allow \wedge in our restricted language. Furthermore, it affects our ability to verify whether for a given expression ψ we have that $\lambda(\psi) < \lambda(\neg\psi)$. Indeed, we can only allow disjunction as part of an operand of the operators \geq or $>$ as otherwise its negation would turn it into a conjunction, which we do not allow. As such, we obtain the fragment \mathcal{L}_{\geq} , defined in BNF as:

$$d ::= a \mid \neg a \mid d_1 \vee d_2 \quad \phi ::= a \mid \neg a \mid d_1 \geq d_2 \mid d_1 > d_2$$

Contexts in this language can easily be evaluated, once we have the λ -values of the literals $lit(A)$:

$$\begin{aligned} \lambda(\phi \vee \psi) &= \min(\lambda(\phi), \lambda(\psi)) \\ \lambda(\phi \geq \psi) &= \begin{cases} 1 & \lambda(\neg\phi) \geq \lambda(\neg\psi) \\ \infty & \text{otherwise} \end{cases} \end{aligned}$$

and equivalently for $\lambda(\phi > \psi)$. As before, we say that ϕ is true iff $\lambda(\phi) < \lambda(\neg\phi)$. Even though enforcing tractability carries a penalty in terms of the expressive power, we still retain a language that takes advantage of the new connectives we have introduced, thus allowing us to reason over the plausibility of statements.

3.3 EFFICIENTLY MODELLING ISOLATED UNCERTAIN BELIEFS

As a final step in the representation of uncertain beliefs for a BDI agent, we introduce the concept of a global uncertain belief set (GUB) which applies to both Section 3.1 and 3.2.

Definition 5. A global uncertain belief set \mathcal{G} is a set $\{\Phi_1, \dots, \Phi_n\}$ with each Φ_i an epistemic state over the domain $A_i \subseteq \mathcal{At}$ such that $\{A_1, \dots, A_n\}$ is a partition of \mathcal{At} .

Each local (or *isolated*) epistemic state models beliefs that are semantically related, e.g. the colour of the signal or the condition of the track, and that are governed by the same

form of uncertainty. A GUB then groups a set of such local epistemic states. A GUB is therefore a representation of the overall beliefs of an agent, yet it differs in three significant ways from a global epistemic state. First, it avoids the exponential representation of a global epistemic state by partitioning the beliefs. Second, it allows for a general framework where each local epistemic state can use a different representation. Third, it does not include a revision strategy (as each local epistemic state can have a distinct revision strategy), i.e. it is not itself an epistemic state.

Despite these differences, we can use a GUB to determine if a context ϕ is true according to the agent's collective beliefs. Intuitively, ϕ can be evaluated directly if it applies to a single local epistemic state Φ_i , i.e. we can verify whether $\Phi_i \models \phi$. Otherwise, we need to break ϕ apart up until the point where we can evaluate it directly. An expression can be split when the connective is either \wedge or \vee . Since both operands will either be true or false such a decomposition is trivial. However, this also implies that we cannot decompose \geq or $>$, since in this paper we require both operands to be from the same local epistemic state. Indeed, in general, stratifications of different formulas in different local epistemic states are incomparable due to the varying underlying structures. The problem of comparing the plausibilities of different local epistemic states is left for future work.

To formalise this intuition, we use $\mathcal{L}_{\geq}^{A_i}$ to denote the language \mathcal{L}_{\geq} limited to atoms $a \in A_i$, i.e. the language corresponding to the epistemic state Φ_i . A formula ϕ is broken apart by (*simp*)plifying it, which returns the evaluation of ϕ by evaluating the operands (or it returns \perp if the connective is \geq or $>$ and both operands are incomparable). We can then define $val_{GUB}(\phi)$ as:

$$val_{GUB}(\phi) = \begin{cases} \top & \text{if } \phi \in \mathcal{L}_{\geq}^{A_i}, \Phi_i \models \phi \\ \perp & \text{if } \phi \in \mathcal{L}_{\geq}^{A_i}, \Phi_i \not\models \phi \\ simp(\phi) & \text{otherwise} \end{cases}$$

$$simp(\phi \wedge \psi) = val_{GUB}(\phi) \wedge val_{GUB}(\psi)$$

$$simp(\phi \vee \psi) = val_{GUB}(\phi) \vee val_{GUB}(\psi)$$

$$simp(\phi \geq \psi) = \perp$$

and $simp(\phi > \psi)$ equivalently defined as $simp(\phi \geq \psi)$.

Definition 6. Let \mathcal{G} be a GUB and ϕ a formula in \mathcal{L}_{\geq} . We say that ϕ is entailed by \mathcal{G} , written as $\mathcal{G} \models \phi$, if and only if $val_{GUB}(\phi) \equiv \top$.

A visual representation of a GUB is given in Figure 2.

4 DEALING WITH UNCERTAIN BELIEFS IN A BDI AGENT

In the previous section we discussed how the beliefs of an agent can be represented as a set of local epistemic states. We also discussed how a GUB, and the underlying strat-

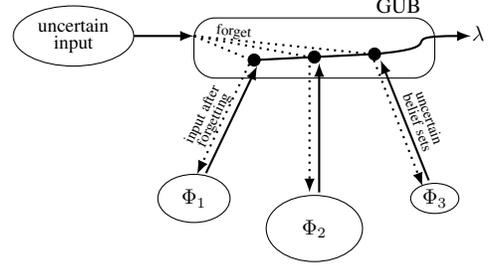

Figure 2: A GUB models the belief of an agent as a set of epistemic states Φ_i , each having its own representation (Definition 5). Commensurability is obtained by stratifying the possible worlds, with each stratum constituting an (uncertain) belief set (Definition 3). These stratifications can be combined to compute the λ -value of any arbitrary propositional formula. When new input is received, the local epistemic states are revised by ignoring (or forgetting) irrelevant information, as discussed in Section 4.

ification of the local epistemic states, can be used to ensure commensurability. In this section, we extend CAN to CAN+ by adding to it a GUB to represent uncertain beliefs and by extending its syntax so that a CAN+ agent can reason about its uncertain beliefs. After Definition 8, we introduce how a GUB can be revised directly, thus allowing an agent to revise its beliefs irrespective of the various forms of uncertainty that govern those beliefs. In our extension CAN+, a context ψ is taken to be a sentence from the language \mathcal{L}_{\geq} . We assume the language for a plan body to be defined as in CAN, where we will gradually modify the language throughout this section. First though, we redefine the concept of configurations in CAN+. Rather than considering a belief base to model the knowledge, we will thus use a GUB to represent the uncertain beliefs of the agent. We have:

Definition 7. A basic configuration is a tuple $\langle \mathcal{G}, \mathcal{A}, P \rangle$ with \mathcal{G} a GUB, \mathcal{A} the list of executed actions and P a plan body being executed (i.e. the current intention). An agent (configuration) is a tuple $\langle \mathcal{N}, \mathcal{D}, \Pi, \mathcal{G}, \mathcal{A}, \Gamma \rangle$ with \mathcal{N} the name of the agent, \mathcal{D} the action description library (defined in Section 5), Π the plan library, Γ the set of current intentions of the agent and \mathcal{G} and \mathcal{A} as before.

With the configurations redefined we can extend the first set of rules from CAN, i.e. the rule for a test goal ($?\phi$) and the rule for plan selection (*select*):

$$\frac{\mathcal{G} \models \phi}{\langle \mathcal{G}, \mathcal{A}, ?\phi \rangle \longrightarrow \langle \mathcal{G}, \mathcal{A}, nil \rangle} ?\phi$$

$$\frac{\psi_i : P_i \in \Delta \quad \mathcal{G} \models \psi_i \theta}{\langle \mathcal{G}, \mathcal{A}, (|\Delta|) \rangle \longrightarrow \langle \mathcal{G}, \mathcal{A}, P_i \theta \triangleright (|\Delta| \setminus P_i) \rangle} select$$

We retain the notation as used in [Sardiña et al., 2006] to denote unification as e.g. $\phi\theta$, i.e. variables are dealt with in the customary way. The modified rules make clear that verifying whether a belief or context holds is now done against

the GUB. The language has implicitly been extended in both cases, since test goals and contexts can now include statements to reason over uncertain beliefs, i.e. $\phi, \psi_i \in \mathcal{L}_{\geq}$.

So far we have looked at how we can reason about the agent's (uncertain) beliefs, but we also want to revise these beliefs. When new input is presented (e.g. due to an internal belief change or the effects of an action), a naive approach would be to compute the global epistemic state as the Cartesian product of the local epistemic states, apply the input and then marginalise the outcome. However, such an approach is computationally too expensive. Instead, we will apply the input directly to the relevant epistemic states. First though, we define the notion of an *uncertain belief*.

Definition 8. Let ϕ be a sentence in the language $\mathcal{L}^{A_{in}}$ with $A_{in} \subseteq A$. Let $\mu \in (\mathbb{Z} \cup \{-\infty, +\infty\})$. We say that $b = (\phi, \mu)$ is an uncertain belief.

An input b , which is an uncertain belief, corresponds to a sequence of inputs $refine(b, \Phi_i)$ for any given local epistemic state $\Phi_i \in \mathcal{G}$. We have:

$$refine(b, \Phi_i) = \begin{cases} forget(b, \Phi_i) & A_{in} \cap A_i \neq \emptyset \\ \langle \rangle & \text{otherwise} \end{cases}$$

with $forget(b, \Phi_i)$ a sequence of inputs defined as $\langle (m', \mu) \mid b = (\phi, \mu), m \in Mod(\phi), m' = m \cap lit(A_i) \rangle$ and m' in (m', μ) treated as a conjunction of literals. When $A_{in} \subseteq A_i$ we could equivalently take $forget(b, \Phi_i) = \langle b \rangle$.

By $\mathcal{G} \circ b$ we denote that we want to revise the current beliefs of the agent with the input b , such that $\mathcal{G} \circ b = \{\Phi_i \circ refine(b, \Phi_i) \mid \forall \Phi_i \in \mathcal{G}\}$ with \circ a revision operator. That is, revising a global uncertain belief set is taken as revising the local epistemic states with the given input. Each input (m', μ) in the sequence $refine(b, \Phi_i)$ corresponds to a simple epistemic state from [Ma and Liu, 2011], i.e. to an epistemic state Φ_{in} with the domain 2^{A_i} such that $\Phi_{in}(\omega) = \mu$ iff $\omega \models m'$ and $\Phi_{in}(\omega) = 0$ otherwise. An epistemic state Φ can be revised by a simple epistemic state Φ' with the same domain Ω , denoted as $\Phi \circ \Phi'$, as $\forall \omega \in \Omega, (\Phi \circ \Phi')(\omega) = \Phi(\omega) + \Phi'(\omega)$.⁴ As such, when the input has been transformed to $refine(b, \Phi_i)$ for a given local epistemic state Φ_i , the revision is equivalent to iterated revision using the simple epistemic states in $refine(b, \Phi_i)$. The final output of this iterated revision is unique regardless of the order in which we revise Φ_i with simple epistemic states Φ_{in} in $forget(b, \Phi_i)$ based on postulates B5 and B6 in [Ma and Liu, 2011] (i.e. weights are cumulative and the order of updating does not affect the result).

Now we can introduce the $\circ b$ rule to CAN+ for belief change. The intuition of this new rule is clear; we want to change the beliefs encoded in the GUB with the uncertain belief b . We have:

⁴For other epistemic states these values can be extrapolated.

$$\overline{\langle \mathcal{G}, \mathcal{A}, \circ b \rangle} \longrightarrow \overline{\langle \mathcal{G} \circ b, \mathcal{A}, nil \rangle} \circ b$$

The rule for belief change can serve as a template to define the rules for classical belief addition $+\phi$ and deletion $-\phi$. Those rules would become:

$$\overline{\langle \mathcal{G}, \mathcal{A}, +\phi \rangle} \longrightarrow \overline{\langle \mathcal{G} \circ (\phi, \max_{\mathcal{G}}), \mathcal{A}, nil \rangle} +\phi$$

$$\overline{\langle \mathcal{G}, \mathcal{A}, -\phi \rangle} \longrightarrow \overline{\langle \mathcal{G} \circ (\phi, \min_{\mathcal{G}}), \mathcal{A}, nil \rangle} -\phi$$

with $\max_{\mathcal{G}} = \max \{\max_{\Phi_i} \mid \Phi_i \in \mathcal{G}\}$ and $\min_{\mathcal{G}}$ analogously defined. Notice that we transform the formula ϕ into an uncertain belief by assigning to it the weight $\max_{\mathcal{G}}$ ($\min_{\mathcal{G}}$). This ensures that ϕ will be true (false) after revision. We can also define belief addition and deletion as syntactic sugar on top of the belief change semantics. Indeed, a statement such as $+\phi$ is nothing more than a shorthand for the statement $\circ(\phi, \max_{\mathcal{G}})$. Similarly, $-\phi$ can be considered a shorthand for $\circ(\phi, \min_{\mathcal{G}})$. As we try to keep the semantics as concise as possible, we opt to define these operators in the latter way. Such a choice will also need to be made in the next section, where we will directly present the approach based on syntactic sugar.

In conclusion, the new language for a plan body in CAN+ is given in BNF as:

$$P ::= nil \mid \circ b \mid act \mid ?\phi \mid !e \mid P_1; P_2 \mid P_1 \parallel P_2 \mid P_1 \triangleright P_2 \mid (|\Delta|) \mid Goal(\phi_s, P, \phi_f)$$

with b an uncertain belief and $\phi, \phi_s, \phi_f \in \mathcal{L}_{\geq}$. We also modified the rules for $?\phi$ and *select*, while dropping the rules for $+\phi$ and $-\phi$ and introducing a new rule for $\circ b$. The rules in CAN dealing with program flow do not require any changes and can be integrally applied to the CAN+ semantics. The rules on declarative goals do need to be modified, but in a straightforward way similar to $?\phi$, i.e. we need to verify ϕ_s and ϕ_f against \mathcal{G} .

5 DEALING WITH UNCERTAIN ACTIONS IN A BDI AGENT

The primitive actions of a BDI agent are affected by uncertainty in a variety of ways. Usually described in a STRIPS-like style such as $act : \psi \leftarrow \phi^-; \phi^+$, an action *act* can have uncertainty in the precondition ψ , uncertainty as to a specific effect (where the effect will change the epistemic state and possibly the belief set) or uncertainty as to the outcome of an action (with a probability for each outcome).

The first form of uncertainty is the easiest to incorporate. Similar to how the rule *select* for plan selection allows us to consider uncertain information, we can take $\psi \in \mathcal{L}_{\geq}$ and verify whether this context, or precondition, is satisfied.

Next, ϕ^- and ϕ^+ are usually taken to be *delete* and *add* lists of atoms. Nothing in the semantics for CAN+ prevents

us from instead considering a list of uncertain beliefs ϕ^u as the results of an action. Not only does this considerably increase the expressive powers of action effects, but it also allows to define ϕ^- and ϕ^+ as special cases of ϕ^u with each being a list of propositions $\phi \in \mathcal{L}$ to which the weight \min_{Φ} and \max_{Φ} is assigned, respectively. As we did before, we assume hereafter that ϕ^- and ϕ^+ are forms of syntactic sugar for which we will not explicitly define the semantics.

Finally, the effects of an action may not be known in advance. This form of uncertainty has already been extensively considered in the literature, leading to variations of the STRIPS language that consider various outcomes with associated probabilities. Rather than a single outcome $\phi^-; \phi^+$ we consider a set of outcomes $\{\langle p_1, \phi_1^-, \phi_1^+ \rangle, \dots, \langle p_n, \phi_n^-, \phi_n^+ \rangle\}$ with $\sum_{i=1}^n p_i = 1$.

By adopting a STRIPS-like probabilistic action library \mathcal{D} , populated by *probabilistic action description rules* – each representing a single independent action – we can model these three forms of uncertainty with rules of the form:

$$act : \psi_{act} \leftarrow \{\langle p_1, \phi_1^u \rangle, \dots, \langle p_n, \phi_n^u \rangle\}$$

such that $p_i \geq 0$, $\sum_{i=1}^n p_i = 1$ with ψ_{act} an uncertain belief and ϕ_i^u a list of uncertain beliefs.

Example 4. Consider the running example from the introduction and Figure 1. We can model the actions to slow down and to continue at the same speed as

$$\begin{aligned} slow : true &\leftarrow \{\langle 0.4, [(junc, \max_G), (sp, -20)] \rangle, \\ &\quad \langle 0.6, [(late, \max_G), (sp, -20)] \rangle\} \\ cont : sd \geq \neg sd &\leftarrow \{\langle 0.75, [(junc, \max_G)] \rangle, \\ &\quad \langle 0.25, [(late, \max_G)] \rangle\} \end{aligned}$$

The first action can always be applied and has two outcomes. With 40% chance the junction is reached in time and with 60% the train is late. In both cases the (speed) is reduced. The second action encodes an agent in a hurry: the agent will not wait until there is a safe distance, i.e. the agent continues whenever he thinks it is at least more plausible that there is still a safe distance (or when the agent is ignorant and doesn't care).

While we already know how to correctly deal with uncertain beliefs, we do not yet have the machinery in the operational semantics to deal with probabilistic effects. To model a probabilistic action we use the notion of a probabilistic transition $C \xrightarrow{p} C'$ where p represents the transition probability between the configurations C and C' [Di Piero and Wiklicky, 1998]. Notice that all the transition rules used thus far are special cases of probabilistic transition rules where the probability of the transition is 1. As such we assume in CAN+ that all transition rules are probabilistic transition rules, where the probability is 1 unless explicitly specified. The *act* derivation rule can then be defined as:

$$\frac{(a : \psi \leftarrow effects) \in \mathcal{D} \quad a\theta = act \quad \mathcal{G} \models \psi\theta}{\langle \mathcal{G}, \mathcal{A}, act \rangle \xrightarrow{p_i} \langle \mathcal{G} \circ \phi_i^u\theta, \mathcal{A} \cdot act, nil \rangle} act$$

with *effects* the set $\{\langle p_1, \phi_1^u \rangle, \dots, \langle p_n, \phi_n^u \rangle\}$. As expected, the transition will depend on the probabilities of the different effects associated with the action *act*.

Thus far we have only discussed how CAN+, which extends CAN, adds the ability to model and reason about uncertain information. A parallel endeavour is to extend CANPLAN into CANPLAN+. The main difference between CAN and CANPLAN is the ability of the latter to perform lookahead planning by means of the *Plan*(\cdot) action. A similar idea can be incorporated in CAN+ to arrive at CANPLAN+.

We know from the way we extended the *act* rule that, during the BDI execution, it is the probability of the transition that determines the effect of a primitive action. Furthermore, when a BDI agent tries to achieve some intention, this may involve the execution of a large number of plans. However, merely selecting the plan with the highest probability of reaching the next state without taking future actions into account may lead to poor performance. Indeed, this single step may not be on the same path that offers the highest overall chance of achieving our goal. Such issues can be addressed by using lookahead planning. During planning performed through the *Plan*(\cdot) action we can take the probability of the different transitions into account and thus maximise the probability of achieving our intention.

To formalise this idea, we introduce the notion of maximising the overall transition probability. Intuitively, given two configurations C and C'' , there may be more than one option such that $C \xrightarrow{\text{plan}^*} C''$. When a transition is labelled with ‘plan’ or ‘bdi’, the transition is resp. only valid in the planning context or during BDI execution. We want to take the transition $C \xrightarrow{\text{plan}} C'$ such that C' is the next configuration on the path which offers us the highest overall chance of reaching our goal, which we will denote as $C \xrightarrow{\text{max}^*} C''$.

Definition 9. Let C and C'' be configurations such that $C \xrightarrow{\text{plan}^*} C''$. Furthermore, let p be such that $p = \prod_{i=0}^n p_i$ and $C \xrightarrow{\text{plan}}_{p_1} C' \xrightarrow{\text{plan}}_{p_2} \dots \xrightarrow{\text{plan}}_{p_n} C''$. We say that $C \xrightarrow{\text{max}^*} C''$ when there does not exist a configuration D' that is different from C' in either its belief base, executed actions or plan body such that $C \xrightarrow{\text{plan}}_{p'_1} D' \xrightarrow{\text{plan}}_{p'_2} \dots \xrightarrow{\text{plan}}_{p'_m} C''$ and $p' > p$ with $p' = \prod_{i=0}^m p'_i$.

In other words: C' is the next configuration on the most probable path to reach C'' . Using Definition 9 we can extend the operational semantics of the *Plan*(\cdot) construct to take into account that we are dealing with uncertain actions. In CANPLAN the rule for *Plan*(\cdot) is as follows:

$$\frac{C \xrightarrow{\text{plan}} C' \quad C' \xrightarrow{\text{plan}^*} C''}{\langle \mathcal{B}, \mathcal{A}, Plan(P) \rangle \xrightarrow{\text{bdi}} \langle \mathcal{B}', \mathcal{A}', Plan(P') \rangle} plan$$

with the configurations C, C' and C'' defined as $\langle \mathcal{B}, \mathcal{A}, P \rangle$, $\langle \mathcal{B}', \mathcal{A}', P' \rangle$ and $\langle \mathcal{B}'', \mathcal{A}'', nil \rangle$, respectively. Intuitively, this rule states that the next action to execute is the one that, according to our lookahead planning, will *eventually* lead us to achieving our goal.

The rule in CANPLAN+ for $Plan(\cdot)$, which not only ensures that we reach our goal but also maximises the chances of reaching our goal, is then defined as:

$$\frac{C \xrightarrow{plan} C' \quad C \xrightarrow{\max_C^*} C''}{\langle \mathcal{G}, \mathcal{A}, Plan(P) \rangle \xrightarrow{bdi} \langle \mathcal{G}', \mathcal{A}', Plan(P') \rangle} \text{plan}$$

with C, C' and C'' defined as $\langle \mathcal{G}, \mathcal{A}, P \rangle$, $\langle \mathcal{G}', \mathcal{A}', P' \rangle$ and $\langle \mathcal{G}'', \mathcal{A}'', nil \rangle$, respectively.

Example 5. Consider the running example from Figure 1. Assume we are at the decision point just after reaching the signal. An agent that plans ahead for the goal of reaching the station in time, will make the rational choice to slow down. If the agent did not perform lookahead planning and only looked at the highest chance to reach the junction, then continuing at the same speed would be preferred.

6 RELATED WORK

The BDI framework [Rao and Georgeff, 1991] is notable for treating beliefs and intentions as two distinct ideas in an agent-based setting. However, due to the complex temporal modal logic being used and the assumption of unlimited resources there was a disconnect between the theory and implementations based on BDI. This problem was mostly resolved in [Rao, 1996] where an abstract agent-based language, called AgentSpeak, was proposed. This language was strongly related to the original BDI theory, while being easily implementable.

CAN [Winikoff et al., 2002] follows up on this approach of AgentSpeak and provides operational semantics for dealing with declarative goals. Such goals allow more flexibility, e.g. plans can be stopped when the goal is reached instead of being blindly executed until the end. Declarative goals also make it easier to define semantics for planning in a BDI setting. Most approaches on planning [de Silva and Padgham, 2005, Walczak et al., 2006, Meneguzzi et al., 2007] had been ad-hoc approaches without a semantical background for the integration of planning in BDI. Such a semantical background was provided in [Sardiña et al., 2006, Sardiña and Padgham, 2011] with the introduction of CANPLAN, an extension of CAN with a $Plan(\cdot)$ action that allows for offline lookahead planning.

Notable work on the integration of uncertainty in a BDI context has been done in the setting of graded BDI [Casali et al., 2005]. In graded BDI it is assumed that the beliefs, desires and intentions have a degree of uncertainty. While of theoretical interest, their framework uses a

complex modal logic axiomatisation which makes it hard to implement the work directly. Later, in [Criado et al., 2014], the graded BDI system was further extended to incorporate norms, i.e. patterns of behaviour that should be adhered to in given circumstances. These norms are acquired and enforced in an uncertain environment. To accommodate this, norms have an associated salience to reflect their importance in the given uncertain environment.

Implementations that deal with uncertain percepts in a BDI setting [Chen et al., 2013] have not been based on the graded BDI framework but approached the problem more pragmatically. Our work extends upon the ideas of graded beliefs (i.e. what the agent knows), where we allow more fine-grained control by dividing the beliefs into isolated parts, each with their own representation and revision strategies. Contrary to graded BDI, our work has a vested interest in the feasibility of implementations while still providing strong theoretical underpinnings. In that sense, our work is close to the spirit of CANPLAN.

7 CONCLUSIONS

In this paper we showed how operational semantics for a BDI agent can be devised to deal with uncertain beliefs and actions affected by various forms of uncertainty. We introduced CANPLAN+, an extension of CANPLAN, in which we introduce a novel way of representing the agent's beliefs as a set of epistemic states. We furthermore introduced the idea of stratifying the domains of epistemic states. This allows an agent to reason about the plausibility of his beliefs within a local epistemic state and allows commensurability over the evaluation of these local results. As such, an agent can select more appropriate plans and can revise his current beliefs with uncertain information from the environment. In addition, it gives a BDI agent system designer the freedom to choose the best representation for the beliefs at hand. We also established a way to model actions triggered by uncertain beliefs, have uncertain effects and have effects that may introduce extra uncertainty into the beliefs. Finally, we extended the $Plan(\cdot)$ action from CANPLAN to allow a BDI agent to plan for the most optimal plan, i.e. with the highest chance of achieving the goal.

For future work, we plan to develop complete algorithms as well as approximate/tractable algorithms to use in BDI implementations that model and allow to reason about the uncertain beliefs of an agent. Moreover, we want to explore how existing planners under uncertainty can be extended to deal with the various forms of uncertainty faced in a SCADA environment.

Abstract

Dual decomposition provides the opportunity to build complex, yet tractable, structured prediction models using linear constraints to link together submodels that have available MAP inference routines. However, since some constraints might not hold on every single example, such models can often be improved by relaxing the requirement that these constraints always hold, and instead replacing them with soft constraints that merely impose a penalty if violated. A dual objective for the resulting MAP inference problem differs from the hard constraint problem's associated dual decomposition objective only in that the dual variables are subject to box constraints. This paper introduces a novel primal-dual block coordinate descent algorithm for minimizing this general family of box-constrained objectives. Through experiments on two natural language corpus-wide inference tasks, we demonstrate the advantages of our approach over the current alternative, based on copying variables, adding auxiliary submodels and using traditional dual decomposition. Our algorithm performs inference in the same model as was previously published for these tasks, and thus is capable of achieving the same accuracy, but provides a 2-10x speedup over the current state of the art.

1 INTRODUCTION

We often need complex structured prediction models that encode rich global and local dependencies and constraints among the outputs, but this can render efficient prediction difficult. Therefore, *dual decomposition* is quite useful, since it enables efficient inference in models composed of various submodels with available black-box MAP inference routines (Komodakis *et al.*, 2007; Sontag *et al.*, 2011; Rush & Collins, 2012).

In some cases, the flexibility and robustness of such models can be improved by using *soft constraints*, where the model imposes a cost if a constraint is violated, but does not require that it is satisfied. In natural language processing, for example, soft constraints have enabled accuracy gains for named entity recognition (Finkel *et al.*, 2005; Sutton & McCallum, 2006), parsing (Smith & Eisner, 2008; Rush *et al.*, 2012), and citation field segmentation (Chang *et al.*, 2012; Anzaroot *et al.*, 2014). Using soft constraints is reasonable in these applications because the constraints are not required in order to define feasible outputs, but are instead a modeling layer imposed to improve predictive accuracy. Soft constraints are advantageous over hard constraints because they allow the model to trade off evidence for and against a constraint being satisfied.

In all of these examples besides Rush *et al.* (2012) and Anzaroot *et al.* (2014), inference is performed using standard techniques for inference in loopy graphical models such as belief propagation or MCMC. However, these have poor optimality guarantees and can also be difficult to generalize to prediction problems that are not graphical models. An alternative method for handling soft constraints is to make copies of variables participating in soft constraints, constrain each variable to equal its copy, and apply dual decomposition (Rush *et al.*, 2012). While this exhibits better flexibility, scalability, and guarantees, it requires inference in auxiliary submodels and copying variables prevents the feasibility of the output during intermediate iterations before convergence, since the two copies of a variable may have different values.

Recently, Anzaroot *et al.* (2014) employed an attractive alternative algorithm for performing MAP subject to soft constraints that offers the optimality guarantees and generality of dual decomposition, but avoids variable copying and auxiliary models completely. Their algorithm requires an extremely straightforward modification to existing dual decomposition objectives: if the model penalizes the violation of a constraint with a penalty of c , then the dual variable is subject to a *box constraint*, where it can not exceed c . They minimize this objective with projected subgradient

descent.

While this projected subgradient algorithm is simple, its convergence can be slow and sensitive to a choice of step size schedule. On the other hand, block coordinate descent algorithms, such as MPLP (Globerson & Jaakkola, 2007), are parameter-free and often converge much faster than subgradient descent for dual decomposition objectives, subject to our ability to obtain *max-marginals* from the subproblems (Sontag *et al.*, 2011).

In response, we contribute the following:

1. An extension of the projected subgradient algorithm of Anzaroot *et al.* (2014) to general pairwise soft constraints (Section 5) that are capable of modeling arbitrary pairwise graphical model factors (Section 8).
2. An adaptation of the MPLP algorithm beyond graphical models to alternative structured prediction problems with certain structure (Section 6).
3. Box-MPLP, a primal-dual message passing algorithm for solving the box-constrained dual decomposition objective for soft constraints (Section 7). Its update rule and derivation differ substantially from MPLP.
4. Experiments on two corpus-wide prediction tasks from natural language processing (Section 2) demonstrating both the advantages of using Box-MPLP v.s. projected subgradient and of using a box-constrained dual objective v.s. variable copying and hard-constraint dual decomposition (Section 10).

2 CORPUS-WIDE INFERENCE

We first motivate the use of soft constraints by describing the application that we will explore in our experiments. In natural language processing, it is common to part-of-speech (POS) tag and dependency parse every sentence in a corpus of documents. Both tasks can be posed as efficient MAP inference, but a drawback of these algorithms is that they process each sentence in isolation, despite the fact that there is discriminative information shared across the corpus. In response, Rush *et al.* (2012) performed *corpus-wide inference*. Specifically, for word types that did not appear in the training data, they introduced global model terms that encouraged every occurrence of the word in the test corpus to receive the same POS tag, or to be assigned a dependency parent with the same POS tag. A similar model appeared in Chieu & Teow (2012).

Rush *et al.* (2012) model these cross-sentence relationships among sets of occurrences that are encouraged to agree, by introducing one *consensus structure*, described in the Figure 1 caption, per set. There is a soft constraint between every variable at the bottom of the consensus set, and the one at the top. If the underlying sentence-level models are graphical models, the corpus-wide inference problem could be posed as a large loopy graphical model and we can per-

Figure 1: One *consensus set*. The circles at the bottom represent words of the same type, and the boxes represent arbitrary sentence-level prediction problems that they are contained in. The circle at the top is a *consensus variable* introduced to encourage consensus among the bottom circles, where the squares are soft constraints penalizing disagreement. The corpus is linked together by a web of consensus structures.

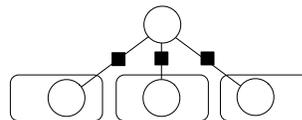

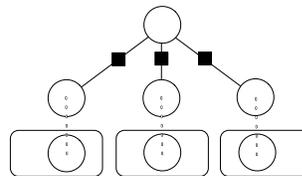

Figure 2: The variable-copying version of Fig. 1, where dashed lines denote equality constraints.

form approximate MAP using standard techniques. An alternative solution, depicted in Figure 2, is to copy variables that participate in consensus sets, introduce an auxiliary tree-structured subproblem, and use dual decomposition for corpus-wide MAP. This has superior optimality guarantees and flexibility to use sentence-level problems that are not graphical models. In practice, this algorithm can be slow to converge, however. In response, we introduce a new approach for performing MAP subject to soft constraints that when applied to corpus-wide inference allows us to work directly in the soft constraint problem of Figure 1, yet yields the same flexibility and optimality guarantees as Rush *et al.* (2012) and substantially faster runtimes. The techniques are general and apply to a wide range of additional applications.

3 NOTATION AND STRUCTURED LINEAR MODELS

Bold-faced lower-case letters, such as \mathbf{x} , represent column vectors, and bold-faced upper case letters, such as \mathbf{A} , represent matrices. The i -th coordinate of vector \mathbf{x} is $\mathbf{x}(i)$ and the i, j th coordinate of a matrix \mathbf{A} is $\mathbf{A}(i, j)$. Lower-case greek letters such as $\boldsymbol{\lambda}$ represent either vector-valued or matrix-valued dual variables. We use $\mathbf{x}^{(t)}$ for \mathbf{x} at iteration t . The term 'constraint' either refers to a constraint between scalars or a set of coordinate-wise constraints between vectors (or matrices). In the latter case, the associated dual variable is a vector (or matrix).

We consider structured prediction problems defined by

structured linear models such as conditional random fields (Lafferty *et al.*, 2001) and maximum spanning tree parsers (McDonald *et al.*, 2005). These assign a score to each possible output labeling by decomposing each candidate output into a collection of *parts*, each of which can be active or inactive in a given labeling. For example, in first-order dependency parsing, each part corresponds to a single dependency arc (Smith, 2011). In a conditional random field, there is a part for each possible setting of each clique.

We write the indicator vector for the parts of a specific labeling of a dataset k as \mathbf{x}_k . It is a binary vector with one coordinate per possible part, which is zero if the part is not present in the structured output and one if it is. The model for candidate outputs is called *linear* because the score of a given labeling is the dot product $\langle \mathbf{w}_k, \mathbf{x}_k \rangle$ of a weight vector \mathbf{w}_k and the indicator vector over the parts. In many models, such as conditional random fields, the score of each part is a function of some observed features, and in many cases this mapping from features to weights is also linear. We focus only on inference, however, and make no assumptions about how the weights are set. In non-trivial structured linear models, not all assignments of values to these parts are valid, since they typically represent some over-complete view of the structured output or are subject to global structural constraints, such as projectivity for dependency parsing (Smith, 2011). For an instance k we refer to the set of valid assignments to parts as \mathcal{U}_k .

We refer to the problem of finding the highest-scoring valid collection of parts as *MAP inference*:

$$\max_{\mathbf{x}_k} \langle \mathbf{w}_k, \mathbf{x}_k \rangle \quad \text{s.t.} \quad \mathbf{x}_k \in \mathcal{U}_k.$$

4 DUAL DECOMPOSITION

Following Sontag *et al.* (2011); Rush & Collins (2012); Komodakis *et al.* (2007), we consider the problem:

$$\max_{\mathbf{x}} \sum_k \langle \mathbf{w}_k, \mathbf{x}_k \rangle \quad (1)$$

$$\text{s.t.} \quad \forall k \quad \mathbf{x}_k \in \mathcal{U}_k \quad (2)$$

$$\sum_k \mathbf{A}_k \mathbf{x}_k = 0, \quad (3)$$

where each \mathbf{x}_k represents the vector of parts for a specific structured linear ‘submodel.’ The formulation can easily be adapted to account for a nonzero right hand side of (3). If (3) did not exist, the problem would reduce to independent MAP inference in each subproblem.

Dualizing the linear constraints in (3), but not the $\mathbf{x}_k \in \mathcal{U}_k$ constraints, results in the Lagrange dual problem:

$$\min_{\lambda} D(\lambda) = \sum_k \max_{\mathbf{x}_k \in \mathcal{U}_k} \langle \mathbf{w}_k + \mathbf{A}_k^T \lambda, \mathbf{x}_k \rangle. \quad (4)$$

Algorithm 1 Dual Decomposition with Subgradient Descent

```

1:  $\lambda \leftarrow \mathbf{0}$ 
2: while has not converged do
3:   for submodel  $i$  do
4:      $\mathbf{x}_k^* \leftarrow \max_{\mathbf{x}_k \in \mathcal{U}_k} \langle \mathbf{w}_k + \mathbf{A}_k^T \lambda, \mathbf{x}_k \rangle$ 
5:    $\lambda \leftarrow \lambda - \eta^{(t)} \sum_k \mathbf{A}_k \mathbf{x}_k^*$ 

```

The dual objective $D(\lambda)$ is convex and piece-wise linear, as it is the sum of the supremum of linear functions of λ , and hence can be solved with known convex optimization techniques, including subgradient methods. Any particular element of the subgradient of the dual function with respect to λ can be written as

$$\partial D(\lambda) = \sum_k \mathbf{A}_k \mathbf{x}_k^*, \quad (5)$$

where each \mathbf{x}_k^* is some maximizer of a MAP inference problem with shifted weights:

$$\mathbf{x}_k^* \in \operatorname{argmax}_{\mathbf{x}_k \in \mathcal{U}_k} \langle \mathbf{w}_k + \mathbf{A}_k^T \lambda, \mathbf{x}_k \rangle. \quad (6)$$

We consider cases, where these MAP subproblems are tractable and solving their linear programming relaxations returns an integral value for any weight vector. Therefore, one can use subgradient descent, Algorithm 1, to minimize the dual problem. Subject to conditions on the sequence of step sizes $\eta^{(t)}$ and the feasibility of the constraints that link the subproblems, the subgradient method is guaranteed to converge to the optimum, where (3) will be satisfied (Nesterov, 2003; Sontag *et al.*, 2011).

5 SOFT DUAL DECOMPOSITION

5.1 PROBLEM STATEMENT

This paper focuses on applications of dual decomposition where the underlying prediction problem has at least two distinct sets of outputs $\mathbf{x}_1 \in \mathcal{U}_1$ and $\mathbf{x}_2 \in \mathcal{U}_2$, and linear constraints are imposed between them not as a requirement to define feasible outputs, but as an extra layer of modeling to encourage global regularity of the outputs. This contrasts with problems with a single output \mathbf{x} subject to the linear constraints $\mathbf{x} \in \mathcal{U}_1 \cap \mathcal{U}_2$, and while these are unmanageable directly, \mathcal{U}_1 and \mathcal{U}_2 can each be handled in isolation. Here, dual decomposition can be employed via a copy variable \mathbf{x}_2 , and constraints $\mathbf{x} \in \mathcal{U}_1$, $\mathbf{x}_2 \in \mathcal{U}_2$, and $\mathbf{x}_1 = \mathbf{x}_2$ (Koo *et al.*, 2010; Rush & Collins, 2012). The first family is precisely where it can make sense to employ soft constraints, since they will not threaten the output’s feasibility.

Anzaroot *et al.* (2014) recently performed MAP with soft constraints by performing projected gradient descent in a box-constrained dual objective. Our message passing algorithm requires using a slightly more restrictive set of global

constraint structures to be converted into soft constraints than what they considered, which are of the form (3). Specifically, we assume the global constraints decompose into sets of pairwise equality constraints between components of submodels:

$$\max_{\mathbf{x}} \quad \sum_k \langle \mathbf{w}_k, \mathbf{x}_k \rangle \quad (7)$$

$$\text{s.t.} \quad \forall k \quad \mathbf{x}_k \in \mathcal{U}_k \quad (8)$$

$$\forall (\mathbf{A}_p, \mathbf{B}_p, p_1, p_2) \in \mathcal{P} \quad \mathbf{A}_p \mathbf{x}_{p_1} = \mathbf{B}_p \mathbf{x}_{p_2}. \quad (9)$$

A given product $\mathbf{A}_p \mathbf{x}_{p_1}$ or $\mathbf{B}_p \mathbf{x}_{p_2}$ is allowed to appear in multiple $p \in \mathcal{P}$, so \mathcal{P} effectively defines a collection of linear measurements of the structured output and a graph of equality constraints among them. These can be defined over differently-size mapping matrices. Define s_p to be the length of the vector $\mathbf{A}_p \mathbf{x}_{p_1}$ (also the length of $\mathbf{B}_p \mathbf{x}_{p_2}$).

Defining a dual variable $\lambda_p \in \mathbb{R}^{s_p}$ for every $p \in \mathcal{P}$, we have the following convex dual decomposition objective:

$$\sum_k \max_{x_k} \left\langle \mathbf{w}_k + \sum_{p:p_1=k} \mathbf{A}_p^T \lambda^p - \sum_{p:p_2=k} \mathbf{B}_p^T \lambda^p, \mathbf{x}_k \right\rangle. \quad (10)$$

A soft constraint formulation of (7) with penalty matrices $\mathbf{c}_p \in \mathbb{R}^{s_p \times s_p}$ subtracts a penalty of $\mathbf{c}_p(i, j)$ from the score of the global MAP problem whenever $\mathbf{A}_p \mathbf{x}_{p_1}$ is set to value i and $\mathbf{B}_p \mathbf{x}_{p_2}$ is *not* set to value j . In the subsequent exposition, we leave the constraints $\mathbf{x}_k \in \mathcal{U}_k$ implicit, since we assume we have available black-box algorithms for maximizing over these constraint sets. Therefore, we have:

$$\max_{\mathbf{x}} \sum_k \langle \mathbf{w}_k, \mathbf{x}_k \rangle - \sum_p \sum_{i,j} \mathbf{c}_p(i, j) [\mathbf{A}_p \mathbf{x}_{p_1}(i) - \mathbf{B}_p \mathbf{x}_{p_2}(j)]_+ \quad (11)$$

where $[\cdot]_+ = \max(0, \cdot)$. Using a matrix-valued penalty is important in order to support a mapping between arbitrary graphical model factors and soft constraints (see Section 8). In Section 7.1, we consider diagonal \mathbf{c}_p , which are sufficient for the model to penalize when certain components of the structured output do not take on the same value.

An alternative to (11) for expressing soft constraints is to create copies of both of the terms appearing in each $p \in \mathcal{P}$ and enforce the constraints that terms equal their copy:

$$\max_{\mathbf{x}} \quad \sum_k \langle \mathbf{w}_k, \mathbf{x}_k \rangle - \sum_p \sum_{i,j} \mathbf{c}_p(i, j) [\mathbf{v}_p(i) - \mathbf{u}_p(j)]_+ \\ \text{s.t.} \quad \forall p \in \mathcal{P} \quad \mathbf{A}_p \mathbf{x}_{p_1} = \mathbf{v}_p, \mathbf{B}_p \mathbf{x}_{p_2} = \mathbf{u}_p. \quad (12)$$

Here, the second term is not a structured linear model, but it is concave, can be handled efficiently in isolation, and

has integral optima. Therefore, we can apply standard dual decomposition techniques. In Figure 2, we demonstrate how Rush *et al.* (2012) similarly use variable copying to make MAP tractable with dual decomposition. Rather than employing pairwise hinge losses as auxiliary submodels, they introduce a single tree-structured graphical model with pairwise factors that encourage agreement. In Section (10) we use this as a baseline to demonstrate the deficiencies of using variable copying to implement soft constraints.

5.2 DUAL OBJECTIVE AND BOX CONSTRAINTS

Problem (11) can be rewritten as a linear program by introducing matrices of auxiliary variables $\mathbf{z}_p \in \mathbb{R}^{s_p \times s_p}$:

$$\max_{\mathbf{x}, \mathbf{z}} \quad \sum_k \langle \mathbf{w}_k, \mathbf{x}_k \rangle - \sum_p \sum_{i,j} \mathbf{c}_p(i, j) \mathbf{z}_p(i, j) \quad (13)$$

$$\text{s.t.} \quad \forall (i, j), \quad \mathbf{z}_p(i, j) \geq \mathbf{A}_p \mathbf{x}_{p_1}(i) - \mathbf{B}_p \mathbf{x}_{p_2}(j) \quad (14) \\ \mathbf{z}_p \geq 0$$

This problem is well-defined only if \mathbf{c}_p is non-negative in every coordinate. In this case, we have that problems (11) and (13) have the same optimal value and maximizing \mathbf{x} .

We defer a full derivation of the associated Lagrange dual problem for (13) to Appendix 1, since it parallels Anzaro *et al.* (2014). The dual is similar to (10), but imposes coordinate-wise box constraints:

$$\min_{\nu} \quad \sum_k \max_{x_k} \left\langle \mathbf{w}_k + \sum_{p:p_2=k} \mathbf{B}_p^T \nu_p^T \mathbf{1} - \sum_{p:p_1=k} \mathbf{A}_p^T \nu_p \mathbf{1}, \mathbf{x}_k \right\rangle \\ \text{s.t.} \quad 0 \leq \nu_p \leq \mathbf{c}_p. \quad (15)$$

Unlike for hard constraints, we have a matrix-valued dual variable $\nu_p \in \mathbb{R}_+^{s_p \times s_p}$ for every $p \in \mathcal{P}$, where $\nu_p(i, j)$ corresponds to the constraint in (14) for a particular (i, j) , and \mathbb{R}_+ denotes the non-negative real numbers. We use $\mathbf{1}$ to be a column vector of all ones, where its length is determined by the context.

These box constraints exist for the same reason that they occur in the dual problem for soft-margin SVMs (Cortes & Vapnik, 1995), since the second term in (11) is a sum of negative hinge losses. The box constraints on the dual variables ν can be interpreted as the Lagrangian penalizing the violation of constraints, but only so much as the primal problem would penalize their violation.

The only qualitative difference between the dual problems in (15) and (4) is the box constraints. Therefore, we can employ the projected subgradient method, shown in Algorithm 2, which will converge to the global MAP optimum if \mathcal{P} is feasible. At the end of Appendix 1, we derive the following complementary slackness criteria used for detecting convergence. These will hold for every $p \in \mathcal{P}$ and every coordinate pair (i, j) when maximizing over the primal variables:

Algorithm 2 Projected subgradient soft dual decomposition for general matrix-valued soft constraint penalties.

```

1:  $\nu \leftarrow \mathbf{0}$ 
2: while has not converged do
3:   for submodel  $k$  do
4:      $\tilde{\mathbf{w}}_k \leftarrow \mathbf{w}_k + \sum_{p:p_2=k} \mathbf{B}_p^T \nu_p^T \mathbf{1} - \sum_{p:p_1=k} \mathbf{A}_p^T \nu_p \mathbf{1}$ 
5:      $\mathbf{x}_k^* \leftarrow \max_{\mathbf{x}_k \in \mathcal{U}_k} \langle \tilde{\mathbf{w}}_k, \mathbf{x}_k \rangle$ 
6:     for soft constraint  $p \in \mathcal{P}$  do
7:        $\nu^p(i, j) \leftarrow \min(\mathbf{c}_p(i, j), \max(0, \nu_p(i, j) - \eta^{(t)}(\mathbf{A}_p \mathbf{x}_{p_1}^*(i) - \mathbf{B}_p \mathbf{x}_{p_2}^*(j))))$ 

```

$$\begin{aligned}
&\text{either } \mathbf{A}_p \mathbf{x}_{p_1}^*(i) = \mathbf{B}_p \mathbf{x}_{p_2}^*(j) \\
&\text{or } \mathbf{A}_p \mathbf{x}_{p_1}^*(i) = 1 \text{ and } \nu_p(i, j) = 0 \\
&\text{or } \mathbf{A}_p \mathbf{x}_{p_1}^*(i) = 0 \text{ and } \nu_p(i, j) = \mathbf{c}_p(i, j).
\end{aligned} \tag{16}$$

6 MAX-MARGINALS AND MPLP

Using the subgradient method in Algorithm 2 is undesirable due to its sensitivity to step-size schedule and slow convergence in practice. In response, we now revisit hard-constraint dual objectives of the form (10) in order to explore previous use of block coordinate descent, which is parameter-free. We introduce an adaptation of the MPLP algorithm (Globerson & Jaakkola, 2007) to problems with general structured linear models as subproblems, and emphasize a primal-dual interpretation of the algorithm’s updates, which we will draw on when we derive our new algorithm in the following section.

MPLP is a convergent alternative to max-product belief propagation that was shown in Sontag *et al.* (2011) to be performing block coordinate descent in a dual decomposition objective for a certain instance of (10). Specifically, there is a submodel for every node and every factor in a factor graph, and an element $p \in \mathcal{P}$ between every node and every factor that it touches. MPLP generalizes to additional cases (10) when the elements of \mathcal{P} satisfy the following condition, and when the subproblems admit efficient computation of max-marginals, defined below.

Definition Let e_j denote the vector that is all zeros, except for a one in the j th coordinate. We say that the product $\mathbf{A}\mathbf{x}_k$ is a *projection variable* if it satisfies the following property:

$$\forall \mathbf{x}_k \in \mathcal{U}_k, \exists j \text{ s.t. } \mathbf{A}\mathbf{x}_k = e_j. \tag{17}$$

Unlike the previous subgradient algorithms, MPLP requires every element of \mathcal{P} to be defined between projection variables, which can be used to represent any set of mutually-exclusive states of the structured output. This is

not a strong restriction, as they can be used, for example, to zoom in on a specific graphical model node or dependency parse arc and to optionally further coarsen the values of these individual outputs. Also, the hinge loss of the previous section and 0-1 loss are equivalent for projection variables, so we are truly penalizing the event that a constraint is violated, and not imposing a linear penalty on the degree to which it is violated. Defining projection variables is necessary because MPLP requires max-marginals, and the following definition is only well-posed for projection variables:

Definition For a given projection variable $\mathbf{A}\mathbf{x}_k$ and weight vector \mathbf{w} , the max-marginals $\mathbf{m}_\mathbf{w}^A$ are a vector where the j th component is given by best possible score achievable by a valid structured output when the projection variable takes on value j , i.e.,

$$\mathbf{m}_\mathbf{w}^A(j) = \max_{\mathbf{x}_k \in \mathcal{U}_k} \langle \mathbf{w}, \mathbf{x}_k \rangle \text{ s.t. } \mathbf{A}\mathbf{x}_k = e_j. \tag{18}$$

For a MAP assignment \mathbf{x}^* with respect to \mathbf{w} , we have

$$\mathbf{A}\mathbf{x}^* = e_{i^*}, \text{ where } i^* = \operatorname{argmax}_i \mathbf{m}_\mathbf{w}^A(i). \tag{19}$$

In other words, locally maximizing max-marginals is equivalent to finding a globally-optimal value (unless there are ties in the max-marginals).

Furthermore, max-marginals change linearly with respect to changes to \mathbf{w} in the direction of their projection variable:

$$\mathbf{m}_{\mathbf{w} + \mathbf{A}^T \alpha}^A(i) = \mathbf{m}_\mathbf{w}^A(i) + \alpha(i). \tag{20}$$

For example, if we shift the scores for a given factor in a graphical model by a vector α , and otherwise leave the model’s potentials unchanged, then the max-marginals for this factor increase by exactly α . This fact, proven in Appendix 2, applies to arbitrary projection variables, and is crucial in deriving both MPLP and our new algorithm in the next section.

In Algorithm 3, we consider a version of MPLP where block coordinate descent is performed by iteratively selecting an element $p \in \mathcal{P}$ and updating the vector-valued dual variable λ_p . Note this differs from the algorithms in Globerson & Jaakkola (2007) and Sontag *et al.* (2011) slightly because we pass messages (i.e., dual variables) directly between submodels, rather than from submodels to primal variables and from primal variables to submodels. This results from the fact that we pose (10) via equality constraints between different parts of the structured output, not between variables and their copies (Werner, 2008).

We discuss the optimality of this choice of λ_p in more detail in Appendix 3, which presents a different primal-dual argument than Sontag *et al.* (2011), in order to motivate the techniques used by the new algorithm that we will introduce later. The high level idea is to invoke (20) to observe that the chosen value for λ_p shifts the subproblems’

Algorithm 3 An adaptation of the MPLP algorithm of Sontag *et al.* (2011) to dual decomposition with pairwise constraints between general structured linear submodels.

```

1:  $\lambda \leftarrow \mathbf{0}$ 
2: converged  $\leftarrow false$ 
3: while ( $\neg$ converged) and (iteration < maxIterations) do
4:   converged  $\leftarrow true$ 
5:   for equality constraint  $p \in \mathcal{P}$  do
6:      $\tilde{w}_{p_1} \leftarrow \mathbf{w}_{p_1} + \sum_{\substack{p':p'_1=p_1 \\ p' \neq p}} \mathbf{A}_{p'}^T \lambda_{p'} - \sum_{\substack{p':p'_2=p_1 \\ p' \neq p}} \mathbf{B}_{p'}^T \lambda_{p'}$ 
7:      $\mathbf{m}_1 \leftarrow \text{MaxMargs}(\tilde{w}_{p_1})$ 
8:      $\tilde{w}_{p_2} \leftarrow \mathbf{w}_{p_2} + \sum_{\substack{p':p'_1=p_2 \\ p' \neq p}} \mathbf{A}_{p'}^T \lambda_{p'} - \sum_{\substack{p':p'_2=p_2 \\ p' \neq p}} \mathbf{B}_{p'}^T \lambda_{p'}$ 
9:      $\mathbf{m}_2 \leftarrow \text{MaxMargs}(\tilde{w}_{p_2})$ 
10:    if ( $\text{argmax}_i \mathbf{m}_1(i) \cap \text{argmax}_i \mathbf{m}_2(i) = \emptyset$ ) then
11:      converged  $\leftarrow false$ 
12:     $\lambda_p \leftarrow \frac{1}{2} (\mathbf{m}_1 - \mathbf{m}_2)$ 

```

weights such that max-marginals for the two projection variables in p become identical in all coordinates. Therefore, with this setting of the dual variables, it is feasible to achieve the equality $\mathbf{A}_p \mathbf{x}_{p_1} = \mathbf{B}_p \mathbf{x}_{p_2}$ when maximizing over the primal variables. As a result, by strong duality, the dual of (7) is minimized with respect to λ_p , since the primal constraints for this block are satisfied. Algorithm 3 monitors convergence by checking if all constraints are satisfied when maximizing over the primal variables. See Sontag *et al.* (2011) for a discussion of the convergence guarantees of MPLP and Meshi *et al.* (2012) for its convergence rate.

The algorithm may require multiple passes to converge, since updates for one λ_p may break the above optimality condition for other $p \in \mathcal{P}$. Furthermore, every time the dual variables are updated for some $p \in \mathcal{P}$, max-marginals need to be recalculated for subproblems p_1 and p_2 . MPLP, and the algorithm in the next section, can not be applied for constraints between projection variables in the same submodel, since their max-marginals interact with each other. Therefore, it could not have been applied in the hard constraint experiments of Anzaroot *et al.* (2014), since they impose constraints within a chain-structured graphical model.

7 MESSAGE PASSING FOR SOFT CONSTRAINT DUAL DECOMPOSITION

We now introduce the primary contribution of the paper: a general dual block coordinate descent framework for minimizing the box-constrained dual objective (15) and Box-MPLP, a novel algorithm for solving a common special case of the problem. Naively applying the MPLP updates may violate the box constraints, and we can not simply follow them with a projection step, as this will not guarantee a decrease in the dual objective.

Analogous to Algorithm (3), our block coordinate descent steps update one vector ν_p at a time. Since we now focus on a specific $p \in \mathcal{P}$, we define $\mathbf{y}_1 := \mathbf{A}_p \mathbf{x}_{p_1}$, $\mathbf{y}_2 := \mathbf{B}_p \mathbf{x}_{p_2}$. While MPLP is a purely dual algorithm, i.e., the update to λ_p in Algorithm 3 line 12 does not require reasoning about optimal settings of the corresponding primal variables, Box-MPLP requires explicitly constructing a primal-dual pair.

The algorithm has two overall steps (a) fixing all dual variables besides ν_p , define a small block-specific optimization problem, and efficiently determine what the optimal values \mathbf{y}_1^* and \mathbf{y}_2^* should be for it, and (b) construct a value for ν_p^* for which maximizing over the primal variables yields the values determined in step (a) and satisfies the complementary slackness conditions (16) (a). Therefore, by construction of a primal-dual certificate, ν_p^* minimizes the block coordinate descent objective.

In step (a), we seek primal optimizers \mathbf{y}_1^* and \mathbf{y}_2^* . With all dual variables besides ν_p fixed, MAP inference in the subproblems p_1 and p_2 is with respect to shifted weight vectors \tilde{w}_{p_1} and \tilde{w}_{p_2} as defined in Algorithm 3 lines 6 and 8 (which doesn't include ν_p in the shift). Using (19) we can reduce the choice of \mathbf{y}_1^* and \mathbf{y}_2^* to a local optimization problem by obtaining max-marginals \mathbf{m}_1 and \mathbf{m}_2 for the subproblems, as in Algorithm 3 lines 7 and 9. With these, we have $(\mathbf{y}_1^*, \mathbf{y}_2^*) = (e_{i^*}, e_{j^*})$, where

$$(i^*, j^*) = \arg \max_{(i,j)} \mathbf{m}_1(i) + \mathbf{m}_2(j) - \sum_{j' \neq j} \mathbf{c}_p(i, j'). \quad (21)$$

Step (b) constructs a ν_p^* that satisfies (16) and for which optimizing over the primal variables yields $(\mathbf{y}_1, \mathbf{y}_2) = (i^*, j^*)$. Invoking the ‘linearity’ of max-marginals (20), this can be expressed as the following conditions on ν_p :

$$\forall i, \mathbf{m}_1(i^*) - \sum_j \nu_p(i^*, j) \geq \mathbf{m}_1(i) - \sum_j \nu_p(i, j) \quad (22)$$

$$\forall j, \mathbf{m}_2(j^*) + \sum_i \nu_p(i, j^*) \geq \mathbf{m}_2(j) + \sum_i \nu_p(i, j). \quad (23)$$

Satisfying (16) along with (22) and (23) ensures that the independent maximizations of the reweighted problems will have the same score and same maximizing values as the joint maximization in equation (21), and thus we have a primal-dual pair for the coordinate descent subproblem.

Solving the maximization in (21) can be done, in the worst case, by enumerating all s_p^2 possible i and j . Selecting ν_p that satisfies conditions (16), (22), and (23) requires solving a linear feasibility problem, however. While this can be done in time polynomial in s_p , we focus in the next section on an important special case where it is particularly tractable, and leave exploration of general algorithms for this feasibility problem to future work.

7.1 AGREEMENT FACTORS

Next, we focus on a particular structure of \mathbf{c}_p that is both reasonable for applications and for which finding ν_p satisfying (16), (22), and (23) can be done in time $O(s_p)$. This results in the block coordinate descent Algorithm 4.

Definition Let \mathbf{y}_1 and \mathbf{y}_2 be two projection variables with values i and j , and define vector $\alpha \in \mathbb{R}_+^{s_p}$. An *agreement factor* between \mathbf{y}_1 and \mathbf{y}_2 is a structured linear model that assigns a score of 0 if they agree and a score of $-\alpha(i)$ if they disagree. This is equivalent to a penalty matrix:

$$\mathbf{c}_p(i, j) = \begin{cases} \alpha(i) & \text{if } i = j \\ 0 & \text{otherwise.} \end{cases} \quad (24)$$

For many applications, it is sufficient to use agreement factors rather than full matrix penalties $\mathbf{c}_p(i, j)$, since they allow the model to impose a penalty if two components of the structured output are not equal. This, for example, supports the soft constraints of Rush *et al.* (2012) that we employ in our experiments. However, we show in Section 8 that matrix penalties are important to support a mapping between general graphical model factors and soft constraints.

Given the structure (24) on the penalties, there are effectively only s_p dual variables in the matrix ν_p , as the off-diagonal elements are constrained to be equal to 0 by the box constraints (15). We refer to the dual variable and costs as $\nu_p(i)$ and $\mathbf{c}_p(i)$, and equations (22) and (23) reduce to

$$\mathbf{m}_1(i^*) - \nu_p(i^*) \geq \mathbf{m}_1(i) - \nu_p(i) \quad \forall i, j \quad (25)$$

$$\mathbf{m}_2(j^*) + \nu_p(j^*) \geq \mathbf{m}_2(j) + \nu_p(j) \quad \forall i, j \quad (26)$$

In Appendix 4 we derive an $O(s_p)$ method for choosing ν_p that satisfies (16), (22), and (23). The overall insight is that (25) and (26) can be manipulated to yield simple upper and lower bounds on feasible values of $\nu_p(i)$ for $i \neq i^*, j^*$, for which we choose the midpoint of the feasible interval (Algorithm 4, line 22). Also, if $i^* \neq j^*$, then $\nu_p(i^*)$ and $\nu_p(j^*)$ are determined by complementary slackness (line 18) and otherwise, we can set them by similarly taking the mid-point of a feasible interval obtained from (25) and (26) (line 15). If we make the further restriction that the agreement factor uniformly penalizes disagreement between values of \mathbf{y}_1 and \mathbf{y}_2 , i.e. \mathbf{c}_p is α in all coordinates, then we have the added benefit that Algorithm 4 line 11 can be solved in $O(s_p)$ time. See the end of Appendix 4.

8 SOFT CONSTRAINTS V.S. FACTORS

As identified in the introduction, a traditional way to model soft constraints is to add global factors to a graphical model. In this case, the factors contribute scores when variables are set to certain values, which differs from our

Algorithm 4 Box-MPLP: block coordinate descent for soft dual decomposition with agreement factors.

```

1: converged  $\leftarrow$  false
2: while !converged do
3:   converged  $\leftarrow$  true
4:   for constraint  $p \in \mathcal{P}$  do
5:      $\tilde{w}_{p_1} \leftarrow \mathbf{w}_{p_1} + \sum_{\substack{p': p_2=p_1 \\ p' \neq p}} \mathbf{B}_{p'}^T \nu_{p'} - \sum_{\substack{p': p_1=p_1 \\ p' \neq p}} \mathbf{A}_{p'}^T \nu_{p'}$ 
6:      $\mathbf{m}_1 \leftarrow \text{MaxMargs}(\tilde{w}_{p_1})$ 
7:      $\tilde{w}_{p_2} \leftarrow \mathbf{w}_{p_2} + \sum_{\substack{p': p_2=p_2 \\ p' \neq p}} \mathbf{B}_{p'}^T \nu_{p'} - \sum_{\substack{p': p_1=p_2 \\ p' \neq p}} \mathbf{A}_{p'}^T \nu_{p'}$ 
8:      $\mathbf{m}_2 \leftarrow \text{MaxMargs}(\tilde{w}_{p_2})$ 
9:     if (16) not satisfied then
10:      converged  $\leftarrow$  false
11:       $i^*, j^* \leftarrow \underset{i, j}{\text{argmax}} \mathbf{m}_1(i) + \mathbf{m}_2(j) - \mathbf{c}_p(i)\delta(i \neq j)$ 
12:      if  $i^* = j^*$  then
13:         $U \leftarrow \min_{i \neq i^*} \mathbf{m}_1(i^*) - \mathbf{m}_1(i)$ 
14:         $L \leftarrow \max_{j \neq j^*} \mathbf{m}_2(j) - \mathbf{m}_2(j^*) + \mathbf{c}_p(j)$ 
15:         $\nu_p(i^*) \leftarrow \frac{1}{2}(U + L)$ 
16:      else
17:         $\nu_p(i^*) \leftarrow 0$ 
18:         $\nu_p(j^*) \leftarrow \mathbf{c}_p(j^*)$ 
19:      for all  $i$  such that  $i \neq i^*, i \neq j^*$  do
20:         $L \leftarrow -\mathbf{m}_1(i) + \mathbf{m}_1(i^*) + \nu_p(i^*)$ 
21:         $U \leftarrow \mathbf{m}_2(j^*) - \mathbf{m}_2(j) + \nu_p(j^*)$ 
22:         $\nu_p(i) \leftarrow \frac{1}{2}(U + L)$ 

```

use of penalties that contribute negative score when variables are *not* set to certain values. We prove in Appendix 5 that the expressivity of factors and our soft constraints are equivalent, though, as long as the soft constraints are defined between projection variables. Specifically, any table of factor scores can be mapped into a penalty matrix \mathbf{c}_p by solving an associated linear system. This may require using Algorithm 2 for inference, though, since Box-MPLP only applies to diagonal \mathbf{c}_p .

Though the two formulations are similar, soft constraints have attractive properties compared to factors. For example our algorithms maintain primal feasibility during intermediate iterations and avoid variable copying, which fractures the evidence for variables' MAP values across sub-models and requires an entire dual decomposition iteration for information to travel between output variables and their copies. Our experiments support the desirability of avoiding variable copying. In future work, we will explore solving problems that are natively expressed using factors by first mapping them to problems with soft constraints.

9 RELATED WORK

There is a precedent for constructing message passing schemes for inference problems by minimizing an associated dual problem that decomposes into local interactions (Wainwright *et al.*, 2005; Komodakis *et al.*, 2007;

Globerson & Jaakkola, 2007; Ravikumar *et al.*, 2010; Martins *et al.*, 2012; Schwing *et al.*, 2012). Many of these are based on block coordinate descent. The generalizations we make in Section 6, such as working in terms of projection variables to make MPLP apply to more general structured prediction problems than graphical models, could also be applied to a variety of these other algorithms, where the requirement that the subproblems yield max-marginals would be replaced with other requirements, such as the ability to perform MAP in the presence of additional strongly-convex terms. Our algorithm, particularly in the context of the application we consider in the next section, can also be seen as an example of special-case handling of factors that have a specific combinatorial structure (Duchi *et al.*, 2007; Martins *et al.*, 2012; Mezzumano *et al.*, 2013).

Our message passing algorithm has the same optimality guarantees as those for MPLP discussed in Sontag *et al.* (2011). Unlike (projected) subgradient descent, block coordinate descent may return sub-optimal outputs because our objective is non-smooth and not strongly convex (Luo & Tseng, 1992). Analysis of the convergence rate for smoothed versions of MPLP (Meshi *et al.*, 2012) is doable, however, and we encourage exploration of (smoothed) parallel versions of Box-MPLP (Richtárik & Takáč, 2012).

10 EXPERIMENTS

We evaluate soft constraint algorithms that vary along two dimensions: whether they solve box-constrained dual decomposition objectives or unconstrained ones based on variable copying and whether they employ (projected) subgradient descent or block coordinate descent. The first dimension is captured by the distinction between Figure 1, where the consensus variable at the top is an isolated structured linear model and there are soft constraints between this and the variables in the sentences, and Figure 2, which requires variable copying and an auxiliary tree-structured submodel. While Rush *et al.* (2012) did not employ MPLP, max-marginals can be obtained for the CRF tagger and projective parser they used (Smith, 2011). Also, note that the soft constraint penalties of Rush *et al.* (2012) used in both figures take the form of agreement factors. Therefore, we can apply Box-MPLP. We compare:

- Subgradient: Algorithm 1 applied to Figure 2
- Box-Subgradient: Algorithm 2 applied to Figure 1
- MPLP: Algorithm 3 applied to Figure 2
- Box-MPLP: Algorithm 4 applied to Figure 1

The specific problem considered by Anzaroot *et al.* (2014) problem does not admit a baseline algorithm that uses variable copying and hard-constraint dual decomposition. Therefore, besides providing experimental evidence for the effectiveness of Box-MPLP, we also seek to demonstrate the overall effectiveness of using a box-constrained objective for soft dual decomposition as an alternative to variable copying, regardless of what inference algorithm is used for

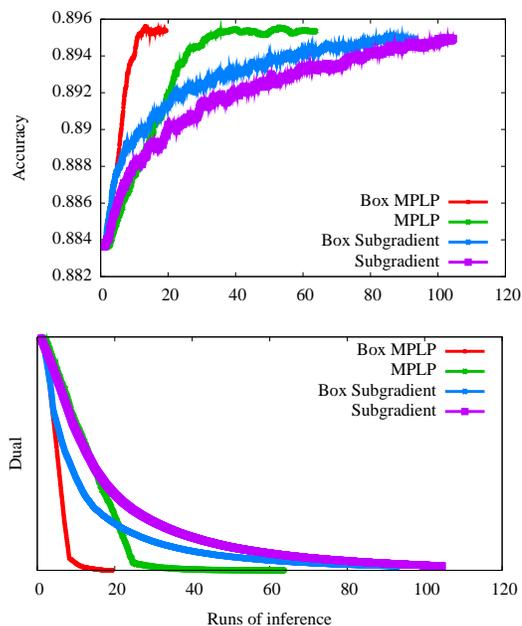

minimizing the box-constrained objective. Finally, note that all algorithms provide an $O(\frac{1}{\sqrt{t}})$ convergence rate, so they can only be compared empirically.

We mirror the experimental setup of Rush *et al.* (2012) for both tagging and parsing. To measure the speed of the algorithms, we record the total number of calls to inference in sentence-level problems, which we normalize by the number of sentences in the corpus to facilitate comparison across experiments. After the first pass, we only perform inference when relevant dual variables change.

Measuring inference calls rather than wall-clock time yields a more reliable experimental setting for the following two reasons: (1) it is independent of the implementation used, and (2) it allows us to be generous to the baseline algorithms we seek to outperform. First, we ignore the cost of running MAP inference in the tree-structured auxiliary problem in Figure 2. Second, we assign a pessimistic multiplier of two for all inference calls that require max-marginals. For NLP models with millions of features, this is an exaggeration because computing the model’s score vector w is typically the most costly step.

10.1 POS TAGGING

Figure 3: Accuracy (top) and dual objective (bottom) v.s. runs of sentence-level inference for WSJ-200 POS tagging.

Following Rush *et al.* (2012), we learn models on subsets of 50, 100, 200, and 500 sentences from the first chapter of the Penn Treebank and test on the Penn Treebank chapters test set (Marcus *et al.*, 1993). We use a bigram CRF tagger (Lafferty *et al.*, 2001). For all experiments, we report average sentence-level accuracy and the gains we obtain from corpus-wide inference in Appendix 6. Both are consistently comparable to Table 4 of Rush *et al.* (2012).

Table 1: Normalized number of inference runs for each algorithm to attain quantiles of the best dual solution in the WSJ-200 tagging experiment. If a quantile was not reached during 100 iterations, we show ‘na’.

Accuracy quantile	80%	85%	90%	95%
Subgradient	70	92	na	na
MPLP	22	23	25	30
Box-Subgradient	20	35	40	54
Box-MPLP	8	9	10	10
Dual Quantile	80%	85%	90%	95%
Subgradient	24	34	56	na
MPLP	21	22	23	35
Box-Subgradient	30	35	40	54
Box-MPLP	7	7	8	9

We present results from where we train on 200 sentences, but they are representative of the others, given in Appendix 6.1. Figure 3 shows the corpus-wide tagging accuracy and dual objective as a function of the sentence-level MAP calls. Recall that we double-count all calls to max-marginal routines. Table 1 shows how much inference is necessary to reach various percentile gains in accuracy and percentile reductions in the dual objective. Box-MPLP substantially outperforms both Box-Subgradient and MPLP, and the box-constrained versions of both algorithms outperform their variable-copying-based counterparts. Compared to the baseline subgradient algorithm used by Rush *et al.* (2012), we require 10x fewer MAP calls.

10.2 DEPENDENCY PARSING

Table 2: Iteration costs for the parsing experiments.

PTB to QTB				
Accuracy quantile	80%	85%	90%	95%
Subgradient	4.1	4.3	5.2	6.1
MPLP	4.3	4.3	4.3	‘na’
Box-Subgradient	2.1	2.1	2.4	2.8
Box-MPLP	2.6	2.8	3	‘na’
Dual quantile	80%	85%	90%	95%
Subgradient	3.0	3.2	3.4	3.9
MPLP	4.2	4.4	4.9	4.9
Box-Subgradient	1.6	1.7	1.8	2.0
Box-MPLP	2.5	2.5	2.5	2.6
QTB to PTB				
Dual quantile	80%	85%	90%	95 %
Subgradient	15	16	18	22
MPLP	14	15	16	17
Box-Subgradient	8.1	9.2	10	12
Box-MPLP	6.9	7.4	7.9	8.6

Our corpus-wide parsing experiments present a characteristically different regime for comparing the four algorithms because the graph of connections between the subproblems is much more sparse and the overall number of necessary iterations for the algorithms to converge is much lower.

Following Rush *et al.* (2012), each set of POS tags around a token defines a context, and identical contexts are encour-

aged to have parents with similar POS tags by introducing various consensus structures. We mirror their domain adaptation experiments, training on the Penn Treebank (PTB) and testing on the Question Treebank (QTB), and vice-versa (Judge *et al.*, 2006). We parse with a first-order projective arc-factored parser (McDonald *et al.*, 2005) using dynamic programming for inference, which has lower accuracy than the second-order projective parser used in Rush *et al.* (2012). Table 2 summarizes our results.

In the PTB-to-QTB experiment, the box-constrained algorithms uniformly outperform their counterparts based on variable copying. Unlike our POS experiments, however, Box-MPLP does not outperform Box-Subgradient. Since all the algorithms converge so quickly, the extra computation to obtain max-marginals is too costly (in the factor-2 scheme). Box-MPLP is still about 2x faster than Subgradient, which is what Rush *et al.* (2012) used, though. For the QTB-to-PTB experiment we were unable to reproduce accuracy increases as reported in Rush *et al.* (2012); none of the optimization algorithms managed to improve the accuracy for any setting of the penalties. This is probably due to our simpler parser. However, regarding dual optimization, each coordinate descent method outperforms its corresponding subgradient method, and the boxed algorithms outperform their variable-copying alternatives. Again, Box-MPLP was about 2x faster than Subgradient. See Appendix 6.2 for accuracy and dual figures.

11 CONCLUSION AND FUTURE WORK

Soft constraints can be easily modeled by imposing box constraints on an associated dual decomposition objective. This yields fast, simple-to-implement algorithms. Box-MPLP, a block coordinate descent algorithm, provides a competitive alternative to projected subgradient descent.

Future work will explore ways to adapt the alternative message passing algorithms discussed in Section 9 to handle box constraints and consider additional combinatorial factors besides soft constraints that can be ‘optimized out’ by imposing constraints in an associated dual problem.

Abstract

Even swaps is a method for solving deterministic multi-attribute decision problems where the decision maker iteratively simplifies the problem until the optimal alternative is revealed (Hammond et al. 1998, 1999). We present a new practical decision support system that takes a Bayesian approach to guiding the even swaps process, where the system makes queries based on its beliefs about the decision maker’s preferences and updates them as the interactive process unfolds. Through experiments, we show that it is possible to learn enough about the decision maker’s preferences to measurably reduce the cognitive burden, i.e. the number and complexity of queries posed by the system.

1 INTRODUCTION

In deterministic multi-attribute problems, the decision maker (or DM, for short) chooses among N alternatives, each of which has M attributes. An alternative \mathbf{x} is a vector of consequences for each attribute:

$$\mathbf{x} = \{x_i : i = 1, \dots, M\}, \quad (1)$$

where x_i is the consequence for attribute i . This is often represented as a *consequence table* such as the one illustrated in Fig 1(a), which displays alternatives and attributes for a hiring problem along its columns and rows respectively.

The DM’s preferences for the various attributes can be modeled using a *value function* $v(\mathbf{x})$. Additive value functions are a popular choice, mainly due to the ease with which they can be elicited:

$$v(\mathbf{x}) = \sum_{i=1}^M w_i v_i(x_i), \quad (2)$$

where attribute weights $\mathbf{w} = \{w_i : i = 1, \dots, M\}$ are non-negative and sum to 1 and the $v_i(x_i)$ represent one-dimensional marginal value functions. Note that we make a distinction between value and utility functions, following Keeney and Raiffa (1976), who reserve the term ‘utility function’ to characterize preferences under uncertainty.

There are several well-known approaches to eliciting additive value functions. The most popular ones tackle direct elicitation, where the DM reveals their trade-offs by answering questions pertaining to the weights and marginal value functions. von Winterfeldt and Edwards (1986) and Belton and Stewart (2002) review some well known weighting techniques. An alternate approach is that of *even swaps*, which is an indirect preference elicitation method that simultaneously solves a specific decision problem (Hammond et al. 1998, 1999). Here the DM answers a few simple and pointed queries to iteratively reduce the number of columns and rows in the consequence table until the optimal alternative is revealed. Mustajoki and Hämäläinen (2005, 2007) coined the term *smart swaps* to refer to guided even swaps, i.e. using a decision support system to provide process suggestions.

In this paper, we propose a Bayesian approach to guiding the even swaps process, whereby the system makes queries based on its beliefs about the DM’s preferences and updates them as the interactive process unfolds. The literature on Bayesian techniques for learning a DM’s preferences is vast and varied, spanning domains such as management science, artificial intelligence, expert systems and machine learning (e.g. Eliashberg and Hauser 1985, Jimison et al. 1992, Poh and Horvitz 1993, Chajewska et al. 2000, Anderson and Hobbs 2002, Boutilier 2002, Scott and Shachter 2005).

We review the even swaps method in Section 2. The subsequent three sections summarize our main contributions. In Section 3, we present some properties of even swaps, providing conditions under which they are feasible. In Section 4, we describe our swaps algorithm

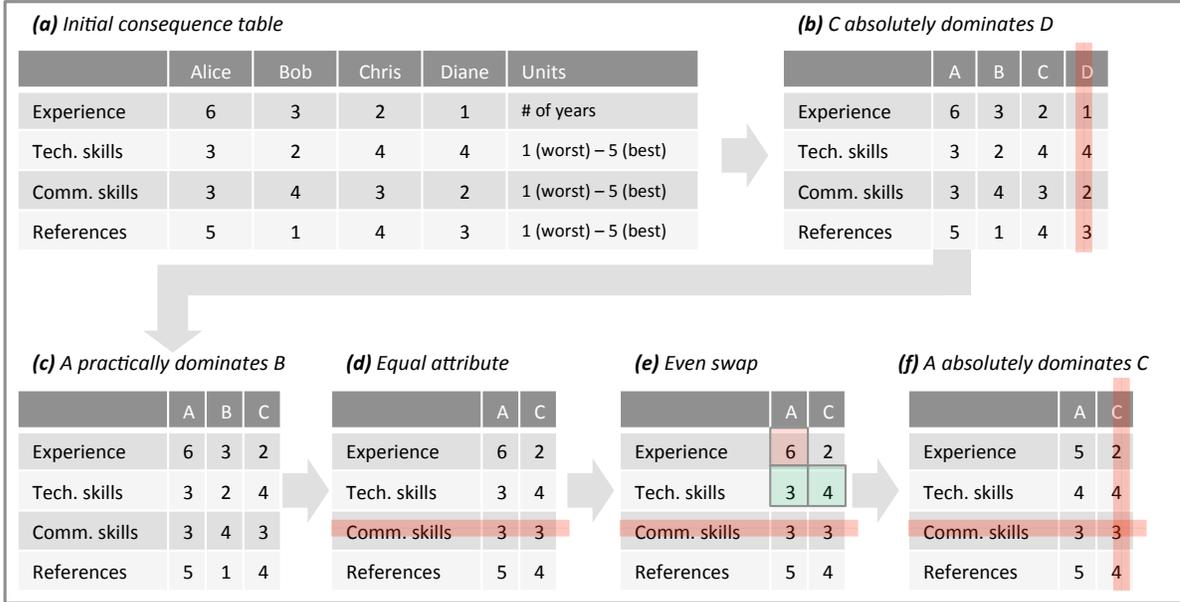

Figure 1: The even swaps method applied to a hiring problem.

in detail. In Section 5, we discuss the results of some experiments that study the effect of problem size and Bayesian learning on the number and type of queries made to the DM. We are not aware of any previous work with computer experiments that explores the effect of smart swaps on a set of consequence tables and DMs. Finally, we conclude in Section 6.

2 EVEN AND SMART SWAPS

We will explain the even swaps method with the help of the following illustrative example:

A Hiring Example. Figure 1(a) presents the consequence table for a manager Zoe who faces a hiring decision and must choose among four candidates — Alice, Bob, Chris and Diane — across four attributes: Experience (in # of years) and qualitative measures such as Technical Skills, Communication Skills and References, all scored on a scale of 1 (worst) to 5 (best).

Zoe chooses to pursue the even swaps method to determine the optimal hire. First, she recognizes that Chris scores at least as well as Diane on all attributes, and therefore removes Diane from consideration in 1(b). This is an example of *absolute dominance*. Next, she observes that Alice fares better on most attributes as compared to Bob, except for Technical Skills where Bob scores 1 point higher. Feeling that Alice compensates for this deficit along the other attributes, i.e. that Alice exhibits *practical dominance* over Bob, Zoe removes Bob from consideration in 1(c).¹

¹The original even swaps literature introduced practical

Zoe then notices that the remaining candidates, Alice and Chris, have the same score (3) on Communication Skills. Reasoning that she need not be concerned with this attribute in subsequent iterations, as she can make subsequent value judgments conditional on this common score, she greys this attribute out in 1(d). In the even swaps literature, this task is referred to as identifying an irrelevant attribute; for reasons explained in the next section, we prefer the term *equal attribute*, and say that this attribute has become inactive.

Now Zoe makes the move that gives the *even swap* method its name. She observes that Alice fares worse on Technical Skills, but better on the remaining active attributes. She answers the following question, indicated by the three boxes in 1(e): how many years of Experience would she be willing to give up for Alice to improve her Technical Skills score from 3 to 4? An even swap produces a hypothetical equivalent alternative in which a change in the consequences of one attribute balances the change in the consequences of another, and is a specific kind of matching query (Delquie 1993). The DM’s response is determined by her value judgments; in this case, she determines that Alice’s Experience should change from 6 to 5 years. She then replaces Alice with her hypothetical clone in the consequence table in 1(f). In the final step, she recognizes that Alice absolutely dominates Chris, thereby revealing Alice to be the optimal candidate. □

dominance as an intuitive but vague notion. Subsequent work on smart swaps proposed a definition with some practical drawbacks. A major contribution of our work is a precise definition and demonstration of its practicality.

The key idea that differentiates indirect methods like even swaps from direct elicitation techniques is that the analyst/system need not have a complete picture of the DM’s preferences to find the optimal alternative for a particular decision. It is therefore often beneficial to use such techniques for reducing elicitation burden and potential inaccuracies, as people are highly susceptible to cognitive biases (Lichtenstein and Slovic 2006).

The even swaps method appears to be suitable for small problems where the interactive nature of the method, the access to the alternatives and the (almost) instant gratification from solving the problem appeal to the DM. It is particularly useful for DMs who either find it difficult to answer questions about their trade-offs in terms of weight ratios, or who need to view/consider the alternatives to construct their preferences. Kajanus et al. (2001) provide an application to strategy selection in rural enterprises.

Even swaps was originally intended to be self-guided; Mustajoki and Hämäläinen (2005, 2007) propose a decision support system for smart swaps using preference programming, i.e. by recognizing the feasible region of weights for fixed bounds on marginal value functions. Their model makes the practical dominance notion precise by recommending it through pairwise dominance, which occurs when there is no way an alternative can be most preferred, based on the feasible weight region and bounds. Their method however has several limitations. For instance, there is little the system can do if it proposes a practical dominance query and the DM rejects it, aside from changing bounds midway through the process. Crucially, they are unable to recognize swaps that are not feasible.

Here we propose a Bayesian approach that exploits prior information about the feasible weight region as represented by a prior probability distribution. We introduce the notion of probable dominance as well as a heuristic that recommends even swaps through probabilistic computations. The system easily handles rejection of practical dominance queries. We also present new results about feasibility conditions for even swaps, using them to recognize and adapt to declarations of infeasible swaps. Our approach is particularly adept at providing inexperienced users with specific recommendations. However, as discussed in the conclusions, our method possesses its own set of limitations.

3 PROPERTIES OF EVEN SWAPS

The overarching even swaps method gets its name from the even swap query, which is crucial towards reducing the size (and therefore complexity) of the consequence table. In this section, we specify our assumptions for the class of multi-attribute problems under considera-

tion, and then present some results pertaining to the properties of even swaps.

3.1 ASSUMPTIONS

We address multi-attribute problems where the DM has an additive value function, i.e. of the form in equation (2). This is applicable only when attributes are mutually preferentially independent. As noted by previous authors, this is a common assumption and is widely applied in practice (Keeney and Raiffa 1976, Stewart 1996, Belton and Stewart 2002).

In theory, the even swaps method is applicable for all value functions and is not restricted to the additive form. However, the method can be challenging to apply when there is value dependence, in which case the DM would have to consider consequence levels of all attributes while making a judgment about an even swap. In that sense, no attribute would be ‘irrelevant’ when the DM makes the even swap based on their trade-offs. It is difficult to imagine the method being implemented successfully in such a situation without an analyst in the room to guide the DM. The additive assumption therefore makes an automated decision support system more likely to be used (and perhaps misused).

We also assume that the one-dimensional marginal value functions are continuous, bounded and monotonic. Since they are bounded, these functions can be normalized such that $0 \leq v_i(x_i) \leq 1$, $v_i(x_i^0) = 0$ and $v_i(x_i^*) = 1$ for all attributes, where x_i^0 and x_i^* represent the least and most preferred consequences for attribute i . The domain of an attribute is denoted D_i , therefore for an attribute where more is preferred to less, $D_i = [x_i^0, x_i^*]$. Monotonic attributes are common in practice; non-monotonic attributes can sometimes be redefined so as to render them monotonic. Furthermore, a discrete attribute can often be approximated as continuous. For instance, in the hiring problem in Figure 1, three of the four attributes are measured as integers on a scale of 1 to 5, but they could easily be approximated as continuous attributes. These assumptions are therefore not too restrictive.

3.2 NOTATION AND PROPERTIES

The even swaps method attempts to guide the DM by simplifying the consequence table. During this interactive process, the DM must carefully consider pairs of alternatives and their consequences along specific attributes. A consequence x_i is deemed to be preferred over y_i if it has higher marginal value:

$$x_i \succ y_i \Leftrightarrow v_i(x_i) > v_i(y_i). \quad (3)$$

Any pair of alternatives \mathbf{x} and \mathbf{y} can therefore be associated with the following three sets of attributes:

dominating set $D(\mathbf{x}, \mathbf{y}) = \{i : x_i \succ y_i\}$, **non-dominating set** $N(\mathbf{x}, \mathbf{y}) = \{i : x_i \prec y_i\}$, and **equal set** $E(\mathbf{x}, \mathbf{y}) = \{i : x_i = y_i\}$. Note that $N(\mathbf{x}, \mathbf{y}) = D(\mathbf{y}, \mathbf{x})$.

The task with perhaps the lowest cognitive load for the DM and the lowest computational load for a system is identifying equal attributes. While somewhat more complex for a DM, it is also trivial for a system to discover absolute dominance, denoted $\mathbf{x} \succeq^A \mathbf{y}$, using non-dominating attribute sets:

$$\mathbf{x} \succeq^A \mathbf{y} \Leftrightarrow N(\mathbf{x}, \mathbf{y}) = \emptyset. \quad (4)$$

For a replicate pair of solutions, i.e. where both $N(\mathbf{x}, \mathbf{y}) = \emptyset$ and $D(\mathbf{x}, \mathbf{y}) = \emptyset$, either \mathbf{x} or \mathbf{y} can be removed from the table at random.

Practical dominance comes under consideration when one of the sets $N(\mathbf{x}, \mathbf{y})$ and $D(\mathbf{x}, \mathbf{y})$ has many more elements than the other. While practical dominance claims help remove some solutions, the DM may eventually have to perform an even swap to manipulate the consequence table and make further progress. We denote an even swap as $s(x_i \rightarrow x'_i, x_j \rightarrow x'_j)$, where the alternative \mathbf{x} is modified by the DM, such that the change from x_i to x'_i along attribute i is compensated by the change from x_j to x'_j along attribute j .

Consider the even swap in the hiring example, where the DM provided a response to a change from the score 3 to 4 on Technical Skills, along Experience. Note that the swap performed was specifically designed to make consequences identical for Technical Skills. This type of swap is relatively cognitively comfortable for the DM, since they are able to observe the numbers along a specific row. Moreover, ensuring equal consequences simplifies the table and allows for potential ease of elicitation in future tasks. We refer to such a swap as an **equalizing even swap**, defined as an even swap that makes the consequences of two alternatives equal along an attribute. For any two alternatives \mathbf{x} and \mathbf{y} , $s(x_i \rightarrow y_i, x_j \rightarrow x'_j)$ is an equalizing even swap because it makes attribute i 's consequences for both alternatives equal, thereby increasing the set $E(\mathbf{x}, \mathbf{y})$.

Is an even swap always possible? No. The following proposition provides the conditions under which an even swap is feasible, assuming that the DM's response is consistent with their value function.

Proposition 1 (Even Swap Feasibility). *The even swap $s(x_i \rightarrow x'_i, x_j \rightarrow x'_j)$, $i \neq j$, $x_i, x'_i \in D_i$ is feasible only if:*

- (i) When $x'_i \succ x_i$: $v_j(x_j) \geq \frac{w_i}{w_j} [v_i(x'_i) - v_i(x_i)]$
- (ii) When $x'_i \prec x_i$: $1 - v_j(x_j) \geq \frac{w_i}{w_j} [v_i(x_i) - v_i(x'_i)]$

Proof. If $x'_i \succ x_i$, the swap is not feasible when even a response of $x'_j = x_j^0$ cannot compensate for the change, which occurs when $w_j [v_j(x_j) - v_j(x_j^0)] < w_i [v_i(x'_i) - v_i(x_i)]$. The result follows after recognizing $v_j(x_j^0) = 0$. The other case is similar. \square

The fact that not all swaps are feasible is potentially problematic for a system attempting to guide the process by recommending equalizing even swaps. Since the system is not exactly aware of the DM's preferences during the process, it is possible for the system to propose a swap that is infeasible for the DM. Fortunately, as determined in the following proposition, if the swap $s(x_i \rightarrow y_i, x_j \rightarrow x'_j)$ is not feasible, its **conjugate swap** $s(x_j \rightarrow y_j, x_i \rightarrow x'_i)$ must be feasible.

Proposition 2 (Equalizing Even Swap Feasibility). *For any two alternatives \mathbf{x} and \mathbf{y} that do not dominate each other over attributes i and j , at least one of the equalizing even swaps $s(x_i \rightarrow y_i, x_j \rightarrow x'_j)$ or $s(x_j \rightarrow y_j, x_i \rightarrow x'_i)$ is feasible.*

Proof. Suppose that $y_i \succ x_i$. If the swap $s(x_i \rightarrow y_i, x_j \rightarrow x'_j)$ is not feasible, then from Proposition 1(i), $v_j(x_j) < \frac{w_i}{w_j} [v_i(y_i) - v_i(x_i)]$. Rearranging, $w_i v_i(x_i) + w_j v_j(x_j) < w_i v_i(y_i)$. For the conjugate swap, by definition, $w_i v_i(x_i) + w_j v_j(x_j) = w_i v_i(x'_i) + w_j v_j(y_j)$. Using the condition from the infeasibility of the original swap, $w_i v_i(x'_i) + w_j v_j(y_j) < w_i v_i(y_i) \implies w_i v_i(x'_i) < w_i v_i(y_i) \implies x'_i \prec y_i$. The conjugate swap is therefore indeed feasible. The other case is similar. \square

The implication of these results is that a feasible swap can always be found: if the DM declares that a given even swap is infeasible, then the conjugate swap will be feasible, and the system can recommend it.

Note that both propositions assume that a DM's response is consistent with their value function. However, behavioral research on bi-matching suggests people may provide inconsistent responses between queries pertaining to a swap vs. its conjugate (Delquie 1997, Willemsen and Keren 2003). In the algorithm described in the next section, we assume the DM is willing to make either a swap or its conjugate, but we allow for noise in the response to an even swap query.

4 BAYESIAN SMART SWAPS

In our formulation of guiding an interactive even swap, we assume the system has prior beliefs $p(\mathbf{w})$ about the DM's weights in their additive value function. If there is no a priori information available, the system may choose a uniform prior over the weight simplex: $p(\mathbf{w}) \sim \text{Dirichlet}(\boldsymbol{\alpha})$ where $\boldsymbol{\alpha}$ is a vector of 1s.

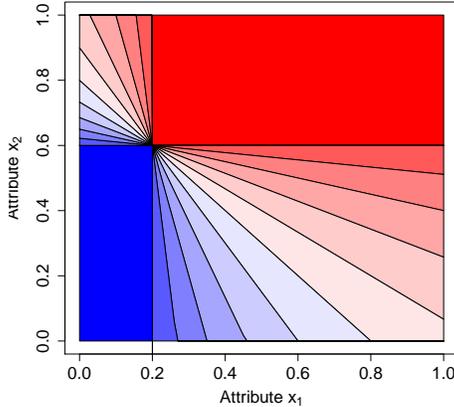

Figure 2: Regions of absolute and practical dominance for the two-attribute example when $w_1 \sim \text{Uniform}(0,1)$.

We also assume for now that the system knows the DM’s marginal value functions, perhaps through prior assessments. Since these are one-dimensional functions, they are usually easier to elicit than weights that reflect trade-offs. In sub-section 4.4 we briefly outline how our algorithm may be extended to the case of unknown marginal functions.

We explore how a system can cope with uncertainty about the DM’s weights, incorporating responses to recommended practical dominance and even swap queries from the DM. In our algorithm, the system gradually learns the user’s preferences and exploits it for the sole purpose of reaching the optimal alternative as soon as possible. In the following sub-sections, we describe various aspects of our overall approach.

4.1 ABSOLUTE VS. PROBABLE DOMINANCE

One of the central notions of the original even swaps method is that of practical dominance, according to which an alternative can be discarded if it appears to be *nearly* absolutely dominated by another. In this section, we view practical dominance through a Bayesian lens, with the intent of reducing the cognitive burden of DMs. To motivate our approach, let us first study absolute dominance.

Consider an alternative \mathbf{x} whose consequences have been normalized; therefore it lies somewhere in the unit cube. \mathbf{x} dominates a proportion of other alternatives given by the volume $\prod_{i=1}^M x_i$, and is dominated by a proportion $\prod_{i=1}^M (1 - x_i)$. Note that if a family of problems is built by generating alternatives uniformly over the consequence domains, then the probability that any particular alternative dominates another decreases exponentially with the number of attributes M . Therefore absolute dominance does not occur with sufficient frequency to be a basis for a practical decision support algorithm. Moreover, in real-world set-

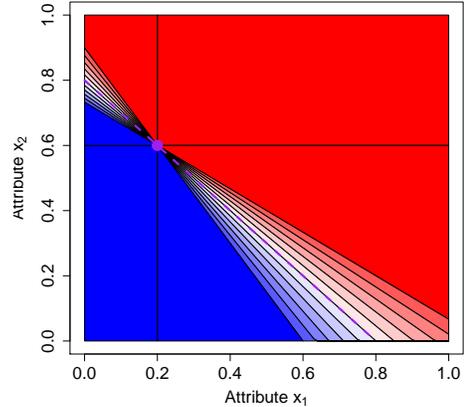

Figure 3: Regions of absolute and practical dominance for the two-attribute example when $w_1 \sim \text{Uniform}(0.4, 0.6)$.

tings, absolutely dominated alternatives would likely be shelved before reaching the conference room.

A relationship that might be more useful is that of **probable dominance**, which measures the system’s beliefs about whether the DM prefers an alternative to another. The probability that alternative \mathbf{x} dominates \mathbf{y} is denoted $p_{\mathbf{x}\mathbf{y}}$, where:

$$p_{\mathbf{x}\mathbf{y}} = \int_{\mathbf{w}} \left(\sum_{i=1}^M w_i [v_i(x_i) - v_i(y_i)] \geq 0 \right) p(\mathbf{w}) d\mathbf{w}. \quad (5)$$

If the system believes that the DM is likely to prefer an alternative over another, perhaps it can recommend them as a candidate pair for practical dominance. Although the DM makes the eventual judgment, the system recommends the pair in the hope that it will simplify the problem. We therefore propose probable dominance above a certain threshold p_T to recognize potential practical dominance, $p_{\mathbf{x}\mathbf{y}} \geq p_T$.

Let us study the following simple example to compare the occurrence of absolute and probable dominance:

A Two-attribute Example. Suppose $M = 2$ and that the DM’s marginal value functions are linear and normalized to between 0 and 1. As a reference, suppose that the DM’s trade-offs are accurately captured by weights $w_1 = 0.5$ and $w_2 = 0.5$.

Figure 2 illustrates the regions of absolute and practical dominance with respect to a chosen alternative $\mathbf{x} = (0.2, 0.6)$ (represented as a purple dot) when the system believes that $w_1 \sim \text{Uniform}(0,1)$. Alternatives that absolutely dominate \mathbf{x} are shown in dark red, while those that are absolutely dominated by \mathbf{x} are shown in dark blue. The regions of potential practical dominance (as determined by probable dominance) for various values of the probability p appear as bands of lighter red and blue, in increments of 0.1, ranging from $p = 0.9$ to 1.0 (almost deep red) down to $p = 0$ to 0.1 (almost deep blue).

Figure 3 illustrates almost the same situation except now the system believes that $w_1 \sim \text{Uniform}(0.4, 0.6)$, possibly by learning from responses to previous queries. It is immediately apparent that the reduced uncertainty yields enlarged regions in which there is a high certainty that \mathbf{x} dominates or is dominated. These regions now appear as large triangles flanking the rectangular regions of absolute dominance. From a practical perspective, such regions are effectively equivalent to those of absolute dominance.

Relative to Fig. 2, the region of uncertainty is much more tightly clustered around the diagonal line $x_1 + x_2 = 0.8$ that represents the boundary between $x \succ y$ and $y \succ x$. This is due to the reduced uncertainty about the true value of \mathbf{w} , and illustrates the benefits of reducing the uncertainty: it allows the system to be more confident in suggesting potential practical dominance to the DM. \square

The simple example illustrates that a pair of alternatives chosen at random is more likely to exhibit probable rather than absolute dominance, making it more useful in practice. Further numerical simulations were performed, demonstrating that the probability for a given vector \mathbf{x} to practically dominate a given vector \mathbf{y} above a given threshold p_T is insensitive to the number of attributes M . This suggests that probable dominance may be a useful concept in practice.

Algorithm 1 summarizes the system’s approach to recommending practical dominance and updating beliefs. We assume that the DM responds accurately to this query based on their preferences, since this is a comparison question that is typically associated with low cognitive load. This implies that the polytope of the weight region can be updated to incorporate the following condition:

$$\sum_{i=1}^M w_i [v_i(x_i) - v_i(y_i)] \geq (\leq) 0, \quad (6)$$

depending on whether the user responds ‘yes’ or ‘no’ to the question: do you prefer \mathbf{x} over \mathbf{y} ? The implications and potential limitations of assuming an accurate response to this query are discussed in the conclusions.

4.2 EVEN SWAPS

Recommending an effective even swap is more challenging than computing practical dominance. In Section 3, we explored some properties, discovering that not all swaps are feasible. The notion of an equalizing even swap was introduced as a practical means of forming a simpler consequence table. To make an equalizing even swap $s(x_i \rightarrow y_i, x_j \rightarrow x'_j)$, the system needs an alternative pair \mathbf{x}, \mathbf{y} and an attribute pair $i,$

Algorithm 1 Practical Dominance Query

Input: N alternatives, threshold p_T , prior $p(\mathbf{w})$
Initialize $p_D^{max} = 0$
for each pair of vectors \mathbf{x} and \mathbf{y} **do**
 Compute $p_{\mathbf{x}\mathbf{y}}$ from equation (5)
 if $p_{\mathbf{x}\mathbf{y}} \geq \max(p_T, p_D^{max})$ **then**
 Store pair \mathbf{x}, \mathbf{y} ; $p_D^{max} = p_{\mathbf{x}\mathbf{y}}$
 end if
end for
if $p_D^{max} \neq 0$ **then**
 Recommend potential practical dominance for \mathbf{x}, \mathbf{y} , inquiring whether $\mathbf{x} \succeq \mathbf{y}$
 Update $p(\mathbf{w})$ in accordance with DM’s response, using equation (6)
else
 There is no candidate pair
end if

j . Moreover, the system should be able to handle an infeasible swap.

We present a heuristic for recommending an even swap that identifies the most suitable alternative and attribute pairs. There are two main steps involved. In the first step, the system identifies alternatives \mathbf{x}, \mathbf{y} where it believes \mathbf{x} might be preferred over \mathbf{y} . It is natural to use probable dominance to quantify this belief. In the second step, the system identifies attributes $i \in N(\mathbf{x}, \mathbf{y})$ and $j \in D(\mathbf{x}, \mathbf{y})$ such that swap $s(x_i \rightarrow y_i, x_j \rightarrow x'_j)$ is likely to decrease $|N(\mathbf{x}, \mathbf{y})|$.

The intuition behind the heuristic is that an even swap query potentially pushes a pair of alternatives towards dominance of some sort, making it eventually evident to both the system and the DM. Focusing on a pair where one is likely to dominate the other and reducing the non-dominated attribute set ensures that this occurs. As shown in Section 3, an infeasible swap always possesses a feasible conjugate swap, so the heuristic is guaranteed to make progress (from a normative perspective). Note that the cognitive effort expended by the user in trying to respond to the original (failed) swap will be helpful in responding to its conjugate. Note also that the heuristic is myopic in that it attempts to find the ‘best’ swap at the current moment, without regard to long-term savings. It can be viewed as a dominance-focused heuristic, as it tries to drive alternative pairs towards dominance.

Suppose that the system is considering the equalizing even swap $s(x_i \rightarrow y_i, x_j \rightarrow x'_j)$ based on the aforementioned heuristic. By definition:

$$v_j(x'_j) = \frac{w_i (v_i(x_i) - v_i(y_i)) + w_j v_j(x_j)}{w_j}, \quad (7)$$

if it is feasible, i.e. satisfies Proposition 1.

Algorithm 2 Even Swap Query

Input: N alternatives, swap response noise δ , prior $p(\mathbf{w})$
Set threshold $p_T = 0$ and find alternative pair \mathbf{x}, \mathbf{y} from Algorithm 1
Initialize $p_S^{max} = 0$
for each pair of attributes i in $N(\mathbf{x}, \mathbf{y})$ and j in $D(\mathbf{x}, \mathbf{y})$ **do**
 Compute p_S from equation (8)
 if $p_S \geq p_S^{max}$ **then**
 Store pair i, j ; $p_S^{max} = p_S$
 end if
end for
Recommend the swap $s(x_i \rightarrow y_i, x_j \rightarrow x'_j)$
if Response is x'_j **then**
 Update $p(\mathbf{w})$ with conditions from equation (9)
else if DM declares swap is infeasible **then**
 Recommend conjugate swap $s(x_j \rightarrow y_j, x_i \rightarrow x'_i)$
 Update $p(\mathbf{w})$ using equation (9), after swapping i and j
end if

Suppose that i and j are both attributes where more is preferred to less. Then x_i is increased to y_i for the swap (because $i \in N(\mathbf{x}, \mathbf{y})$), therefore x_j is decreased to x'_j if the swap is feasible. The probability that this swap will decrease the non-dominated set p_S is:

$$\begin{aligned}
p_S &= P(x'_j \geq y_j) = P(v_j(x'_j) \geq v_j(y_j)) \\
&= \int_{\mathbf{w}} \left(\sum_{k=i,j} w_k [v_k(x_k) - v_k(y_k)] \geq 0 \right) p(\mathbf{w}) d\mathbf{w},
\end{aligned} \tag{8}$$

where the final step is a result of integration after rearranging (7). For the sake of brevity, we have notationally omitted specifying that p_S is a function of the swap; it should be inferred that it is associated with swap $s(x_i \rightarrow y_i, x_j \rightarrow x'_j)$. Also, note that although equation (8) applies only when i and j have monotonically increasing marginal value functions, it is easy to generalize it to include all other cases.

Algorithm 2 summarizes the system’s approach to recommending even swaps and updating beliefs. Since an even swap is associated with a significant cognitive load, the system treats the response to lie within a noise band measured using the *swap response noise* δ . For instance, if a user responds to an even swap query with normalized consequence 0.6 and $\delta = 0.2$, then the system forms a lower bound $L_\delta = 0.5$ and upper bound $U_\delta = 0.7$. This noise band is subject to the other constraints posed on a response, i.e. it must lie within the domain. Therefore a response of 0.05 with $\delta = 0.2$ results in $L_\delta = 0$ and $U_\delta = 0.15$. If more of attribute j is preferred to less, the polytope

of the weight region can be updated with conditions from two inequalities involving w_i and w_j :

$$L_\delta \leq \frac{x'_j - x_j^0}{x_j^* - x_j^0} \leq U_\delta, \tag{9}$$

where L_δ and U_δ are bounds on normalized consequences ($L_\delta, U_\delta \in [0, 1]$) that depend on the DM’s response and δ as described above, and x'_j is a function of the weights and marginal values as in equation (7). This equation could be easily modified for the case where less of attribute j is preferred.

4.3 HIGH-LEVEL ALGORITHM

Now that we have outlined the two main sub-routines – practical dominance and even swaps – Algorithm 3 provides the high-level routine for our proposed interactive even swaps method. The algorithm identifies absolute dominance and equal attributes, recommends practical dominance when it is confident enough, and recommends an equalizing even swap based on a dominance focused heuristic. The algorithm terminates when the optimal alternative is revealed.

4.4 EXTENSION: UNKNOWN MARGINAL VALUE FUNCTIONS

In the algorithm described here, we assumed that the system already knew the marginal value functions, perhaps through initial assessments. There is a natural extension to the case of unknown marginal value functions along the lines of Mustajoki and Hämäläinen

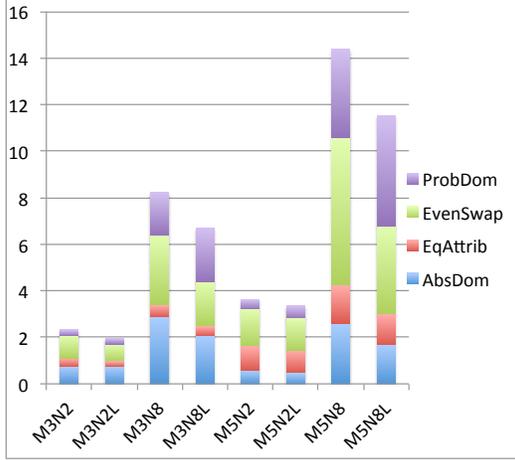

Figure 4: The effect of learning upon the number and type of queries and events. Average number of absolute dominance and equal attribute events, as well as probable dominance and even swap queries per scenario, for $M = \{3, 5\} \times N = \{2, 8\}$, with learning turned on (L) and off.

(2005, 2007), using previously determined lower and upper bounds on the marginal value functions. Subsequently, for all probabilistic computations — in this case those pertaining to computing probable dominance and the probability that the swap will decrease the non-dominated set — the system could use probability bounds for making recommendations and update its beliefs based on inequalities from these bounds. The current algorithm could be updated to incorporate these changes.

5 EXPERIMENTAL RESULTS

A first set of experiments were conducted to assess the degree to which learning reduces the number and complexity of queries directed to the DM. The high-level algorithm described in Section 4 was applied to a set of 100 randomly generated scenarios, each involving a randomly generated set of N alternatives with M attributes. Each of the NM values in the consequence table was generated from a Uniform distribution (0, 1). The user’s true weights were drawn uniformly from the $(M - 1)$ -dimensional unit simplex, and the prior was the same uniform distribution over the simplex. For simplicity, the marginal value functions were assumed to be linear and ranging from 0 to 1.

For each scenario, the probability threshold for a probable dominance query was set relatively high (0.9) to ensure that the queries might not be too onerous for real humans to answer. The probability that $\mathbf{x} \succ \mathbf{y}$ for the DM was computed by randomly generating at least 10000 weight vectors uniformly in the $(M - 1)$ -dimensional unit simplex. First, rejection sampling

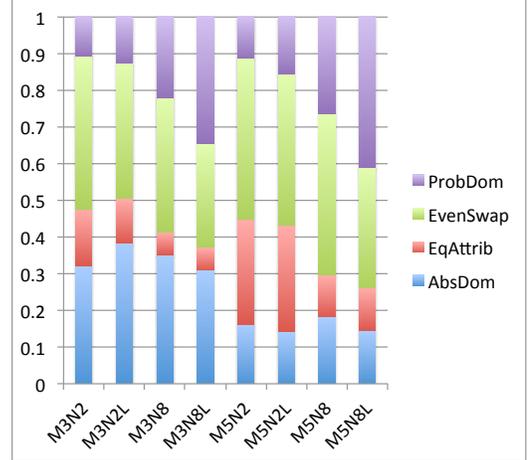

Figure 5: Same data as in Figure 4, except that the scales are normalized to 1 to illustrate the relative contributions of the different types queries and events.

was employed, i.e. the randomly generated weight vectors were reduced to a set that satisfied any constraints introduced during the interactive process. Then the probable dominance probability was computed as the fraction of weight vectors for which $\mathbf{x} \succ \mathbf{y}$. Particularly in cases where several even swaps had been applied, the weights were pinned down so precisely that the number of samples satisfying the constraints dropped below 100, in which case more points were generated to ensure that the probable dominance probability was computed from reasonable statistics. To simulate the DM answering a probable dominance or even swaps query, the true weight vector was used to generate the response that the DM would have generated. The DM’s noise about the swap value was modeled using a modest swap response noise of $\delta = 0.2$.

For each scenario, the number of absolute dominance and equal-attribute events (accomplished purely through system computations) were recorded. The number of probable dominance and even swap queries (including both regular and conjugate swaps) were recorded as well; these are queries that must be answered by the DM and therefore entail some cognitive burden. Eight sets of 100 scenarios were run, with the number of attributes set to $M = \{3, 5\}$, the number of solutions set to $N = \{2, 8\}$, and the method’s learning element both turned on and turned off. The results are summarized in Figure 4.

For the smallest scenarios ($(M, N) = (3, 2)$), an average of just two queries and/or events is required, and typically there is one absolute dominance event and one even swap, with probable dominance and elimination by virtue of equal attributes playing a relatively minor role. Due to the small number of queries and/or

events, learning has little impact. The average number of queries and/or events decreases from 2.33 ± 0.11 to 1.96 ± 0.11 — a drop that is of marginal statistical significance. On the other hand, when the number of solutions is increased from 2 to 8, the average number of queries and/or events rises to 8.22 ± 0.34 without learning and 6.7 ± 0.23 with learning — a statistically significant decrease of 18%. When the number of attributes is increased from 3 to 5, a similar trend is observed. For $N = 2$ solutions, the number of queries and/or events is 3.63 ± 0.27 without learning and 3.35 ± 0.24 with learning — an insignificant difference — whereas for $N = 8$ solutions the number of queries and/or events is 14.37 ± 0.57 and 11.51 ± 0.41 — a statistically significant drop of 20%.

Figure 5 provides another view of the same data, in which the relative contribution of the various types of queries and events is obtained by normalization. As anticipated, the impact of absolute dominance decreases as the number of solutions N increases from 2 to 8. This is a consequence of the exponential decrease in the probability for any given vector to absolutely dominate another with the number of attributes. Another trend evident here is that as N increases, the relative impact of probable dominance queries grows stronger. Moreover, for larger problems, the effect of learning is to further increase the relative importance of probable dominance over even swap queries.

Having established that learning can substantially reduce the number of queries and/or events required to identify the optimal alternative, and moreover that it shifts the balance more from even swaps to probable dominance queries as the problem size grows, a second series of experiments were conducted with learning turned on. The objective of these experiments was to chart in greater detail how the number and type of queries and/or events change as the number of attributes and alternatives are varied. The results depicted in Figure 6 demonstrate the same basic trends, including the waning importance of absolute dominance as the number of attributes M grows and the ascendancy of probable dominance as N grows.

6 CONCLUSIONS

In this paper, we have presented a method for guiding the DM through the even swaps process using an overall Bayesian approach with a dominance focused heuristic. We have demonstrated through experiments that one can effectively learn about the DM’s preferences in the course of a single session to guide them quickly to a final choice. A potential next step is to implement a tool and test its efficacy through experiments with real human subjects. Belton et al. (2005)

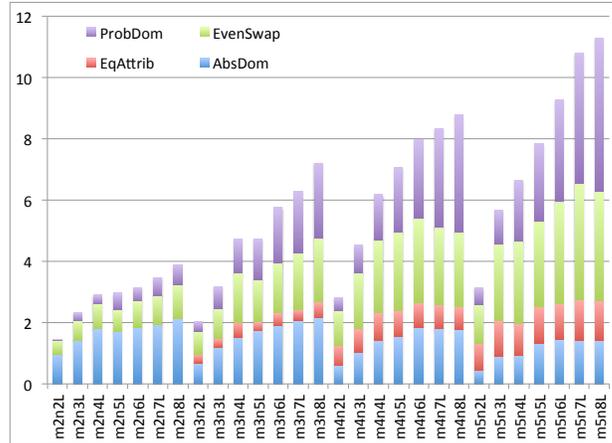

Figure 6: The effect of M and N on the number and type of queries and events. Average number of queries/events of each type, from left to right, for $M = \{2, 3, 4, 5\}$ and $N = \{2, 3, 4, 5, 6, 7, 8\}$.

conduct some user experiments involving even swap queries but such studies remain few and far between.

Our approach appears to be practical for modest-sized decision problems ($N < 10$). One could argue that direct elicitation techniques might be appropriate for large N (~ 100); however, if the DM prefers to use even swaps (for reasons highlighted in Section 2), it may be prudent to focus on learning the DM’s preferences rather than myopically trying to find the most likely pair of alternatives such that one might dominate the other.

Here we used a simple model for incorporating potential noise in a DM’s response to an even swap query; it was chosen to enable conditions represented as inequalities. In future research, we envision more nuanced noise models accounting for cognitive effects such as attribute conflict (e.g. Fischer et al. 2000, Delquíe 2003). Also, although we have used probable dominance to measure practical dominance, it remains unclear how the metric would work for large problems because it may be difficult for a DM to compare any two arbitrary alternatives; note that comparison queries are also subject to various cognitive biases in general (e.g. Tversky et al. 1988, Tversky and Kahneman 1991). Finally, regarding the computations for simulation, rejection sampling is sufficient when only a few queries are asked in a single setting. If several queries are asked back-to-back, efficient methods such as hit and run sampling may be more effective.

Abstract

Crowdsourcing services like Amazon’s Mechanical Turk have facilitated and greatly expedited the manual labeling process from a large number of human workers. However, spammers are often unavoidable and the crowdsourced labels can be very noisy. In this paper, we explicitly account for four sources for a noisy crowdsourced label: worker’s dedication to the task, his/her expertise, his/her default labeling judgement, and sample difficulty. A novel mixture model is employed for worker annotations, which learns a prediction model directly from samples to labels for efficient out-of-sample testing. Experiments on both simulated and real-world crowdsourced data sets show that the proposed method achieves significant improvements over the state-of-the-art.

1 INTRODUCTION

Supervised learning requires labels. However, the collection of labeled data from users is often expensive, tedious and time-consuming. Recently, the use of crowdsourcing allows this mundane process of obtaining manual labels from a great number of human workers to be greatly expedited. For example, in Amazon’s Mechanical Turk (AMT), a “requester” can pose tasks known as HITs (Human Intelligence Tasks). Workers then choose to complete any of the existing HITs and get rewarded by a certain amount of monetary payment set by the requester. Researchers in different areas, such as computer vision (Sorokin and Forsyth, 2008) and natural language processing (Snow et al., 2008), have benefited from these crowdsourcing services and acquired labels for large data sets.

However, in practice, the crowdsourced labels are often noisy. On one hand, their quality depends on the labeling task. For example, if the labeling task is not well designed or not clearly described by the requester, the worker’s motivation to participate may decrease, and the noisy level of

the crowdsourced labels will increase (Zheng et al., 2011). Moreover, different labeling tasks can have different difficulties. If samples in one task are very challenging to annotate, the obtained crowdsourced labels may be less reliable (Whitehill et al., 2009; Yan et al., 2010; Zhou et al., 2012). On the other hand, workers’ qualities can vary drastically and lead to different noise levels in their annotations. For example, their expertise differs due to their diverse knowledge backgrounds (Whitehill et al., 2009; Welinder et al., 2010). Moreover, their dedications to performing the task can also greatly affect their annotation accuracies. In the worst case, some workers may just randomly guess the labels without actually looking at the samples (Welinder et al., 2010). In particular, it is common to have “spammers”, who provide wrong labels most of the time. The extraction of “true” labels from a large pool of crowdsourced labels is thus very important.

A popular and simple approach is to perform a majority vote on workers. However, it implicitly assumes that all workers are equally accurate, which is rarely the case in practice. It can also be misleading when there is a significant portion of spammers. To obtain a more accurate consensus, a number of algorithms have been proposed that model different aspects of the labeling noise (such as worker expertise and sample difficulty) (Whitehill et al., 2009; Welinder et al., 2010; Raykar and Yu, 2012; Liu et al., 2012; Zhou et al., 2012). Interested readers are referred to the recent survey in (Sheshadri and Lease, 2013). Yet, these models can only make estimations for samples with crowdsourced labels. For out-of-sample testing (i.e. prediction on an unseen test sample), the user has to first crowdsource its labels before these algorithms can be run.

To alleviate this problem, one can build a prediction model directly from the sample to the label. A popular approach is the two-coin model (Raykar et al., 2010). It assumes that each worker generates its label by flipping the ground-truth label with a certain probability. Depending on whether the true label being zero or one, the flipping probabilities are in general different. A prediction model is then built on the hidden “denoised” labels. This is further extended in

Table 1: Comparison between the existing methods and ours.

(Yan et al., 2010) by allowing the flipping probability to be different from sample to sample. Another approach is to formulate the crowdsourcing problem as a multitask learning problem (Evgeniou and Pontil, 2004). Each worker is considered a task, and the final prediction model is a linear combination of the worker models (Kajino et al., 2012, 2013). However, this may not be robust when many workers are spammers or incompetent.

In this paper, we propose a novel model for the generation of crowdsourced labels. Specifically, we assume that the label noise can come from four sources: (i) the worker is not an expert; (ii) the worker is not dedicated to the task; (iii) the worker’s default label judgement is incorrect; and (iv) the sample is difficult. Note that some of these have been considered in the literature (Table 1). Moreover, they can be highly inter-correlated. For example, if a sample is easy, even an uncommitted non-expert can output the correct label. On the other side, if the sample is very difficult, even a dedicated expert can only rely on his default judgement. If his prior knowledge happens to be incorrect, the label will be wrong.

With these various factors, we employ a mixture model for the worker annotation of the crowdsourced data. If the worker is dedicated to the labeling task or if he considers the sample as easy, the corresponding label is generated according to his underlying decision function. Otherwise, the label is generated based on his default labeling judgement. To model sample difficulty, we use the usual intuition that a sample is difficult if it is close to the worker’s underlying decision boundary, and vice versa. Obviously, we do not know in which way the worker generates the label of a sample. For inference, we use the expectation maximization (EM) algorithm (Dempster et al., 1977).

The rest of this paper is organized as follows. Section 2 presents our worker annotation model, and Section 3 presents the inference procedure. Experiments are presented in Section 4, and the last section gives some concluding remarks.

2 PROPOSED MODEL

In this paper, we assume that the crowdsourced task is a binary classification problem, with T workers and N query samples. The i th sample $\mathbf{x}^{(i)} \in \mathbb{R}^d$ is annotated by the set of workers $S_i \subseteq \{1, 2, \dots, T\}$. The annotation provided by the t th worker (with $t \in S_i$) is denoted $y_t^{(i)} \in \{0, 1\}$.

2.1 GENERATION OF GROUND TRUTH

We assume that for each sample $\mathbf{x}^{(i)}$, its ground truth label $y^{*(i)} \in \{0, 1\}$ is generated by a logistic regression model with parameter \mathbf{w}^* . In other words, $y^{*(i)}$ follows the Bernoulli distribution

$$p(y^{*(i)} = 1 | \mathbf{w}^*, \mathbf{x}^{(i)}) = \sigma(\mathbf{w}^{*T} \mathbf{x}^{(i)}), \quad (1)$$

where $\sigma(z) = 1/(1 + \exp(-z))$ is the logistic function. To avoid over-fitting, we assume a normal prior on \mathbf{w}^* :

$$\mathbf{w}^* | \gamma \sim \mathcal{N}\left(\mathbf{0}, \frac{1}{\gamma} \mathbf{I}\right),$$

where $\gamma > 0$ is a constant (in the experiments, this is tuned by the validation set). Other priors can also be readily added. For example, if \mathbf{w}^* is expected to be sparse, the Laplace prior can be used instead.

As will be seen later, training the model only requires access to the features but not the ground-truth labels. This is more realistic in many crowdsourced applications, as the features can often be readily extracted using standard unsupervised feature extraction.

2.2 WORKER ANNOTATION: EXPERTISE AND DEDICATION

For worker t , we assume that his failure in correctly annotating $\mathbf{x}^{(i)}$ is due to two reasons according to his dedication to the queried sample $\mathbf{x}^{(i)}$. First, he may have tried to annotate with the best effort, but still fails because his expertise is not strong enough. We model this by assuming

that worker t 's annotation $y_t^{(i)}$ follows a similar Bernoulli distribution as (1):

$$p(y_t^{(i)} = 1 | \mathbf{w}_t, \mathbf{x}^{(i)}) = \sigma(\mathbf{w}_t^T \mathbf{x}^{(i)}), \quad (2)$$

where \mathbf{w}_t is the worker's "estimation" of \mathbf{w}^* , and is sampled from the following normal distribution

$$\mathbf{w}_t | \mathbf{w}^*, \delta_t \sim \mathcal{N}(\mathbf{w}^*, \delta_t^2 \mathbf{I}). \quad (3)$$

A small δ_t means that \mathbf{w}_t is likely to be close to \mathbf{w}^* , and thus worker t is an expert, and vice versa. When no additional information on the worker's expertise is available, a uniform hyperprior on $\{\delta_t\}_{t=1}^T$ can be used.

The second reason for worker t 's failure in correctly annotating $\mathbf{x}^{(i)}$ is simply that he is not dedicated to the task and has not even looked at $\mathbf{x}^{(i)}$. In this case, he randomly annotates according to some default judgement. This can be modeled by another Bernoulli distribution:

$$p(y_t^{(i)} = 1 | b_t) = b_t, \quad (4)$$

where $b_t \in [0, 1]$. Again, when no additional information on the worker's default labeling judgement are available, a uniform prior on $\{b_t\}_{t=1}^T$ will be used.

Combining these two causes, we have

$$p(y_t^{(i)} | \mathbf{x}^{(i)}, \mathbf{w}_t, b_t, z_t^{(i)}) = p(y_t^{(i)} | \mathbf{x}^{(i)}, \mathbf{w}_t)^{z_t^{(i)}} p(y_t^{(i)} | b_t)^{(1-z_t^{(i)})}, \quad (5)$$

where $z_t^{(i)} \in \{0, 1\}$ determines whether (3) or (4) should be used to generate $y_t^{(i)}$. Intuitively, an expert worker should have an accurate prediction model (δ_t is small), and be dedicated to the task ($z_t^{(i)} = 1$ on most $\mathbf{x}^{(i)}$'s); whereas a spammer either has a large δ_t or $z_t^{(i)} = 0$ most of the time.

2.3 INCORPORATING SAMPLE DIFFICULTY

The difficulty of a sample can greatly affect the annotation quality (Whitehill et al., 2009; Yan et al., 2010; Zhou et al., 2012). If a sample is vaguely described or too hard, even an expert may have to make a random guess and thus acts as if he has not looked at the sample. On the contrary, if a sample is very easy, even a spammer (especially the lazy ones) can quickly make a correct decision.

To model this effect on worker t , we incorporate the difficulty of $\mathbf{x}^{(i)}$ into the modeling of $z_t^{(i)}$. Intuitively, if $\mathbf{x}^{(i)}$ is difficult to annotate, $z_t^{(i)}$ should be close to 0. From (5), the annotation made is then independent of the decision model of worker t . To measure sample difficulty, we use the popular notion that worker t will perceive $\mathbf{x}^{(i)}$ as difficult if it is close to his decision boundary (Tong and Koller, 2002; Dong et al., 2013; Welinder et al., 2010). Thus, we arrive at the following Bernoulli distribution on $z_t^{(i)}$:

$$p(z_t^{(i)} = 1 | \mathbf{x}^{(i)}, \mathbf{w}_t, \lambda_t) = 2\sigma\left(\lambda_t \frac{\|\mathbf{w}_t^T \mathbf{x}^{(i)}\|^2}{\|\mathbf{w}_t\|^2}\right) - 1. \quad (6)$$

Here, $\frac{\|\mathbf{w}_t^T \mathbf{x}^{(i)}\|}{\|\mathbf{w}_t\|}$ is the distance of $\mathbf{x}^{(i)}$ from worker t 's decision boundary $\mathbf{w}_t^T \mathbf{x} = 0$, and $\lambda_t \geq 0$ models the sensitivity of worker t 's annotation to sample difficulty. Depending on each worker's expertise (as reflected by his \mathbf{w}_t), one worker may consider sample $\mathbf{x}^{(i)}$ difficult while another worker may consider it easy. Moreover, a small λ_t makes an easy sample (with a large $\frac{\|\mathbf{w}_t^T \mathbf{x}^{(i)}\|}{\|\mathbf{w}_t\|}$) look difficult and worker t will rely more on his default judgement, and vice versa. As we are only interested in the value of $\lambda_t \frac{\|\mathbf{w}_t^T \mathbf{x}^{(i)}\|^2}{\|\mathbf{w}_t\|^2}$ in (6), to simplify inference, we reparameterize (6) as

$$p(z_t^{(i)} = 1 | \mathbf{x}^{(i)}, \mathbf{w}_t, \lambda_t) = 2\sigma(\lambda_t \|\mathbf{w}_t^T \mathbf{x}^{(i)}\|^2) - 1. \quad (7)$$

After obtaining \mathbf{w}_t , the sensitivity of worker t 's annotation to sample difficulty can be recovered as $\lambda_t \|\mathbf{w}_t\|^2$.

A graphical model representation for the complete model is shown in Figure 1.

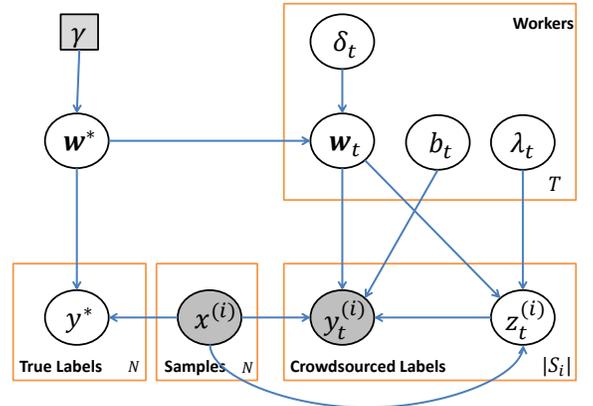

Figure 1: The proposed model incorporating sample difficulty and two sources for worker annotation.

2.4 EXTENSIONS

When the crowdsourced task is a multiclass classification problem, one can simply replace the Bernoulli distribution with a multinomial distribution. Similarly, for regression problems, the normal distribution can be used instead.

For ease of exposition, we use the linear logistic regression model in (1) and (2). This has also been used in most previous works (Raykar et al., 2010; Kajino et al., 2012). It can be easily replaced by any binary classifier. For example, to use a nonlinear kernelized version, one can replace $\mathbf{w}^*^T \mathbf{x}^{(i)}$ in (1) by $\sum_{j=1}^N \alpha^{*(j)} k(\mathbf{x}^{(j)}, \mathbf{x}^{(i)})$, where $k(\cdot, \cdot)$ is an appropriate kernel function. Similarly, $\mathbf{w}_t^T \mathbf{x}^{(i)}$ in (2) is replaced by $\sum_{j=1}^N \alpha_t^{(j)} k(\mathbf{x}^{(j)}, \mathbf{x}^{(i)})$, where $\alpha_t = [\alpha_t^{(1)}, \dots, \alpha_t^{(N)}]$ serves as worker t 's "estimation"

of the ground truth $\boldsymbol{\alpha}^* = [\alpha^{*(1)}, \dots, \alpha^{*(N)}]^T$. Analogous to (3), we can assume that each $\boldsymbol{\alpha}_t$ is sampled from $\mathcal{N}(\boldsymbol{\alpha}^*, \delta_t^2 \mathbf{I})$.

3 INFERENCE

In this section, we use the Expectation Maximization (EM) algorithm (Dempster et al., 1977) to obtain the model parameters $\Theta = \{\mathbf{w}^*, \{\mathbf{w}_t\}_{t=1}^T, \{\delta_t\}_{t=1}^T, \{b_t\}_{t=1}^T, \{\lambda_t\}_{t=1}^T\}$. Let the samples $\mathbf{X} = \{\mathbf{x}^{(1)}, \dots, \mathbf{x}^{(N)}\}$ be independent. By treating $\mathbf{Y} = \{y_t^{(i)}\}$ as the observed data and $\mathbf{Z} = \{z_t^{(i)}\}$ as the missing data, the complete data likelihood can be written as

$$\begin{aligned} \mathcal{L}(\mathbf{Y}, \mathbf{Z}) &= p(\mathbf{Y}, \mathbf{Z} | \mathbf{X}, \Theta) \\ &= p(\mathbf{Y} | \mathbf{Z}, \mathbf{X}, \{\mathbf{w}_t, b_t\}_{t=1}^T) p(\mathbf{Z} | \mathbf{X}, \{\mathbf{w}_t, \lambda_t\}_{t=1}^T) \\ &= \prod_{i=1}^N \prod_{t \in S_i} p(y_t^{(i)} | z_t^{(i)}, \mathbf{w}_t, \mathbf{x}^{(i)}, b_t) p(z_t^{(i)} | \mathbf{w}_t, \mathbf{x}^{(i)}, \lambda_t), \end{aligned} \quad (8)$$

by assuming that the workers annotate independently. The posterior of Θ is then

$$\begin{aligned} p(\mathbf{w}^*, \{\mathbf{w}_t\}_{t=1}^T, \{\delta_t\}_{t=1}^T, \{\lambda_t\}_{t=1}^T, \{b_t\}_{t=1}^T | \mathbf{X}, \mathbf{Y}, \mathbf{Z}) \\ \propto \mathcal{L}(\mathbf{Y}, \mathbf{Z}) p(\mathbf{w}^*) \prod_{t=1}^T p(\mathbf{w}_t | \mathbf{w}^*, \delta_t) p(\delta_t) p(\lambda_t) p(b_t), \end{aligned} \quad (9)$$

3.1 E-STEP

Taking the log of (8), we have

$$\begin{aligned} \log \mathcal{L}(\mathbf{Y}, \mathbf{Z}) &= \sum_{i=1}^N \sum_{t \in S_i} \left(z_t^{(i)} \log p(y_t^{(i)} | \mathbf{w}_t, \mathbf{x}^{(i)}) p(z_t^{(i)} = 1 | \mathbf{w}_t, \mathbf{x}^{(i)}, \lambda_t) \right. \\ &\quad \left. + (1 - z_t^{(i)}) \log p(y_t^{(i)} | b_t) p(z_t^{(i)} = 0 | \mathbf{w}_t, \mathbf{x}^{(i)}, \lambda_t) \right). \end{aligned}$$

The expected value of $z_t^{(i)}$, denoted $\bar{z}_t^{(i)}$, is

$$\bar{z}_t^{(i)} = \frac{1}{Q_t^{(i)}} p(y_t^{(i)} | \mathbf{w}_t, \mathbf{x}^{(i)}) p(z_t^{(i)} = 1 | \mathbf{w}_t, \mathbf{x}^{(i)}, \lambda_t),$$

where $Q_t^{(i)} = p(z_t^{(i)} = 1 | \mathbf{w}_t, \mathbf{x}^{(i)}, \lambda_t) p(y_t^{(i)} | \mathbf{w}_t, \mathbf{x}^{(i)}) + p(z_t^{(i)} = 0 | \mathbf{w}_t, \mathbf{x}^{(i)}, \lambda_t) p(y_t^{(i)} | b_t)$.

As can be seen, whether $\bar{z}_t^{(i)}$ is close to 1 is affected by both the sample difficulty (i.e., $p(z_t^{(i)} = 1 | \mathbf{w}_t, \mathbf{x}^{(i)}, \lambda_t)$) and the confidence of $y_t^{(i)}$ generated from the current estimated function \mathbf{w}_t (i.e., $p(y_t^{(i)} | \mathbf{w}_t, \mathbf{x}^{(i)})$).

¹In the kernelized version, $\Theta = \{\boldsymbol{\alpha}^*, \{\boldsymbol{\alpha}_t\}_{t=1}^T, \{\delta_t\}_{t=1}^T, \{b_t\}_{t=1}^T, \{\lambda_t\}_{t=1}^T\}$ and the EM procedure is similar. In particular, the M-step updates $\boldsymbol{\alpha}^*$ and $\{\boldsymbol{\alpha}_t\}_{t=1}^T$ as \mathbf{w}^* and $\{\mathbf{w}_t\}_{t=1}^T$.

3.2 M-STEP

Here, we use alternating minimization. At each step, one variable is minimized while the other variables are fixed.

- \mathbf{w}_t 's: From (9), the various \mathbf{w}_t 's can be learned independently. The optimization subproblem for \mathbf{w}_t is

$$\begin{aligned} \min_{\mathbf{w}_t} \quad & \frac{1}{\delta_t^2} \|\mathbf{w}_t - \mathbf{w}^*\|^2 - \sum_{i: t \in S_i} \left(\bar{z}_t^{(i)} y_t^{(i)} \log \sigma(\mathbf{w}_t^T \mathbf{x}^{(i)}) \right. \\ & + \bar{z}_t^{(i)} (1 - y_t^{(i)}) \log(1 - \sigma(\mathbf{w}_t^T \mathbf{x}^{(i)})) \\ & + \bar{z}_t^{(i)} \log(2\sigma(\lambda_t \|\mathbf{w}_t^T \mathbf{x}^{(i)}\|^2) - 1) \\ & \left. + (1 - \bar{z}_t^{(i)}) \log(2 - 2\sigma(\lambda_t \|\mathbf{w}_t^T \mathbf{x}^{(i)}\|^2)) \right). \end{aligned}$$

This can be maximized by gradient descent, and the gradient w.r.t. \mathbf{w}_t is

$$\begin{aligned} \frac{2}{\delta_t^2} (\mathbf{w}_t - \mathbf{w}^*) - \sum_{i: t \in S_i} \left(\bar{z}_t^{(i)} (y_t^{(i)} - \sigma(\mathbf{w}_t^T \mathbf{x}^{(i)})) \mathbf{x}^{(i)} \right. \\ \left. + \frac{(\bar{z}_t^{(i)} - 2\sigma(v_t^{(i)} + 1)\sigma(v_t^{(i)})\lambda_t \mathbf{w}_t^T \mathbf{x}^{(i)} \mathbf{x}^{(i)})}{2\sigma(v_t^{(i)}) - 1} \right), \end{aligned}$$

where $v_t^{(i)} = \lambda_t \|\mathbf{w}_t^T \mathbf{x}^{(i)}\|^2$.

- \mathbf{w}^* : The optimization subproblem for \mathbf{w}^* is

$$\min_{\mathbf{w}^*} \sum_{t=1}^T \frac{1}{\delta_t^2} \|\mathbf{w}_t - \mathbf{w}^*\|^2 + \gamma \|\mathbf{w}^*\|^2,$$

with the closed-form solution

$$\mathbf{w}^* = \frac{\sum_{t=1}^T \frac{1}{\delta_t^2} \mathbf{w}_t}{\gamma + \sum_{t=1}^T \frac{1}{\delta_t^2}}. \quad (10)$$

Note that \mathbf{w}^* is a weighted average of all the \mathbf{w}_t 's, with contributions from the experts (those with small δ_t 's) weighted heavier.

- δ_t : The optimization subproblem for δ_t is

$$\begin{aligned} \min_{\delta_t} \quad & \frac{1}{\delta_t^2} \|\mathbf{w}_t - \mathbf{w}^*\|^2 + \log \det(\delta_t^2 \mathbf{I}) \\ & = \min_{\delta_t} \frac{1}{\delta_t^2} \|\mathbf{w}_t - \mathbf{w}^*\|^2 + 2d \log \delta_t, \end{aligned}$$

where \mathbf{I} is the $d \times d$ identity matrix, and d is the number of input features. By setting its derivative w.r.t. δ_t to 0, we obtain

$$\delta_t = \frac{1}{\sqrt{d}} \|\mathbf{w}_t - \mathbf{w}^*\|.$$

- b_t : The optimization subproblem is

$$\max_{b_t} \sum_{i: t \in S_i} (1 - \bar{z}_t^{(i)}) (y_t^{(i)} \log b_t + (1 - y_t^{(i)}) \log(1 - b_t)).$$

By setting its derivative w.r.t. b_t to 0, we have

$$\sum_{i:t \in S_i} (1 - \bar{z}_t^{(i)}) \left(\frac{y_t^{(i)}}{b_t} - \frac{1 - y_t^{(i)}}{1 - b_t} \right) = 0.$$

Rearranging gives the closed-form solution

$$b_t = \frac{\sum_{i:t \in S_i} (1 - \bar{z}_t^{(i)}) y_t^{(i)}}{\sum_{i:t \in S_i} (1 - \bar{z}_t^{(i)})}.$$

Recall that $\bar{z}_t^{(i)} \in [0, 1]$ is the expectation of $y_t^{(i)}$ generated by worker t 's default judgement. Hence, b_t is simply the average of worker t 's labels that are generated by his default judgement.

- $\{\lambda_t\}_{t=1}^T$: The optimization subproblem is

$$\begin{aligned} \max_{\lambda_t} \sum_{i:t \in S_i} \bar{z}_t^{(i)} \log(2\sigma(\lambda_t \|\mathbf{w}_t^T \mathbf{x}^{(i)}\|^2) - 1) \\ + (1 - \bar{z}_t^{(i)}) \log(2 - 2\sigma(\lambda_t \|\mathbf{w}_t^T \mathbf{x}^{(i)}\|^2)). \end{aligned}$$

Again, this can be solved by projected gradient (as $\lambda_t \geq 0$), with the gradient w.r.t. λ_t given by

$$\sum_{i:t \in S_i} \frac{(\bar{z}_t^{(i)} - 2\sigma(v_t^{(i)}) + 1)\sigma(v_t^{(i)}) \|\mathbf{w}_t^T \mathbf{x}^{(i)}\|^2}{2\sigma(v_t^{(i)}) - 1}.$$

4 EXPERIMENTS

In this section, we perform two sets of experiments to evaluate the performance of the proposed method. Section 4.2 simulates a crowdsourced environment with synthetic workers using a standard benchmark data set; while Section 4.3 uses data sets with real labels crowdsourced from the AMT.

4.1 SETUP

The proposed model will be compared with the following groups of algorithms:

1. Algorithms that learn prediction models directly from samples to labels (Table 1). In particular, we will compare with
 - **MTL**: The multitask formulation in (Kajino et al., 2012). Each worker is considered as a task, and the prediction model is a rescaled average of all the learned worker models.
 - **RY**: The two-coin model in (Raykar et al., 2010). It considers the annotation generated by flipping the ground truth label with a certain biased probability.

- **YAN**: This model is proposed in (Yan et al., 2010), and an extension of (Raykar et al., 2010). Its flipping probability is sample-specific and varies with sample difficulty. However, unlike ours, it does not have a clear connection with the worker's decision function.

2. Algorithms that do not learn a prediction model from samples to labels (Table 1). In particular, we will compare with

- **GLAD** (Whitehill et al., 2009)²: It models each sample's difficulty level and each worker's expertise.
- **CUBAM** (Welinder et al., 2010)³:: It considers sample competence, worker expertise and bias.
- **MV**: Majority voting, a popular baseline which essentially treats all the workers as equally accurate.

For prediction on an unseen test sample, these algorithms have to first crowdsource its labels. To avoid this problem, we will proceed as follows: (i) Estimate the "true" labels of the training samples using each of these algorithms; (ii) Use the estimated labels to train a logistic regression model; (iii) Use the trained regression model to make predictions on the test samples.

3. We also include an ideal baseline (**Ideal**), which is a logistic regression model trained using the training samples with ground truth labels.

For performance evaluation, we follow (Raykar et al., 2010) and report the area under ROC curve (AUC). The ROC curve is obtained by varying the prediction threshold. Parameters in all the models are tuned by a validation set (which is constructed by using 20% of the training data). With the chosen parameters, a prediction model is then learned using all the training data.

4.2 UCI DATA SET

Following (Kajino et al., 2012), we use the red wine data in the UCI Wine-Quality data set⁴. There are a total of 1,599 samples, each with 11 features. The original multiclass labels are binarized such that samples with quality levels below 7 are labeled as 0, and 1 otherwise. 70% of the samples are randomly chosen for training, and the remaining 30% for testing. To reduce statistical variability, results are averaged over 5 repetitions.

4.2.1 Generation of Labels

We generate three sets of simulated crowdsourced labels based on different model assumptions:

- Set 1: The crowdsourced labels are generated using the proposed annotation process. The “optimal” \mathbf{w}^* is obtained by training a logistic regression model on all the training and test samples. We generate different numbers (20 and 40) of noisy workers. For each worker, we generate \mathbf{w}_t as in (3) with different settings of δ_t ’s:

1. $\frac{1}{4}$ of the workers have $\delta_t = 10$ (high expertise);
2. $\frac{1}{2}$ of the workers have $\delta_t = 100$ (moderate expertise); and
3. $\frac{1}{4}$ of the workers have $\delta_t = 1000$ (low expertise).

Sample difficulty is generated as in Section 2.3:

1. For the expert workers, we set $\lambda_t = 10,000$, and so most of the samples appear easy;
2. For workers with moderate expertise, set $\lambda_t = 100$; and
3. For workers with low expertise, set $\lambda_t = 1$ (and so most of the samples appear difficult).

For each sample i , we set $z_t^{(i)} = 1$ with probability given in (7). If $z_t^{(i)} = 1$, $y_t^{(i)}$ is labeled 1 with probability defined in (2); otherwise, $y_t^{(i)}$ is always labeled 1 (i.e., b_t in (4) is set to 1).

In summary, $\frac{1}{4}$ of the workers are experts, $\frac{1}{2}$ of them are non-experts but not very noisy; while the remaining $\frac{1}{4}$ are very noisy workers.

- Set 2: The crowdsourced labels are generated using the MTL assumption in (Kajino et al., 2012). Specifically, from the \mathbf{w}_t generated in Set 1, we generate $y_t^{(i)} = 1$ with probability $\sigma(\mathbf{w}_t^T \mathbf{x}^{(i)})$.
- Set 3: The crowdsourced labels are generated using the two-coin assumption in (Raykar et al., 2010). For worker t , let α_t (resp. β_t) be the probability that a ground truth label with value 1 (resp. 0) is flipped.

1. For $\frac{1}{4}$ of the workers, we set $\alpha_t = \beta_t = 0.05$ (experts);
2. For $\frac{1}{2}$ of the workers, set $\alpha_t = \beta_t = 0.25$ (non-experts but not very noisy); and
3. For $\frac{1}{4}$ of the workers, set $\alpha_t = \beta_t = 0.55$ (very noisy workers).

4.2.2 Results on ROC Curves

Figure 2 shows the obtained testing ROC curves (with each point averaged over the five repetitions). The corresponding averaged AUC values are shown in Table 2. As can be seen, the proposed model performs well under various noise generation scenarios.

On Set 1, since the labels are generated using the proposed annotation process, the proposed method performs significantly better than the others as expected. MTL is the second best, as it also builds a prediction model for each worker. RY, YAN, GLAD, CUBAM and MV perform poorly, as their model assumptions are very different from the underlying data generation process.

On Set 2, MTL is the best. The proposed model also yields comparable performance; while the others do not perform well.

On Set 3, MTL, RY, GLAD, CUBAM and the proposed method have comparable performance. Their performance gaps with Ideal are also quite small, which is consistent with the results in (Kajino et al., 2012). As various methods can perform well here, it suggests that the noise generated by the two-coin model is easier to remove than those in the previous two settings.

4.2.3 Separating Experts from Noisy Workers

In this section, we examine the proposed model’s ability to separate experts from noisy workers using the two criteria: worker expertise and worker dedication. Because of the lack of space, we will only show results (averaged over the 5 repetitions) on Set 1.

First, we check if the proposed model can detect workers with high expertise. Figures 3(a) and 3(b) show the contri-

bution of w_t in w^* in (10) (i.e., $\frac{1}{\delta_t^2}/(\gamma + \sum_j \frac{1}{\delta_j^2})$). As can be seen, all the nonzero contributions are from the experts, while the other workers are barely used.

Next, we check if the proposed model can find the dedicated workers. Recall that for experts, most of his $z_t^{(i)}$'s should be close to 1; while most of the $z_t^{(i)}$'s for non-dedicated workers are close to 0. Figures 3(c) and 3(d) show the value of $\hat{z}_t = \sum_{i:t \in S_i} \bar{z}_t^{(i)}$ for each worker. As expected, the \hat{z} 's of experts are large; while those of the others are usually much smaller (especially for the noisy workers).

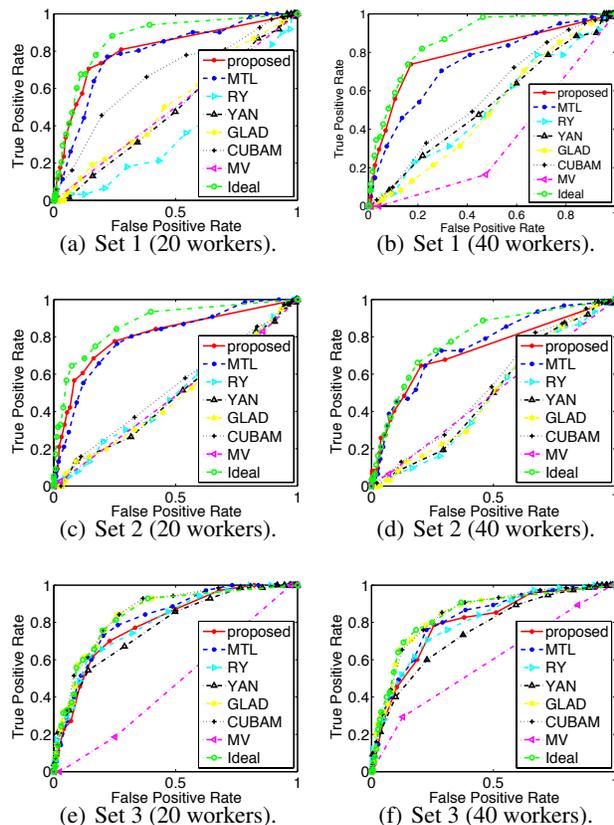

Figure 2: Testing ROC curves on the wine data set.

4.3 DATA SETS CROWDSOURCED FROM AMT

4.3.1 Data Collection and Feature Extraction

For better performance evaluation, it is desirable for the data set to satisfy the following three conditions: (i) It is labeled by a sufficient number of workers so that workers with different expertise and dedications are all involved; (ii) Each worker labels a sufficient amount of data so that one can reliably model the annotating behavior of each worker ; (iii) The ground truth labels are provided. To our best knowledge, very few crowdsourced data sets meet

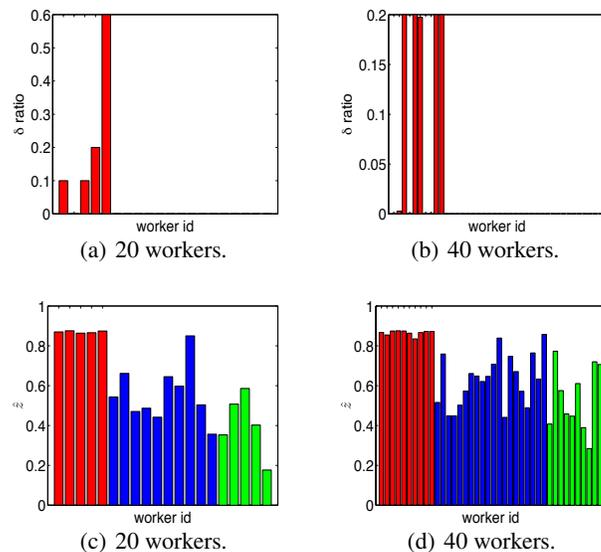

Figure 3: Worker expertise and worker dedication on the Set 1 data. 3(a) and 3(b): Contribution of each worker t towards w^* ($\frac{1}{\delta_t^2}/(\gamma + \sum_j \frac{1}{\delta_j^2})$). 3(c) and 3(d): Average \hat{z} 's of the workers. Columns in red/blue/green correspond to experts/non-experts/noisy workers. In 3(a) and 3(c): workers 1-5 are experts; 6-15 are non-experts; and 16-20 are noisy workers. In 3(b) and 3(d): workers 1-10 are experts; 11-30 are non-experts ; and 31-40 are noisy workers.

all these requirements. Thus, in the following, we build a crowdsourced data set based on the Stanford Dog data set⁵ (Khosla et al., 2011). It contains images of 120 breeds (categories) of dogs collected from the ImageNet⁶ (Deng et al., 2009).

For an image, its raw pixel representation is very high-dimensional and also sensitive to image changes such as scales, object locations, illuminations. Consequently, various image features have been studied by the computer vision community to better represent the image from low level (e.g. SIFT (Lowe, 1999)) to mid-level descriptors (Wang et al., 2012). In this experiment, we extract 4,096-dimensional features from images using the DeCAF (deep convolutional activation feature) algorithm (Donahue et al., 2014). These features are outputs from the intermediate layers of a pre-trained deep convolutional neural network (Krizhevsky et al., 2012). It has been shown that they can be used as generic representations for various vision tasks, and have achieved good performance even when combined with simple linear classifiers (Donahue et al., 2014).

⁵<http://vision.stanford.edu/aditya86/ImageNetDogs/>

⁶<http://www.image-net.org/>

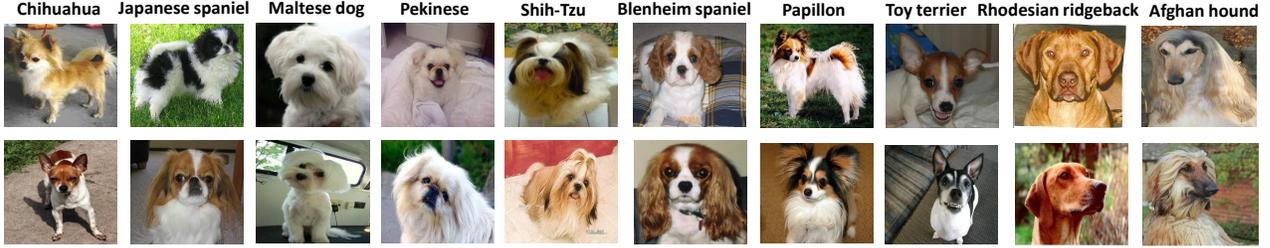

Figure 4: Sample images of the 10 dog categories.

4.3.2 Setup

We select the 10 categories that are most difficult to classify (Khosla et al., 2011) (Figure 4). For each category, images belonging to this category are taken as positive samples; while images from the other categories are treated as negative samples. Some statistics of the data sets are shown in Table 3. The constructed data sets are then randomly split into HITs on the AMT. Each HIT contains 50 images and is labeled by 6 workers. There are a total of 65 HITS and 21 workers over the 10 categories.

Table 3: Statistics on the dog data sets.

data set	#positive sample	#negative sample	avg #samples per worker
Chihuahua	142	157	85
Japanese spaniel	142	157	85
Maltese dog	142	163	85
Pekinese	142	163	85
Shih-Tzu	142	157	83
Blenheim spaniel	142	207	89
Papillon	142	175	92
Toy terrier	142	175	86
Rhodesian ridgeback	142	207	88
Afghan hound	142	207	89

For each category, we randomly use 50% of the samples for training, and the rest for testing. To reduce statistical variability, results are averaged over 5 repetitions.

4.3.3 Results on ROC Curves

The ROC curves are shown in Figure 5, and the corresponding AUC values in Table 4. As can be seen, the proposed method yields the highest AUC on all 10 categories. It is then followed by CUBAM, GLAD, RY and YAN, which are very competitive on some categories. MTL can sometimes achieve good performance (e.g., Blenheim spaniel), but are often much inferior. Overall, the simple MV is the worst.

4.3.4 Experts vs Noisy Workers

As in Section 4.2.3, we examine the obtained δ_t 's and \bar{z}_t 's on the Chihuahua, Japanese spaniel and Maltese dog categories. As the real experts and noisy workers are not known, we assume that workers with high overall accuracy

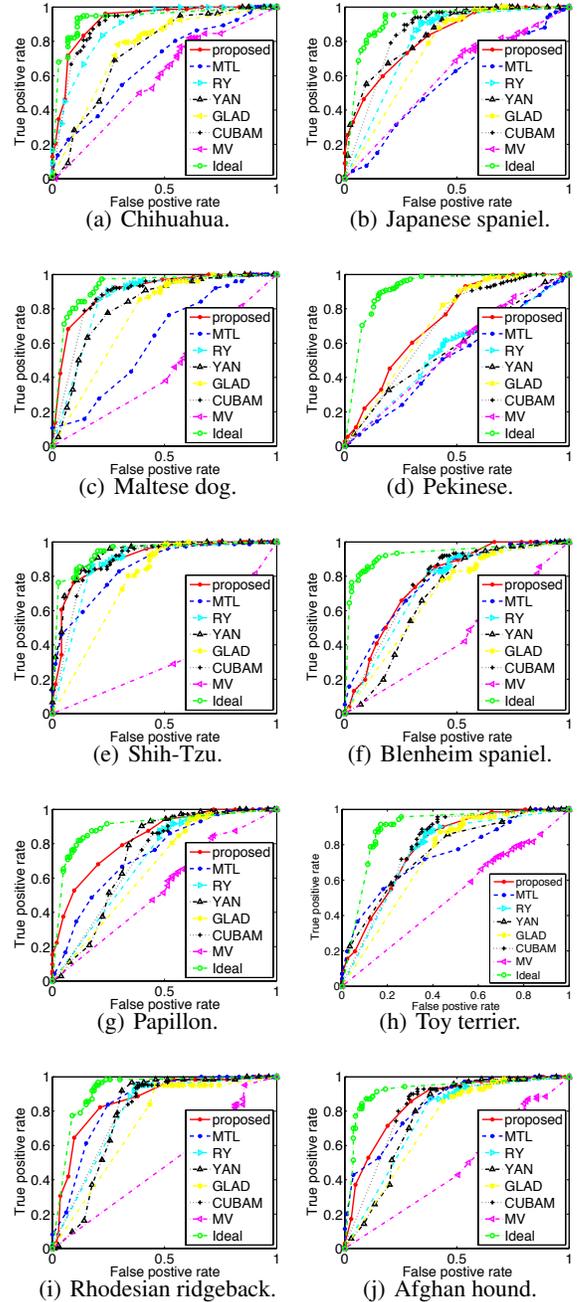

Figure 5: Testing ROC curves of the dog data sets.

Table 4: Testing AUCs on the **dog** data sets. The best results and those that are not statistically worse (according to the paired t-test with p-value less than 0.05) are in bold.

data set	proposed	MTL	RY	YAN	GLAD	CUBAM	MV	Ideal

Papillon	0.83 ± 0.03	0.74 ± 0.07	0.70 ± 0.05	0.74 ± 0.04	0.66 ± 0.04	0.72 ± 0.04	0.53 ± 0.06	0.90 ± 0.03
Toy terrier	0.79 ± 0.02	0.75 ± 0.01	0.76 ± 0.03	0.76 ± 0.03	0.73 ± 0.02	0.79 ± 0.04	0.51 ± 0.05	0.89 ± 0.03
Rhodesian ridgeback	0.86 ± 0.04	0.85 ± 0.03	0.79 ± 0.02	0.78 ± 0.02	0.73 ± 0.05	0.79 ± 0.04	0.50 ± 0.05	0.92 ± 0.01
Afghan hound	0.85 ± 0.02	0.83 ± 0.02	0.76 ± 0.01	0.77 ± 0.01	0.73 ± 0.04	0.81 ± 0.04	0.47 ± 0.05	0.93 ± 0.01

cies (that are computed based on both the training and test samples) are experts. In Figures 6(a),(c) and (e), we first plot the overall accuracies versus average weighting of the workers ($\frac{1}{\delta_t^2}/(\gamma + \sum_j \frac{1}{\delta_j^2})$) over five repetitions. As can be seen, workers with high weights, which are detected as experts in our model, generally have high overall accuracies. Next, we plot the overall accuracies versus average \hat{z}_t 's of the workers over five repetitions (Figures 6(b),(d) and (e)). Workers with high average \hat{z}_t 's are detected as dedicated workers and those with low average \hat{z}_t 's as lazy workers. As shown, the detected dedicated workers generally have high overall accuracies.

5 CONCLUSION

In this paper, we proposed a new model for crowdsourced labels that can perform out-of-sample prediction effectively. We observe that the worker's expertise and dedication to the task greatly affect the labeling process. We employed a mixture of distributions to model the annotation process: one models the worker's expertise and the other one depicts worker's labeling judgement with his random guess. We showed that this model can be easily extended to account for sample difficulty. The proposed model can be solved by the simple EM algorithm. Experiments on both UCI and real-world crowdsourced data sets demonstrate that the proposed method has significant improvements over other state-of-the-art approaches.

Abstract

We analyze variational inference for highly symmetric graphical models such as those arising from first-order probabilistic models. We first show that for these graphical models, the tree-reweighted variational objective lends itself to a compact lifted formulation which can be solved much more efficiently than the standard TRW formulation for the ground graphical model. Compared to earlier work on lifted belief propagation, our formulation leads to a convex optimization problem for lifted marginal inference and provides an upper bound on the partition function. We provide two approaches for improving the lifted TRW upper bound. The first is a method for efficiently computing maximum spanning trees in highly symmetric graphs, which can be used to optimize the TRW edge appearance probabilities. The second is a method for tightening the relaxation of the marginal polytope using lifted cycle inequalities and novel exchangeable cluster consistency constraints.

1 Introduction

Lifted probabilistic inference focuses on exploiting symmetries in probabilistic models for efficient inference [5, 2, 3, 10, 17, 18, 21]. Work in this area has demonstrated the possibility to perform very efficient inference in highly-connected, large tree-width, but *symmetric* models, such as those arising in the context of relational (first-order) probabilistic models and exponential family random graphs [19]. These models also arise frequently in probabilistic programming languages, an area of increasing importance as demonstrated by DARPA’s PPAML program (Probabilistic Programming for Advancing Machine Learning).

Even though lifted inference can sometimes offer order-of-magnitude improvement in performance, approximation is still necessary. A topic of particular interest is the interplay between lifted inference and variational approximate infer-

ence. Lifted loopy belief propagation (LBP) [13, 21] was one of the first attempts at exploiting symmetry to speed up loopy belief propagation; subsequently, counting belief propagation (CBP) [16] provided additional insights into the nature of symmetry in BP. Nevertheless, these work were largely procedural and specific to the choice of message-passing algorithm (in this case, loopy BP). More recently, Bui et al., [3] proposed a general framework for lifting a broad class of convex variational techniques by formalizing the notion of symmetry (defined via automorphism groups) of graphical models and the corresponding variational optimization problems themselves, independent of any specific methods or solvers.

Our goal in this paper is to extend the lifted variational framework in [3] to address the important case of approximate marginal inference. In particular, we show how to lift the tree-reweighted (TRW) convex formulation of marginal inference [28]. As far as we know, our work presents the first lifted *convex* variational marginal inference, with the following benefits over previous work: (1) a lifted convex upper bound of the log-partition function, (2) a new tightening of the relaxation of the lifted marginal polytope exploiting exchangeability, and (3) a convergent inference algorithm. We note that convex upper bounds of the log-partition function immediately lead to concave lower bounds of the log-likelihood which can serve as useful surrogate loss functions in learning and parameter estimation [29, 13].

To achieve the above goal, we first analyze the symmetry of the TRW log-partition and entropy bounds. Since TRW bounds depend on the choice of the edge appearance probabilities ρ , we prove that the quality of the TRW bound is not affected if one only works with suitably symmetric ρ . Working with symmetric ρ gives rise to an explicit lifted formulation of the TRW optimization problem that is equivalent but much more compact. This convex objective function can be convergently optimized via a Frank-Wolfe (conditional gradient) method where each Frank-Wolfe iteration solves a lifted MAP inference problem. We then discuss the optimization of the edge-appearance vector ρ , effectively yielding a lifted algorithm for computing maxi-

mum spanning trees in symmetric graphs.

As in Bui et al.’s framework, our work can benefit from any tightening of the local polytope such as the use of cycle inequalities [1, 23]. In fact, each method for relaxing the marginal polytope immediately yields a variant of our algorithm. Notably, in the case of exchangeable random variables, radically sharper tightening (sometimes even exact characterization of the lifted marginal polytope) can be obtained via a set of simple and elegant linear constraints which we call *exchangeable polytope constraints*. We provide extensive simulation studies comparing the behaviors of different variants of our algorithm with exact inference (when available) and lifted LBP demonstrating the advantages of our approach. The supplementary material [4] provides additional proof and algorithm details.

2 Background

We begin by reviewing variational inference and the tree-reweighted (TRW) approximation. We focus on inference in Markov random fields, which are distributions in the exponential family given by $\Pr(x; \theta) = \exp\{\langle \Phi(x), \theta \rangle - A(\theta)\}$, where $A(\theta)$ is called the *log-partition function* and serves to normalize the distribution. We assume that the random variables $x \in \mathcal{X}^n$ are discrete-valued, and that the features (Φ_i) , $i \in \mathcal{I}$ factor according to the graphical model structure \mathcal{G} ; Φ can be non-pairwise and is assumed to be overcomplete. This paper focuses on the inference tasks of estimating the marginal probabilities $p(x_i)$ and approximating the log-partition function. Throughout the paper, the domain \mathcal{X} is the binary domain $\{0, 1\}$, however, except for the construction of exchangeable polytope constraints in Section 6, this restriction is not essential.

Variational inference approaches view the log-partition function as a convex optimization problem over the marginal polytope $A(\theta) = \sup_{\mu \in \mathcal{M}(\mathcal{G})} \langle \mu, \theta \rangle - A^*(\mu)$ and seek tractable approximations of the negative entropy A^* and the marginal polytope \mathcal{M} [27]. Formally, $-A^*(\mu)$ is the entropy of the maximum entropy distribution with moments μ . Observe that $-A^*(\mu)$ is upper bounded by the entropy of the maximum entropy distribution consistent with any subset of the expected sufficient statistics μ . To arrive at the TRW approximation [26], one uses a subset given by the pairwise moments of a spanning tree¹. Hence for any distribution ρ over spanning trees, an upper bound on $-A^*$ is obtained by taking a convex combination of tree entropies $-B^*(\tau, \rho) = \sum_{s \in V(\mathcal{G})} H(\tau_s) - \sum_{e \in E(\mathcal{G})} I(\tau_e) \rho_e$. Since ρ is a distribution over spanning trees, it must belong to the spanning tree polytope $\mathbb{T}(\mathcal{G})$ with ρ_e denoting the edge appearance probability of e . Combined with a relaxation of the marginal polytope $\text{OUTER} \supset \mathcal{M}$, an upper

¹If the original model contains non-pairwise potentials, they can be represented as cliques in the graphical model, and the bound based on spanning trees still holds.

bound B of the log-partition function is obtained:

$$A(\theta) \leq B(\theta, \rho) = \sup_{\tau \in \text{OUTER}(\mathcal{G})} \langle \tau, \theta \rangle - B^*(\tau, \rho) \quad (1)$$

We note that B^* is linear w.r.t. ρ , and for $\rho \in \mathbb{T}(\mathcal{G})$, B^* is convex w.r.t. τ . On the other hand, B is convex w.r.t. ρ and θ .

The optimal solution $\tau^*(\rho, \theta)$ of the optimization problem (1) can be used as an approximation to the mean parameter $\mu(\theta)$. Typically, the local polytope LOCAL given by pairwise consistency constraints is used as the relaxation OUTER; in this paper, we also consider tightening of the local polytope.

Since (1) holds with any edge appearance ρ in the spanning tree polytope \mathbb{T} , the TRW bound can be further improved by optimizing ρ

$$\inf_{\rho \in \mathbb{T}(\mathcal{G})} B(\theta, \rho) \quad (2)$$

The resulting ρ^* is then plugged into (1) to find the marginal approximation. In practice, one might choose to work with some fixed choice of ρ , for example the uniform distribution over all spanning trees. [14] proposed using the most uniform edge-weight $\arg \inf_{\rho \in \mathbb{T}(\mathcal{G})} \sum_{e \in E} (\rho_e - \frac{|V|-1}{|E|})^2$ which can be found via conditional gradient where each direction-finding step solves a maximum spanning tree problem.

Several algorithms have been proposed for optimizing the TRW objective (1) given fixed edge appearance probabilities. [27] derived the tree-reweighted belief propagation algorithm from the fixed point conditions. [8] show how to solve the dual of the TRW objective, which is a geometric program. Although this algorithm has the advantage of guaranteed convergence, it is non-trivial to generalize this approach to use tighter relaxations of the marginal polytope, which we show is essential for lifted inference. [14] use an explicit set of spanning trees and then use dual decomposition to solve the optimization problem. However, as we show in the next section, to maintain symmetry it is essential that one *not* work directly with spanning trees but rather use symmetric edge appearance probabilities. [23] optimize TRW over the local and cycle polytopes using a Frank-Wolfe (conditional gradient) method, where each iteration requires solving a linear program. We follow this latter approach in our paper.

To optimize the edge appearance in (2), [26] proposed using conditional gradient. They observed that $\frac{\partial B(\theta, \rho)}{\partial \rho_e} = -\frac{\partial B^*(\tau^*, \rho)}{\partial \rho_e} = -I(\tau_e^*)$ where τ^* is the solution of (1). The direction-finding step in conditional gradient reduces to solving $\sup_{\rho \in \mathbb{T}(\mathcal{G})} \langle \rho, I \rangle$, again equivalent to finding the maximum spanning tree with edge mutual information $I(\tau_e^*)$ as weights. We discuss the corresponding lifted problem in section 5.

3 Lifted Variational Framework

We build on the key element of the lifted variational framework introduced in [3]. The automorphism group of a graphical model, or more generally, an exponential family is defined as the group \mathbb{A} of permutation pairs (π, γ) where π permutes the set of variables and γ permutes the set of features in such a way that they preserve the feature function: $\Phi^{\gamma^{-1}}(x^\pi) = \Phi(x)$. Note that this construction of \mathbb{A} is entirely based on the structure of the model and does not depend on the particular choice of the model parameters; nevertheless the group stabilizes² (preserves) the key characteristics of the exponential family such as the marginal polytope \mathcal{M} , the log-partition A and entropy $-A^*$.

As shown in [3] the automorphism group is particularly useful for exploiting symmetries when parameters are tied. For a given parameter-tying partition Δ such that $\theta_i = \theta_j$ for i, j in the same cell³ of Δ , the group \mathbb{A} gives rise to a subgroup called the lifting group \mathbb{A}_Δ that stabilizes the tied-parameter vector θ as well as the exponential family. The orbit partition of the the lifting group can be used to formulate equivalent but more compact variational problems. More specifically, let $\varphi = \varphi(\Delta)$ be the orbit partition induced by the lifting group on the feature index set $\mathcal{I} = \{1 \dots m\}$, let $\mathbb{R}_{[\varphi]}^m$ denote the symmetrized subspace $\{r \in \mathbb{R}^m \text{ s.t. } r_i = r_j \forall i, j \text{ in the same cell of } \varphi\}$ and define the lifted marginal polytope $\mathcal{M}_{[\varphi]}$ as $\mathcal{M} \cap \mathbb{R}_{[\varphi]}^m$, then (see Theorem 4 of [3])

$$\sup_{\mu \in \mathcal{M}} \langle \theta, \mu \rangle - A^*(\mu) = \sup_{\mu \in \mathcal{M}_{[\varphi]}} \langle \theta, \mu \rangle - A^*(\mu) \quad (3)$$

In practice, we need to work with convex variational approximations of the LHS of (3) where \mathcal{M} is relaxed to an outer bound $\text{OUTER}(\mathcal{G})$ and A^* is approximated by a convex function $B^*(\mu)$. We now state a similar result for lifting general convex approximations.

Theorem 1. *If $B^*(\mu)$ is convex and stabilized by the lifting group \mathbb{A}_Δ , i.e., for all $(\pi, \gamma) \in \mathbb{A}_\Delta$, $B^*(\mu^\gamma) = B^*(\mu)$, then φ is the lifting partition for the approximate variational problem*

$$\sup_{\mu \in \text{OUTER}(\mathcal{G})} \langle \theta, \mu \rangle - B^*(\mu) = \sup_{\mu \in \text{OUTER}_{[\varphi]}(\mathcal{G})} \langle \theta, \mu \rangle - B^*(\mu) \quad (4)$$

The importance of Theorem 1 is that it shows that it is equivalent to optimize over a subset of $\text{OUTER}(\mathcal{G})$ where pseudo-marginals in the same orbit are restricted to take the same value. As we will show in Section 4.2, this will allow us to combine many of the terms in the objective, which is where the computational gains will derive from. A

²Formally, \mathbb{G} stabilizes x if $x^g = x$ for all $g \in \mathbb{G}$.

³If $\Delta = \{\Delta_1 \dots \Delta_K\}$ is a partition of S , then each subset $\Delta_k \subset S$ is called a cell.

sketch of its proof is as follows. Consider a single pseudo-marginal vector μ . Since the objective value is the same for every μ^γ for $(\pi, \gamma) \in \mathbb{A}_\Delta$ and since the objective is concave, the *average* of these, $\frac{1}{|\mathbb{A}_\Delta|} \sum_{(\pi, \gamma) \in \mathbb{A}_\Delta} \mu^\gamma$, must have at least as good of an objective value. Furthermore, note that this averaged vector lives in the symmetrized subspace. Thus, it suffices to optimize over $\text{OUTER}_{[\varphi]}$.

4 Lifted Tree-Reweighted Problem

4.1 Symmetry of TRW Bounds

We now show that Theorem 1 can be used to lift the TRW optimization problem (1). Note that the applicability of Theorem 1 is not immediately obvious since B^* depends on the distribution over trees implicit in ρ . In establishing that the condition in Theorem 1 holds, we need to be careful so that the choice of the distribution over trees ρ does not destroy the symmetry of the problem.

The result below ensures that with no loss in optimality, ρ can be assumed to be suitably symmetric. More specifically, let $\varphi^E = \varphi^E(\Delta)$ be the set of \mathcal{G} 's edge orbits induced by the action of the lifting group \mathbb{A}_Δ ; the edge-weights ρ_e for every e in the same edge orbits can be constrained to be the same, i.e. ρ can be restricted to $\mathbb{T}_{[\varphi^E]}$.

Theorem 2. *For any $\rho \in \mathbb{T}$, there exists a symmetrized $\hat{\rho} \in \mathbb{T}_{[\varphi^E]}$ that yields at least as good an upper bound, i.e.*

$$B(\theta, \hat{\rho}) \leq B(\theta, \rho) \quad \forall \theta \in \Theta_{[\Delta]}$$

As a consequence, in optimizing the edge appearance, ρ can be restricted to the symmetrized spanning tree polytope $\mathbb{T}_{[\varphi^E]}$

$$\forall \theta \in \Theta_{[\Delta]}, \inf_{\rho \in \mathbb{T}} B(\theta, \rho) = \inf_{\rho \in \mathbb{T}_{[\varphi^E]}} B(\theta, \rho)$$

Proof. Let ρ be the argmin of the LHS, and define $\hat{\rho} = \frac{1}{|\mathbb{A}_\Delta|} \sum_{\pi \in \mathbb{A}_\Delta} \rho^\pi$ so that $\hat{\rho} \in \mathbb{T}_{[\varphi^E]}$. For all $(\pi, \gamma) \in \mathbb{A}_\Delta$ and for all tied-parameter $\theta \in \Theta_{[\Delta]}$, $\theta^\pi = \theta$, so $B(\theta, \rho^\pi) = B(\theta^\pi, \rho^\pi)$. By theorem 1 of [3], π must be an automorphism of the graph \mathcal{G} . By lemma 7 (see supplementary material), $B(\theta^\pi, \rho^\pi) = B(\theta, \rho)$. Thus $B(\theta, \rho^\pi) = B(\theta, \rho)$. Since B is convex w.r.t. ρ , by Jensen's inequality we have that $B(\theta, \hat{\rho}) \leq \frac{1}{|\mathbb{A}_\Delta|} \sum_{\pi \in \mathbb{A}_\Delta} B(\theta, \rho^\pi) = B(\theta, \rho)$. \square

Using a symmetric choice of ρ , the TRW bound B^* then satisfies the condition of theorem 1, enabling the applicability of the general lifted variational inference framework.

Theorem 3. *For a fixed $\rho \in \mathbb{T}_{[\varphi^E]}$, φ is the lifting partition for the TRW variational problem*

$$\sup_{\tau \in \text{OUTER}(\mathcal{G})} \langle \tau, \theta \rangle - B^*(\tau, \rho) = \sup_{\tau \in \text{OUTER}_{[\varphi]}(\mathcal{G})} \langle \tau, \theta \rangle - B^*(\tau, \rho) \quad (5)$$

4.2 Lifted TRW Problems

We give the explicit lifted formulation of the TRW optimization problem (5). As in [3], we restrict τ to $\text{OUTER}_{[\varphi]}$ by introducing the lifted variables $\bar{\tau}_j$ for each cell φ_j , and for all $i \in \varphi_j$, enforcing that $\tau_i = \bar{\tau}_j$. Effectively, we substitute every occurrence of $\tau_i, i \in \varphi_j$ by $\bar{\tau}_j$; in vector form, τ is substituted by $D\bar{\tau}$ where D is the characteristic matrix of the partition φ : $D_{ij} = 1$ if $i \in \varphi_j$ and 0 otherwise. This results in the lifted form of the TRW problem

$$\sup_{D\bar{\tau} \in \text{OUTER}} \langle \bar{\tau}, \bar{\theta} \rangle - \bar{B}^*(\bar{\tau}, \bar{\rho}) \quad (6)$$

where $\bar{\theta} = D^\top \theta$; \bar{B}^* is obtained from B^* via the above substitution; and $\bar{\rho}$ is the edge appearance per edge-orbit: for every edge orbit \mathbf{e} , and for every edge $e \in \mathbf{e}$, $\rho_e = \bar{\rho}_{\mathbf{e}}$. Using an alternative but equivalent form $B^* = -\sum_{v \in V} (1 - \sum_{e \in N_b(v)} \rho_e) H(\tau_v) - \sum_{e \in E} \rho_e H(\tau_e)$, we obtain the following explicit form for

$$\begin{aligned} \bar{B}^*(\bar{\tau}, \bar{\rho}) = & - \sum_{\mathbf{v} \in \bar{V}} \left(|\mathbf{v}| - \sum_{\mathbf{e} \in N(\mathbf{v})} |\mathbf{e}| d(\mathbf{v}, \mathbf{e}) \bar{\rho}_{\mathbf{e}} \right) H(\bar{\tau}_{\mathbf{v}}) \\ & - \sum_{\mathbf{e} \in \bar{E}} |\mathbf{e}| \bar{\rho}_{\mathbf{e}} H(\bar{\tau}_{\mathbf{e}}) \end{aligned} \quad (7)$$

Intuitively, the above can be viewed as a combination of node and edge entropies defined on nodes and edges of the lifted graph $\bar{\mathcal{G}}$. Nodes of $\bar{\mathcal{G}}$ are the node orbits of \mathcal{G} while edges are the edge-orbits of \mathcal{G} . $\bar{\mathcal{G}}$ is not a simple graph: it can have self-loops or multi-edges between the same node pair (see Fig. 1). We encode the incidence on this graph as follows: $d(\mathbf{v}, \mathbf{e}) = 0$ if \mathbf{v} is not incident to \mathbf{e} , $d(\mathbf{v}, \mathbf{e}) = 1$ if \mathbf{v} is incident to \mathbf{e} and \mathbf{e} is not a loop, $d(\mathbf{v}, \mathbf{e}) = 2$ if \mathbf{e} is a loop incident to \mathbf{v} . The *entropy* at the node orbit \mathbf{v} is defined as

$$H(\bar{\tau}_{\mathbf{v}}) = - \sum_{t \in \mathcal{X}} \bar{\tau}_{\mathbf{v}:t} \ln(\bar{\tau}_{\mathbf{v}:t})$$

and the entropy at the edge orbit \mathbf{e} is

$$H(\bar{\tau}_{\mathbf{e}}) = - \sum_{t, h \in \mathcal{X}} \bar{\tau}_{\{e_1:t, e_2:h\}} \ln(\bar{\tau}_{\{e_1:t, e_2:h\}})$$

where $\{e_1, e_2\}$ for $e_1, e_2 \in V$ is a representative (any element) of \mathbf{e} , $\{e_1:t, e_2:h\}$ is an assignment of the ground edge $\{e_1, e_2\}$, and $\overline{\{e_1:t, e_2:h\}}$ is the assignment orbit. As in [3], we write $\{e_1:t, e_2:t\}$ as $\mathbf{e}:t$, and for $t < h$, $\overline{\{e_1:t, e_2:h\}}$ as $\mathbf{a}:(t, h)$ where \mathbf{a} is the arc-orbit (e_1, e_2) .

When OUTER is the local or cycle polytope, the constraints $D\bar{\tau} \in \text{OUTER}$ yield the lifted local (or cycle) polytope respectively. For these constraints, we use the same form given in [3]. In section 6, we describe a set of additional constraints for further tightening when some cluster of nodes are exchangeable.

Example. Consider the MRF shown in Fig. 1 (left) with 10 binary variables that we denote B_i (for the blue nodes) and

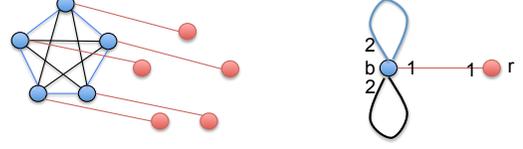

Figure 1: Left: ground graphical model. Same colored nodes and edges have the same parameters. Right: lifted graph showing 2 node orbits (\mathbf{b} and \mathbf{r}), and 3 edge orbits. Numbers on the lifted graph representing the incidence degree $d(\mathbf{v}, \mathbf{e})$ between an edge and a node orbit.

R_i (for the red nodes). The node and edge coloring denotes shared parameters. Let θ_b and θ_r be the single-node potentials used for the blue and red nodes, respectively. Let θ_{r_e} be the edge potential used for the red edges connecting the blue and red nodes, θ_{b_e} for the edge potential used for the blue edges (B_i, B_{i+1}), and θ_{k_e} for the edge potential used for the black edges (B_i, B_{i+2}).

There are two node orbits: $\mathbf{b} = \{B_1, \dots, B_5\}$ and $\mathbf{r} = \{R_1, \dots, R_5\}$. There are three edge orbits: \mathbf{r}_e for the red edges, \mathbf{b}_e for the blue edges, and \mathbf{k}_e for the black edges. The size of the node and edge orbits are all 5 (e.g., $|\mathbf{b}| = |\mathbf{b}_e| = 5$), and $d(\mathbf{b}, \mathbf{r}_e) = d(\mathbf{r}, \mathbf{r}_e) = 1$, $d(\mathbf{b}, \mathbf{b}_e) = d(\mathbf{b}, \mathbf{k}_e) = 2$. Suppose that ρ corresponds to a uniform distribution over spanning trees, which satisfies the symmetry needed by Theorem 2. We then have $\bar{\rho}_{\mathbf{r}_e} = 1$ and $\bar{\rho}_{\mathbf{b}_e} = \bar{\rho}_{\mathbf{k}_e} = \frac{2}{5}$. Putting all of this together, the lifted TRW entropy is given by $\bar{B}^*(\bar{\tau}, \bar{\rho}) = 8H(\bar{\tau}_{\mathbf{b}}) - 5H(\bar{\tau}_{\mathbf{r}_e}) - 2H(\bar{\tau}_{\mathbf{b}_e}) - 2H(\bar{\tau}_{\mathbf{k}_e})$. We illustrate the expansion of the entropy of the red edge orbit $H(\bar{\tau}_{\mathbf{r}_e})$. This edge orbit has 2 corresponding arc-orbits: $\mathbf{rb}_a = \{(R_i, B_i)\}$ and $\mathbf{br}_a = \{(B_i, R_i)\}$. Thus, $H(\bar{\tau}_{\mathbf{r}_e}) = -\bar{\tau}_{\mathbf{r}_e:00} \ln \bar{\tau}_{\mathbf{r}_e:00} - \bar{\tau}_{\mathbf{r}_e:11} \ln \bar{\tau}_{\mathbf{r}_e:11} - \bar{\tau}_{\mathbf{rb}_a:01} \ln \bar{\tau}_{\mathbf{rb}_a:01} - \bar{\tau}_{\mathbf{br}_a:01} \ln \bar{\tau}_{\mathbf{br}_a:01}$.

Finally, the linear term in the objective is given by $\langle \bar{\tau}, \bar{\theta} \rangle = 5 \langle \bar{\tau}_{\mathbf{b}}, \theta_b \rangle + 5 \langle \bar{\tau}_{\mathbf{r}}, \theta_r \rangle + 5 \langle \bar{\tau}_{\mathbf{r}_e}, \theta_{r_e} \rangle + 5 \langle \bar{\tau}_{\mathbf{b}_e}, \theta_{b_e} \rangle + 5 \langle \bar{\tau}_{\mathbf{k}_e}, \theta_{k_e} \rangle$ where, as an example, $\langle \bar{\tau}_{\mathbf{r}_e}, \theta_{r_e} \rangle = \bar{\tau}_{\mathbf{r}_e:00} \theta_{r_e,00} + \bar{\tau}_{\mathbf{r}_e:11} \theta_{r_e,11} + \bar{\tau}_{\mathbf{rb}_a:01} \theta_{r_e,01} + \bar{\tau}_{\mathbf{br}_a:01} \theta_{r_e,10}$

4.3 Optimization using Frank-Wolfe

What remains is to describe how to optimize Eq. 6. Our lifted tree-reweighted algorithm is based on Frank-Wolfe, also known as the conditional gradient method [7, 11]. First, we initialize with a pseudo-marginal vector corresponding to the uniform distribution, which is guaranteed to be in the lifted marginal polytope. Next, we solve the linear program whose objective is given by the gradient of the objective Eq. 6 evaluated at the current point, and whose constraint set is OUTER. When using the lifted cycle relaxation, we solve this linear program using a cutting-plane algorithm [3, 23]. We then perform a line search to find the optimal step size using a golden section search (a type of binary search that finds the maxima of a unimodal function), and finally repeat using the new pseudo-marginal vector. We warm start each linear program using the optimal basis found in the previous run, which makes the LP solves ex-

tremely fast after the first couple of iterations. Although we use a generic LP solver in our experiments, it is also possible to use dual decomposition to derive efficient algorithms specialized to graphical models [24].

5 Lifted Maximum Spanning Tree

Optimizing the TRW edge appearance probability ρ requires finding the maximum spanning tree (MST) in the ground graphical model. For lifted TRW, we need to perform MST while using only information from the node and edge orbits, without referring to the ground graph. In this section, we present a lifted MST algorithm for symmetric graphs which works at the orbit level.

Suppose that we are given a *weighted* graph (\mathcal{G}, w) , its automorphism group $\mathbb{A} = \text{Aut}(\mathcal{G})$ and its node and edge orbits. We aim to derive an algorithm analogous to the Kruskal’s algorithm, but with complexity depends only on the number of node/edge orbits of \mathcal{G} . However, if the algorithm has to return an actual spanning tree of \mathcal{G} then clearly its complexity cannot be less than $O(|V|)$. Instead, we consider an equivalent problem: solving a linear program on the spanning-tree polytope

$$\sup_{\rho \in \mathbb{T}(\mathcal{G})} \langle \rho, w \rangle \quad (8)$$

The same mechanism for lifting convex optimization problem (Lemma 1 in [3]) applies to this problem. Let φ^E be the edge orbit partition, then an equivalent lifted problem is

$$\sup_{\rho \in \mathbb{T}_{[\varphi^E]}} \langle \rho, w \rangle \quad (9)$$

Since ρ_e is constrained to be the same for edges in the same orbit, it is now possible to solve (9) with complexity depending only on the number of orbits. Any solution ρ of the LP (8) can be turned into a solution $\bar{\rho}$ of (9) by letting $\bar{\rho}(\mathbf{e}) = \frac{1}{|\mathbf{e}|} \sum_{e' \in \mathbf{e}} \rho(e')$.

5.1 Lifted Kruskal’s Algorithm

The Kruskal’s algorithm first sorts the edges according to their decreasing weight. Then starting from an empty graph, at each step it greedily attempts to add the next edge while maintaining the property that the used edges form a forest (containing no cycle). The forest obtained at the end of this algorithm is a maximum-weight spanning tree.

Imagine how Kruskal’s algorithm would operate on a weighted graph \mathcal{G} with non-trivial automorphisms. Let $\mathbf{e}_1, \dots, \mathbf{e}_k$ be the list of edge-orbits sorted in the order of decreasing weight (the weights w on all edges in the same orbit by definition must be the same). The main question therefore is how many edges in each edge-orbit \mathbf{e}_i will be added to the spanning tree by the Kruskal’s algorithm. Let \mathcal{G}_i be the subgraph of \mathcal{G} formed by the set of all the edges and nodes in $\mathbf{e}_1, \dots, \mathbf{e}_i$. Let $V(\mathcal{G})$ and $C(\mathcal{G})$ denote the set of nodes and set of connected components of a graph, respectively. Then (see the supplementary material for proof)

Lemma 4. *The number of edges in \mathbf{e}_i appearing in the MST found by the Kruskal’s algorithm is $\delta_V^{(i)} - \delta_C^{(i)}$ where $\delta_V^{(i)} = |V(\mathcal{G}_i)| - |V(\mathcal{G}_{i-1})|$ and $\delta_C^{(i)} = |C(\mathcal{G}_i)| - |C(\mathcal{G}_{i-1})|$. Thus a solution for the linear program (9) is $\bar{\rho}(\mathbf{e}_i) = \frac{\delta_V^{(i)} - \delta_C^{(i)}}{|\mathbf{e}_i|}$.*

5.2 Lifted Counting of the Number of Connected Components

We note that counting the number of nodes can be done simply by adding the size of each node orbit. The remaining difficulty is how to count the number of connected components of a given graph⁴ \mathcal{G} using only information at the orbit level. Let $\bar{\mathcal{G}}$ be the lifted graph of \mathcal{G} . Then (see supplementary material for proof)

Lemma 5. *If $\bar{\mathcal{G}}$ is connected then all connected components of \mathcal{G} are isomorphic. Thus if furthermore \mathcal{G}' is a connected component of \mathcal{G} then $|C(\mathcal{G})| = |V(\mathcal{G})|/|V(\mathcal{G}')|$.*

To find just one connected component, we can choose an arbitrary node u and compute $\bar{\mathcal{G}}[u]$, the lifted graph fixing u (see section 8.1 in [3]), then search for the connected component in $\bar{\mathcal{G}}[u]$ that contains $\{u\}$. Finally, if $\bar{\mathcal{G}}$ is not connected, we simply apply lemma 5 for each connected component of $\bar{\mathcal{G}}$.

The final lifted Kruskal’s algorithm combines lemma 4 and 5 while keeping track of the set of connected components of $\bar{\mathcal{G}}_i$ incrementally. The full algorithm is given in the supplementary material.

6 Tightening via Exchangeable Polytope Constraints

One type of symmetry often found in first-order probabilistic models are large sets of exchangeable random variables. In certain cases, exact inference with exchangeable variables is possible via lifted counting elimination and its generalization [17, 2]. The drawback of these exact methods is that they do not apply to many models (e.g., those with transitive clauses). Lifted variational inference methods do not have this drawback, however local and cycle relaxation can be shown to be loose in the exchangeable setting, a potentially serious limitation compared to earlier work.

To remedy this situation, we now show how to take advantage of highly symmetric subset of variables to tighten the relaxation of the lifted marginal polytope.

We call a set of random variables χ an *exchangeable* cluster iff χ can be arbitrary permuted while preserving the probability model. Mathematically, the lifting group \mathbb{A}_Δ acts on χ and the image of the action is isomorphic to $\mathbb{S}(\chi)$,

⁴Since we are only interested in connectivity in this subsection, the weights of \mathcal{G} play no role. Thus, orbits in this subsection can also be generated by the automorphism group of the unweighted version of \mathcal{G} .

the symmetric group on χ . The distribution of the random variables in χ is also exchangeable in the usual sense.

Our method for tightening the relaxation of the marginal polytope is based on lift-and-project, wherein we introduce auxiliary variables specifying the joint distribution of a large cluster of variables, and then enforce consistency between the cluster distribution and the pseudo-marginal vector [20, 24, 27]. In the ground model, one typically works with small clusters (e.g., triplets) because the number of variables grows exponentially with cluster size. The key (and nice) difference in the lifted case is that we can make use of very large clusters of highly symmetric variables: while the grounded relaxation would clearly blow up, the corresponding lifted relaxation can still remain compact.

Specifically, for an exchangeable cluster χ of arbitrary size, one can add cluster consistency constraints for the entire cluster and still maintain tractability. To keep the exposition simple, we assume that the variables are binary. Let \mathfrak{C} denote a χ -configuration, i.e., a function $\mathfrak{C} : \chi \rightarrow \{0, 1\}$. The set $\{\tau_{\mathfrak{C}}^{\chi} \mid \forall \text{ configuration } \mathfrak{C}\}$ is the collection of χ -cluster auxiliary variables. Since χ is exchangeable, all nodes in χ belong to the same node orbit; we call this node orbit $\mathbf{v}(\chi)$. Similarly, $\mathbf{e}(\chi)$ and $\mathbf{a}(\chi)$ denote the single edge and arc orbit that contains all edges and arcs in χ respectively. Let u_1, u_2 be two distinct nodes in χ . To enforce consistency between the cluster χ and the edge $\{u_1, u_2\}$ in the ground model, we introduce the constraints

$$\exists \tau^{\chi} : \quad \sum_{\mathfrak{C} \text{ s.t. } \mathfrak{C}(u_i)=s_i} \tau_{\mathfrak{C}}^{\chi} = \tau_{u_1:s_1, u_2:s_2} \quad \forall s_i \in \{0, 1\} \quad (10)$$

These constraints correspond to using intersection sets of size two, which can be shown to be the exact characterization of the marginal polytope involving variables in χ if the graphical model only has pairwise potentials. If higher-order potentials are present, a tighter relaxation could be obtained by using larger intersection sets together with the techniques described below.

The constraints in (10) can be methodically lifted by replacing occurrences of ground variables with lifted variables at the orbit level. First observe that in place of the grounded variables $\tau_{u_1:s_1, u_2:s_2}$, the lifted local relaxation has three corresponding lifted variables, $\bar{\tau}_{\mathbf{e}(\chi):00}$, $\bar{\tau}_{\mathbf{e}(\chi):11}$ and $\bar{\tau}_{\mathbf{a}(\chi):01}$. Second, we consider the orbits of the set of configurations \mathfrak{C} . Since χ is exchangeable, there can be only $|\chi| + 1$ χ -configuration orbits; each orbit contains all configurations with precisely k 1's where $k = 0 \dots |\chi|$. Thus, instead of the $2^{|\chi|}$ ground auxiliary variables, we only need $|\chi| + 1$ lifted cluster variables. Further manipulation leads to the following set of constraints, which we call *lifted exchangeable polytope* constraints.

Theorem 6. *Let χ be an exchangeable cluster of size n ; $\mathbf{e}(\chi)$ and $\mathbf{a}(\chi)$ be the single edge and arc orbit of the graphical model that contains all edges and arcs in χ respectively; $\bar{\tau}$ be the lifted marginals. Then there exist*

$c_k^{\chi} \geq 0, k = 0 \dots n$ such that

$$\begin{aligned} \sum_{k=0}^{n-2} \frac{(n-k)(n-k-1)}{n(n-1)} c_k^{\chi} &= \bar{\tau}_{\mathbf{e}(\chi):00} \\ \sum_{k=0}^{n-2} \frac{(k+1)(k+2)}{n(n-1)} c_{k+2}^{\chi} &= \bar{\tau}_{\mathbf{e}(\chi):11} \\ \sum_{k=0}^{n-2} \frac{(n-k-1)(k+1)}{n(n-1)} c_{k+1}^{\chi} &= \bar{\tau}_{\mathbf{a}(\chi):01} \end{aligned}$$

Proof. See the supplementary material. \square

In contrast to the lifted local and cycle relaxations, the number of variables and constraints in the lifted exchangeable relaxation depends linearly on the domain size of the first-order model. From the lifted local constraints given by [3], $\bar{\tau}_{\mathbf{e}(\chi):00} + \bar{\tau}_{\mathbf{e}(\chi):11} + 2\bar{\tau}_{\mathbf{a}(\chi):01} = 1$. Substituting in the expression involved \bar{c}_k^{χ} , we get $\sum_{k=0}^n c_k^{\chi} = 1$. Intuitively, c_k^{χ} represents the approximation of the marginal probability $\Pr(\sum_{i \in \chi} x_i = k)$ of having precisely k ones in χ .

As proved by [2], groundings of unary predicates in Markov Logic Networks (MLNs) gives rise to exchangeable clusters. Thus, for MLNs, the above theorem immediately suggests a tightening of the relaxation: for every unary predicate of a MLN, add a new set of constraints as above to the existing lifted local (or cycle) optimization problem. Although it is not the focus of our paper, we note that this should also improve the lifted MAP inference results of [3]. For example, in the case of a symmetric complete graphical model, lifted MAP inference using the linear program given by these new constraints would find the exact k that maximizes $\Pr(x_{\chi})$, hence recover the same solution as counting elimination. Marginal inference may still be inexact due to the tree-reweighted entropy approximation. We re-emphasize that the complexity of variational inference with lifted exchangeable constraints is guaranteed to be polynomial in the domain size, unlike exact methods based on lifted counting elimination and variable elimination.

7 Experiments

In this section, we provide an empirical evaluation of our lifted tree reweighted (LTRW) algorithm. As a baseline we use a dampened version of the lifted belief propagation (LBP-Dampening) algorithm from [21]. Our lifted algorithm has all of the same advantages of the tree-reweighted approach over belief propagation, which we will illustrate in the results: (1) a convex objective that can be convergently solved to optimality, (2) upper bounds on the partition function, and (3) the ability to easily improve the approximation by tightening the relaxation. Our evaluation includes four variants of the LTRW algorithm corresponding to using different outer bounds: lifted local polytope (LTRW-L), lifted cycle polytope (LTRW-C), lifted local

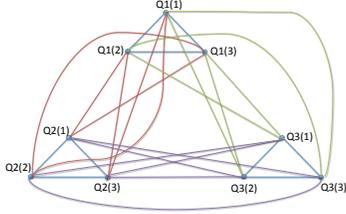

Figure 2: An example of the ground graphical model for the Clique-Cycle model (domain size = 3).

polytope with exchangeable polytope constraints (LTRW-LE), and lifted cycle polytope with exchangeable constraints (LTRW-CE). The conditional gradient optimization of the lifted TRW objective terminates when the duality gap is less than 10^{-4} or when a maximum number of 1000 iterations is reached. To solve the LP problem during conditional gradient, we use Gurobi⁵.

We evaluate all the algorithms using several first-order probabilistic models. We assume that no evidence has been observed, which results in a large amount of symmetry. Even without evidence, performing marginal inference in first-order probabilistic models can be very useful for maximum likelihood learning [13]. Furthermore, the fact that our lifted tree-reweighted variational approximation provides an upper bound on the partition function enables us to maximize a lower bound on the likelihood [29], which we demonstrate in Sec. 7.5. To find the lifted orbit partition, we use the renaming group as in [3] which exploits the symmetry of the unobserved contents in the model.

Rather than optimize over the spanning tree polytope, which is computationally intensive, most TRW implementations use a single fixed choice of edge appearance probabilities, e.g. an (un)weighted distribution obtained using the matrix-tree theorem. In these experiments, we initialize the lifted edge appearance probabilities $\bar{\rho}$ to be the most uniform per-orbit edge-appearance probabilities by solving the optimization problem $\inf_{\bar{\rho} \in \mathbb{T}_{[\varphi, E]}} (\bar{\rho} - \frac{|V|-1}{|E|})^2$ using conditional gradient. Each direction-finding step of this conditional gradient solves a lifted MST problem of the form $\sup_{\bar{\rho}' \in \mathbb{T}_{[\varphi, E]}} \langle -2(\bar{\rho} - \frac{|V|-1}{|E|}), \bar{\rho}' \rangle$ using our lifted Kruskal’s algorithm, where $\bar{\rho}$ is the current solution. After this initialization, we fix the lifted edge appearance probabilities and do not attempt to optimize them further.

7.1 Test models

Fig. 3 describes the four test models in MLN syntax. We focus on the repulsive case, since for attractive models, all TRW variants and lifted LBP give similar results. The parameter W denotes the weight that will be varying during the experiments. In all models except *Clique-Cycle*, W acts like the “local field” potential in an Ising model; a negative (or positive) value of W means the corresponding variable tends to be in the 0 (or 1) state. *Complete-*

Graph is equivalent to an Ising model on the complete graph of size n (the domain size) with homogenous parameters. Exact marginals and the log-partition function can be computed in closed form using lifted counting elimination. The weight of the interaction clause is set to -0.1 (repulsive). *Friends-Smokers (negated)* is a variant of the Friends-Smokers model [21] where the weight of the final clause is set to -1.1 (repulsive). We use the method in [2] to compute the exact marginal for the *Cancer* predicate and the exact value of the log-partition function. *Lovers-Smokers* is the same MLN used in [3] with a full transitive clause and where we vary the prior of the *Loves* predicate. *Clique-Cycle* is a model with 3 cliques and 3 bipartite graphs in between. Its corresponding ground graphical model is shown in Fig. 2.

7.2 Accuracy of Marginals

Fig. 4 shows the marginals computed by all the algorithms as well as exact marginals on the Complete-Graph and Friends-Smokers models. We do not know how to efficiently perform exact inference in the remaining two models, and thus do not measure accuracy for them. The result on complete graphs illustrates the clear benefit of tightening the relaxation: LTRW-Local and LBP are inaccurate for moderate W , whereas cycle constraints and, especially, exchangeable constraints drastically improve accuracy. As discussed earlier, for the case of symmetric complete graphical models, the exchangeable constraints suffice to exactly characterize the marginal polytope. As a result, the approximate marginals computed by LTRW-LE and LTRW-CE are almost the same as the exact marginals; the very small difference is due to the entropy approximation. On the Friends-Smokers (negated) model, all LTRW variants give accurate marginals while lifted LBP even with very strong dampening (0.9 weight given to previous iterations’ messages) fails to converge for $W < 2$. We observed that LTRW-LE gives the best trade-off between accuracy and running time for this model. Note that we do not compare to ground versions of the lifted TRW algorithms because, by Theorem 3, the marginals and log-partition function are the same for both.

7.3 Quality of Log-Partition Upper bounds

Fig. 5 plots the values of the upper bounds obtained by the LTRW algorithms on the four test models. The results clearly show the benefits of adding each type of constraint to the LTRW, with the best upper bound obtained by tightening the lifted local polytope with both lifted cycle and exchangeable constraints. For the Complete-Graph and Friends-Smokers model, the log-partition approximation using exchangeable polytope constraints is very close to exact. In addition, we illustrate lifted LBP’s approximation of the log-partition function on the Complete-Graph (note it is non-convex and not an upper bound).

Table 1: Ground vs lifted TRW runtime on Complete-Graph (milliseconds)

7.4 Running time

As shown in Table 1, lifted variants of TRW are order-of-magnitudes faster than the ground version. Interestingly, lifted TRW with local constraints is observed to be faster as the domain size increases; this is probably due to the fact that as the domain size increases, the distribution becomes more peak, so marginal inference becomes more similar to MAP inference. Lifted TRW with local and exchangeable constraints requires a smaller number of conditional gradient iterations, thus is faster; however note that its running time slowly increases since the exchangeable constraint set grows linearly with domain size.

LBP’s lack of convergence makes it difficult to have a

7.5 Application to Learning

We now describe an application of our algorithm to the task of learning relational Markov networks for inferring protein-protein interactions from noisy, high-throughput, experimental assays [12]. This is equivalent to learning the parameters of an exponential family random graph model [19] where edges in the random graph represent the protein-protein interactions. Despite fully observed data, maximum likelihood learning is challenging because of the intractability of computing the log-partition function and its gradient. In particular, this relational Markov network has over 330K random variables (one for each possible interaction of 813 variables) and tertiary potentials. However, Jaimovich et al. [13] observed that the partition function in

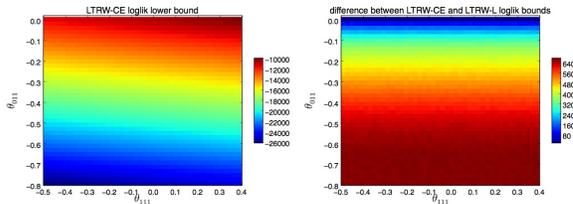

Figure 6: Log-likelihood lower-bound obtained using lifted TRW with the cycle and exchangeable constraints (CE) for the same protein-protein interaction data used in [13] (left) (c.f. Fig. 7 in [13]). Improvement in lower-bound after tightening the local constraints (L) with CE (right).

relational Markov networks is highly symmetric, and use lifted LBP to efficiently perform approximate learning in running time that is independent of the domain size. They use their lifted inference algorithm to visualize the (approximate) likelihood landscape for different values of the parameters, which among other uses characterizes the robustness of the model to parameter changes.

We use precisely the same procedure as [13], substituting lifted BP with our new lifted TRW algorithms. The model has three parameters: θ_1 , used in the single-node potential to specify the prior probability of a protein-protein interaction; θ_{111} , part of the tertiary potentials which encourages cliques of three interacting proteins; and θ_{011} , also part of the tertiary potentials which encourages chain-like structures where proteins A, B interact, B, C interact, but A and C do not (see supplementary material for the full model specification as an MLN). We follow their two-step estimation procedure, first estimating θ_1 in the absence of the other parameters (the maximum likelihood, BP, and TRW estimates of this parameter coincide, and estimation can be performed in closed-form: $\theta_1^* = -5.293$). Next, for each setting of θ_{111} and θ_{011} we estimate the log-partition function using lifted TRW with the cycle+exchangeable vs. local constraints only. Since TRW is an upper bound on the log-partition function, these provide lower bounds on the likelihood.

Our results are shown in Fig. 6, and should be compared to Fig. 7 of [13]. The overall shape of the likelihood landscapes are similar. However, the lifted LBP estimates of the likelihood have several local optima, which cause gradient-based learning with lifted LBP to reach different solutions depending on the initial setting of the parameters. In contrast, since TRW is convex, any gradient-based procedure would reach the global optima, and thus learning is much easier. Interestingly, we see that our estimates of the likelihood have a significantly smaller range over these parameter settings than that estimated by lifted LBP. Moreover, the high-likelihood parameter settings extends to larger values of θ_{111} . For all algorithms there is a sudden decrease in the likelihood at $\theta_{011} > 0$ (not shown in the figure).

8 Discussion and Conclusion

Lifting partitions used by lifted and counting BP [21, 16] can be coarser than orbit partitions. In graph-theoretic

terms, these partitions are called *equitable* partitions. If each equitable partition cell is thought of as a distinct node color, then among nodes with the same color, their neighbors must have the same color histogram. It is known that orbit partitions are always equitable, however the converse is not always true [9].

Since equitable partition can be computed more efficiently and potentially leads to more compact lifted problems, the following question naturally arises: can we use equitable partition in lifting the TRW problem? Unfortunately, a complete answer is non-trivial. We point out here a theoretical barrier due to the interplay between the spanning tree polytope and the equitable partition of a graph.

Let ε be the coarsest equitable partition of edges of \mathcal{G} . We give an example graph in the supplementary material (see example 9) where the symmetrized spanning tree polytope corresponding to the equitable partition ε , $\mathbb{T}_{[\varepsilon]} = \mathbb{T}(\mathcal{G}) \cap \mathbb{R}_{[\varepsilon]}^{|E|}$ is an empty set. When $\mathbb{T}_{[\varepsilon]}$ is empty, the consequence is that if we want ρ to be within \mathbb{T} so that $B(\cdot, \rho)$ is guaranteed to be a convex upper bound of the log-partition function, we cannot restrict ρ to be consistent with the equitable partition. In lifted and counting BP, $\rho \equiv 1$ so it is clearly consistent with the equitable partition; however, one loses convexity and upper bound guarantee as a result. This suggests that there might be a trade-off between the compactness of the lifting partition and the quality of the entropy approximation, a topic deserving the attention of future work.

In summary, we presented a formalization of lifted marginal inference as a convex optimization problem and showed that it can be efficiently solved using a Frank-Wolfe algorithm. Compared to previous lifted variational inference algorithms, in particular lifted belief propagation, our approach comes with convergence guarantees, upper bounds on the partition function, and the ability to improve the approximation (e.g. by introducing additional constraints) at the cost of small additional running time.

A limitation of our lifting method is that as the amount of soft evidence (the number of distinct individual objects) approaches the domain size, the behavior of lifted inference approaches ground inference. The wide difference in running time between ground and lifted inference suggests that significant efficiency can be gained by solving an approximation of the original problem that is more symmetric [25, 15, 22, 6]. One of the most interesting open questions raised by our work is how to use the variational formulation to perform approximate lifting. Since our lifted TRW algorithm provides an upper bound on the partition function, it is possible that one could use the upper bound to guide the choice of approximation when deciding how to re-introduce symmetry into an inference task.

Abstract

This paper presents an approximate method for performing Bayesian inference in models with conditional independence over a decentralized network of learning agents. The method first employs variational inference on each individual learning agent to generate a local approximate posterior, the agents transmit their local posteriors to other agents in the network, and finally each agent combines its set of received local posteriors. The key insight in this work is that, for many Bayesian models, approximate inference schemes destroy symmetry and dependencies in the model that are crucial to the correct application of Bayes' rule when combining the local posteriors. The proposed method addresses this issue by including an additional optimization step in the combination procedure that accounts for these broken dependencies. Experiments on synthetic and real data demonstrate that the decentralized method provides advantages in computational performance and predictive test likelihood over previous batch and distributed methods.

1 INTRODUCTION

Recent trends in the growth of datasets, and the methods by which they are collected, have led to increasing interest in the parallelization of machine learning algorithms. Parallelization results in reductions in both the memory usage and computation time of learning, and allows data to be collected by a network of learning agents rather than by a single central agent. There are two major classes of parallelization algorithms: those that require a globally shared memory/computation unit (e.g., a central fusion processor that each learning agent is in communication with, or the main thread on a multi-threaded computer), and those that do not. While there is as of yet no consensus in the litera-

ture on the terminology for these two types of parallelization, in this work we refer to these two classes, respectively, as *distributed* and *decentralized* learning.

Some recent approaches to distributed learning have involved using streaming variational approximations (Broderrick et al., 2013), parallel stochastic gradient descent (Niu et al., 2011), the Map-Reduce framework (Dean and Ghemawat, 2004), database-inspired concurrency control (Pan et al., 2013), and message passing on graphical models (Gonzalez et al., 2009). When a reliable central learning agent with sufficient communication bandwidth is available, such distributed learning techniques are generally preferred to decentralized learning. This is a result of the consistent global model shared by all agents, with which they can make local updates without the concern of generating conflicts unbeknownst to each other.

Decentralized learning is a harder problem in general, due to asynchronous communication/computation, a lack of a globally shared state, and potential network and learning agent failure, all of which may lead to inconsistencies in the model possessed by each agent. Addressing these issues is particularly relevant to mobile sensor networks in which the network structure varies over time, agents drop out and are added dynamically, and no single agent has the computational or communication resources to act as a central hub during learning. Past approaches to decentralized learning typically involve each agent communicating frequently to form a consensus on the model over the network, and are often model-specific: particle filtering for state estimation (Rosencrantz et al., 2003) involves sending particle sets and informative measurements to peers; distributed EM (Wolfe et al., 2008) requires communication of model statistics to the network after each local iteration; distributed Gibbs sampling (Newman et al., 2007) involves model synchronization after each sampling step; robust distributed inference (Paskin and Guestrin, 2004) requires the formation of a spanning tree of nodes in the network and message passing; asynchronous distributed learning of topic models (Asuncion et al., 2008) requires communication of model statistics to peers after each local

sampling step; and hyperparameter consensus (Fraser et al., 2012) requires using linear network consensus on exponential family hyperparameters.

The method proposed in the present paper takes a different tack; each agent computes an approximate factorized variational posterior using only their local datasets, sends and receives statistics to and from other agents in the network asynchronously, and combines the posteriors locally on-demand. Building upon insights from previous work on distributed and decentralized inference (Broderick et al., 2013, Rosencrantz et al., 2003), a naïve version of this algorithm based on Bayes’ rule is presented. It is then shown that, due to the approximation used in variational inference, this algorithm leads to poor decentralized posterior approximations for unsupervised models with inherent symmetry. Next, building on insights gained from the results of variational and Gibbs sampling inference on a synthetic example, an approximate posterior combination algorithm is presented that accounts for symmetry structure in models that the naïve algorithm is unable to capture. The proposed method is highly flexible, as it can be combined with past streaming variational approximations (Broderick et al., 2013, Lin, 2013), agents can share information with only subsets of the network, the network may be dynamic with unknown topology, and the failure of individual learning agents does not affect the operation of the rest of the network. Experiments on a mixture model, latent Dirichlet allocation (Blei et al., 2003), and latent feature assignment (Griffiths and Ghahramani, 2005) demonstrate that the decentralized method provides advantages in model performance and computational time over previous approaches.

2 APPROXIMATE DECENTRALIZED BAYESIAN INFERENCE

2.1 THE NAÏVE APPROACH

Suppose there is a set of learning agents i , $i = 1, \dots, N$, each with a distribution on a set of latent parameters θ_j , $j = 1, \dots, K$ (all parameters θ_j may generally be vectors). Suppose a fully factorized exponential family distribution has been used to approximate each agent’s posterior $q_i(\theta_1, \dots, \theta_K)$. Then the distribution possessed by each agent i is

$$q_i(\theta_1, \dots, \theta_K) = \prod_j q_{\lambda_{ij}}(\theta_j), \quad (1)$$

where λ_{ij} parameterizes agent i ’s distribution over θ_j . Given the prior

$$q_0(\theta_1, \dots, \theta_K) = \prod_j q_{\lambda_{0j}}(\theta_j), \quad (2)$$

is known by all agents, and the conditional independence of data given the model, the overall posterior distribu-

tion $q(\theta_1, \dots, \theta_K)$ may be approximated by using Bayes’ rule (Broderick et al., 2013) and summing over the λ_{ij} :

$$\begin{aligned} q(\cdot) &\propto q_0(\cdot)^{1-N} \prod_i q_i(\cdot) \\ &= \left(\prod_j q_{\lambda_{0j}}(\theta_j) \right)^{1-N} \prod_i \prod_j q_{\lambda_{ij}}(\theta_j) \\ \therefore q(\cdot) &= \prod_j q_{\lambda_j}(\theta_j) \end{aligned} \quad (3)$$

$$\text{where } \lambda_j = (1 - N)\lambda_{0j} + \sum_i \lambda_{ij}.$$

The last line follows from the use of exponential family distributions in the variational approximation. This procedure is decentralized, as each agent can asynchronously compute its individual posterior approximation, broadcast it to the network, receive approximations from other agents, and combine them locally. Furthermore, this procedure can be made to handle streaming data by using a technique such as SDA-Bayes (Broderick et al., 2013) or sequential variational approximation (Lin, 2013) on each agent locally to generate the streaming local posteriors q_i .

As an example, this method is now applied to decentralized learning of a Gaussian model with unknown mean $\mu = 1.0$ and known variance $\sigma^2 = 1.0$. The prior on μ is Gaussian with mean $\mu_0 = 0.0$ and variance $\sigma_0^2 = 2.0$. There are 10 learning agents, each of whom receives 10 observations $y \sim \mathcal{N}(\mu, \sigma^2)$. Because the Gaussian distribution is in the exponential family, the variational approximation is exact in this case. As shown in Figure 1, the decentralized posterior is the same as the batch posterior. Note that if the approximation is used on a more complicated distribution not in the exponential family, then the batch posterior may in general differ from the decentralized posterior; however, they will both approximate the same true posterior distribution.

2.2 FAILURE OF THE NAÏVE APPROACH UNDER PARAMETER PERMUTATION SYMMETRY

As a second example, we apply decentralized inference to a Gaussian mixture model with three components having unknown means $\mu = (1.0, -1.0, 3.0)$ and cluster weights $\pi = (0.6, 0.3, 0.1)$ with known variance $\sigma^2 = 0.09$. The prior on each mean μ_i was Gaussian with mean $\mu_0 = 0.0$ and variance $\sigma_0^2 = 2.0$, while the prior on the weights π was Dirichlet with parameters $(1.0, 1.0, 1.0)$. First, the true posterior, shown in Figure 2a, was formed using 30 datapoints that were sampled from the generative model. Then, the decentralized variational inference procedure in (3) was run with 10 learning agents, each of whom received 3 of the datapoints, resulting in the approximate decentralized posterior in Figure 2b.

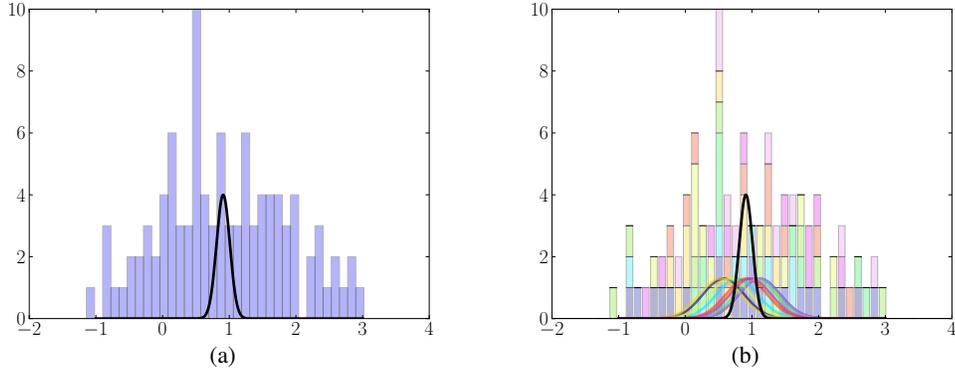

Figure 1: (1a): Batch posterior of μ in black, with histogram of observed data. (1b): Decentralized posterior of μ in black, individual posteriors in color and correspondingly colored histogram of observed data.

The decentralized posterior, in this case, is a very poor approximation of the true batch posterior. The reason for this is straightforward: approximate inference algorithms, such as that presented in Figure 2b). Past work dealing with this issue has focused primarily on modifying the samples of MCMC algorithms by introducing “identifiability constraints” that control the ordering of parameters (Jasra et al., 2005, Stephens, 2000), but these approaches are generally model-specific and restricted to use on very simple mixture models.

2.3 MERGING POSTERiors WITH PARAMETER PERMUTATION SYMMETRY

Indeed, examining the true posterior in Figure 2a, one can identify 6 differently colored regions; each of these regions corresponds to one of the possible $3! = 6$ permutation matrices P . In other words, the true posterior captures the invariance of the distribution to reordering of the parameters correctly.

This section presents a method for locally combining the individual posteriors of decentralized learning agents when the model contains parameter permutation symmetry. Formally, suppose that the true posterior probability of $\theta_1, \dots, \theta_K$ is invariant to permutations of the components of one or more θ_j . In general, there may be subsets of parameters which have coupled symmetry, in that the true posterior is only invariant if the components of all parameters in the subset are permuted in the same way (for example, the earlier Dirichlet mixture model had coupled permutation symmetry in μ and π). It is assumed that any such coupling in the model is known beforehand by all agents. Because the exponential family variational approximation is completely decoupled, it is possible to treat each coupled permutation symmetry set of parameters in the model independently; therefore, we assume below that $\theta_1, \dots, \theta_K$ all have coupled permutation symmetry, for simplicity in the notation and exposition.

To demonstrate that approximate inference algorithms typically do not capture parameter permutation symmetry in a model, consider the same mixture model, learned with 30 datapoints in a single batch using Gibbs sampling and variational Bayesian inference. Samples from 5 random restarts of each method are shown in Figure 3. Both algorithms fail to capture the permutation symmetry in the mixture model, and converge to one of the 6 possible orderings of the parameters. This occurs in variational Bayesian inference and Gibbs sampling for different reasons: Gibbs sampling algorithms often get stuck in local posterior likelihood optima, while the variational approximation explicitly breaks the dependence of the parameters on one another.

In order to properly combine the approximate posterior produced by each learning agent, first the individual posteriors are *symmetrized* (represented by a tilde) by summing over all possible permutations as follows:

In a batch setting, this does not pose a problem, because practitioners typically find the selection of a particular parameter ordering acceptable. However, in the decentralized setting, this causes problems when combining the posteriors of individual learning agents. If each agent effectively picks a parameter ordering at random when per-

$$\tilde{q}_i(\cdot) \propto \sum_P \prod_j q_{P\lambda_{ij}}(\theta_j), \quad (5)$$

where the sum is taken to be over all permutation matrices

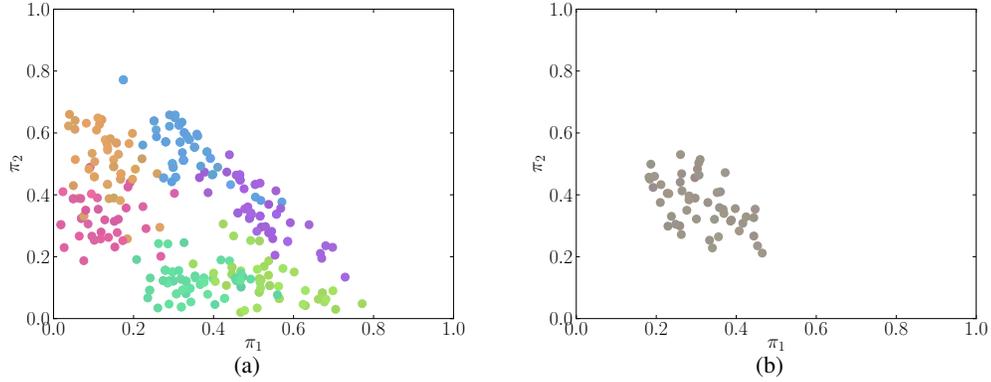

Figure 2: (2a): Samples from the true posterior over μ, π . Each particle’s position on the simplex (with $\pi_3 = 1 - \pi_1 - \pi_2$) represents the sampled weights, while RGB color coordinates of each particle represent the sampled position of the three means. (2b): Samples from the naively constructed decentralized approximate posterior, with the same coloring scheme. Note the disparity with Figure 2a.

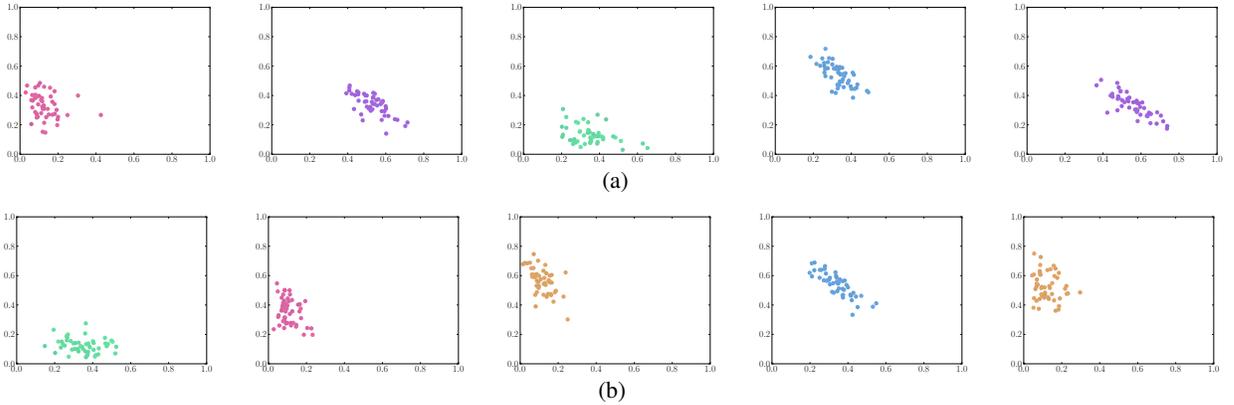

Figure 3: Batch Gibbs sampling (3a) and variational Bayes (3b) approximate posterior samples from 5 random restarts. Comparison to Figure 2a shows that both approximate inference algorithms tend to converge to a random component of the permutation symmetry in the true posterior.

P with the same dimension as λ_{ij} . This process of approximating the true single-agent posterior is referred to as symmetrization because \tilde{q}_i has the same parameter permutation symmetry as the true posterior, i.e. for all permutation matrices P ,

$$\tilde{q}_i(P\theta_1, \dots, P\theta_K) = \tilde{q}_i(\dots). \quad (6)$$

To demonstrate the effect of this procedure, the mixture model example was rerun with batch variational Bayesian inference (i.e. all 30 datapoints were given to a single learner) followed by symmetrization. Samples generated from these new symmetrized posterior distributions over 5 random restarts of the inference procedure are shown in Figure 4. This result demonstrates that the symmetrized distributions are invariant to the random permutation to which the original approximate posterior converged.

It is now possible to combine the individual (symmetrized) posteriors via the procedure outlined in (3):

$$q(\cdot) \propto q_0(\cdot)^{1-N} \prod_i \tilde{q}_i(\cdot)$$

$$\begin{aligned} &= \left(\prod_j q_{\lambda_{0j}}(\theta_j) \right)^{1-N} \prod_i \sum_{P_i} \prod_j q_{P_i \lambda_{ij}}(\theta_j) \quad (7) \\ &= \sum_{\{P_i\}_i} \prod_j \left[q_{\lambda_{0j}}(\theta_j)^{1-N} \prod_i q_{P_i \lambda_{ij}}(\theta_j) \right], \end{aligned}$$

where the outer sum is now over unique combinations of the set of permutation matrices $\{P_i\}_i$ used by the learning agents.

2.4 AMPS - APPROXIMATE MERGING OF POSTERiors WITH SYMMETRY

The posterior distribution in (7) is unfortunately intractable to use for most purposes, as it contains a number of terms that is factorial in the dimensions of the parameters, and exponential in the number of learning agents. Therefore, we approximate this distribution by finding the component with the highest weight – the intuitive reasoning for this is that the component with the highest weight is the one for which the individual posteriors have correctly aligned permutations, thus contributing to each other the most and rep-

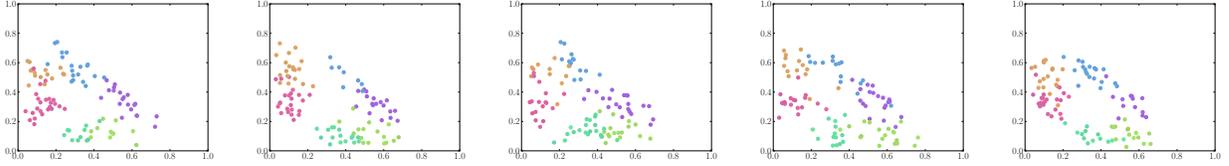

Figure 4: Samples from the symmetrized batch variational Bayes approximate posterior from 5 random restarts. Comparison to Figure 2a shows that symmetrization reintroduces the structure of the true posterior to the approximate posteriors.

representing the overall posterior the best. While the resulting distribution will not be symmetric, it will appear as though it were generated from variational Bayesian inference; this, as mentioned before, is most often fine in practice.

In order to compute the weight of each component, we need to compute its integral over the parameter space. Suppose that each approximate posterior component $q_{\lambda_{ij}}(\theta_j)$ has the following form:

$$q_{\lambda_{ij}}(\theta_j) = h_j(\theta_j) e^{\text{tr}[\lambda_{ij}^T T(\theta_j)] - A_j(\lambda_{ij})} \quad (8)$$

where $h_j(\cdot)$ and $A_j(\cdot)$ are the base measure and log-partition functions for parameter j , respectively. The trace is used in the exponent in case λ_{ij} is specified as a matrix rather than as a single column vector (such as in the example presented in Section 3.1). Thus, given a set of permutation matrices $\{P_i\}_i$, the factor of the weight for the component due to parameter j is

$$W_j(\{P_i\}_i) = \int_{\theta_j} q_{\lambda_{0j}}(\theta_j)^{1-N} \prod_i q_{P_i \lambda_{ij}}(\theta_j). \quad (9)$$

The overall weight of the component is the product over the parameters, so finding the maximum weight component of (7) is equivalent to finding the set of permutation matrices P_i^* that maximizes the product of the W_j ,

$$\{P_i^*\}_i \leftarrow \arg \max_{\{P_i\}_i} \prod_j W_j(\{P_i\}_i). \quad (10)$$

Due to the use of exponential family distributions in the variational approximation, the optimization (10) can be posed as a combinatorial optimization over permutation matrices with a closed-form objective:

$$\begin{aligned} \max_{\{P_i\}_i} \sum_j A_j \left((1-N)\lambda_{0j} + \sum_i P_i \lambda_{ij} \right) \\ \text{s.t. } P_i \in S \quad \forall i \end{aligned} \quad (11)$$

where S is the symmetric group of order equal to the row dimension of the matrices λ_{ij} . Using the convexity of the log-partition function $A_j(\cdot)$, the fact that the objective is affine in its arguments, and the fact that the vertices of the Birkhoff polytope are permutation matrices, one can reformulate (10) as a convex maximization over a polytope:

ulate (10) as a convex maximization over a polytope:

$$\begin{aligned} \max_{\{P_i\}_i} \sum_j A_j \left((1-N)\lambda_{0j} + \sum_i P_i \lambda_{ij} \right) \\ \text{s.t. } P_i^T \mathbf{1} = \mathbf{1}, \quad P_i \mathbf{1} = \mathbf{1}, \quad P_i \geq 0 \quad \forall i \end{aligned} \quad (12)$$

where $\mathbf{1}$ is a vector with all entries equal to 1. Global optimization routines for this problem are intractable for the problem sizes presented by typical Bayesian models (Benson, 1985, Falk and Hoffman, 1986). Thus, the optimization must be solved approximately, where the choice of the approximate method is dependent on the particular form of $A_j(\cdot)$.

As mentioned earlier, this optimization was formulated assuming that all the θ_j were part of a single coupled permutation symmetry set. However, if there are multiple subsets of the parameters $\theta_1, \dots, \theta_K$ that have coupled permutation symmetry, an optimization of the form (12) can be solved for each subset independently. In addition, for any parameter that does not exhibit permutation symmetry, the original naïve posterior merging procedure in (3) may be used. These two statements follow from the exponential family mean field assumption used to construct the individual approximate posteriors q_i .

3 EXPERIMENTS

All experiments were performed on a computer with an Intel Core i7 processor and 12GB of memory.

3.1 DECENTRALIZED MIXTURE MODEL EXAMPLE REVISITED

The AMPS decentralized inference scheme was applied to the Gaussian mixture model example from earlier, with three components having unknown means $\mu = (1.0, -1.0, 3.0)$ and cluster weights $\pi = (0.6, 0.3, 0.1)$, and known variance $\sigma^2 = 0.09$. The prior on each mean μ_i was Gaussian, with mean $\mu_0 = 0.0$ and variance $\sigma_0^2 = 2.0$, while the prior on the weights π was Dirichlet, with parameters $(1.0, 1.0, 1.0)$. The dataset consisting of the same 30 datapoints from the earlier trial was used, where each of 10 learning agents received 3 of the datapoints. Each learning agent used variational Bayesian inference to find their individual posteriors $q_i(\mu, \pi)$, and then used AMPS

to merge them. The only communication required between the agents was a single broadcast of each agent’s individual posterior parameters.

In this example, the AMPS objective¹ was as follows:

$$J_{\text{AMPS}} = -\log \Gamma \left(\sum_{j=1}^3 (\beta_j + 1) \right) + \sum_{j=1}^3 -\frac{\eta_j^2}{4\nu_j} - \frac{1}{2} \log(-2\nu_j) + \log \Gamma(\beta_j + 1) \quad (13)$$

with

$$\begin{aligned} \lambda_{i\mu} &= \begin{bmatrix} \eta_{i1} & \eta_{i2} & \eta_{i3} \\ \nu_{i1} & \nu_{i2} & \nu_{i3} \end{bmatrix}^T, \quad i = 1, \dots, 10 \\ \lambda_{i\pi} &= \begin{bmatrix} \beta_{i1} & \beta_{i2} & \beta_{i3} \end{bmatrix}^T, \quad i = 1, \dots, 10 \\ \lambda_{\mu} &= -9\lambda_{0\mu} + \sum_i P_i \lambda_{i\mu} \equiv \begin{bmatrix} \eta_1 & \eta_2 & \eta_3 \\ \nu_1 & \nu_2 & \nu_3 \end{bmatrix}^T \\ \lambda_{\pi} &= -9\lambda_{0\pi} + \sum_i P_i \lambda_{i\pi} \equiv \begin{bmatrix} \beta_1 & \beta_2 & \beta_3 \end{bmatrix}^T \quad (14) \\ \lambda_{0\mu} &= \begin{bmatrix} 0 & 0 & 0 \\ -0.25 & -0.25 & -0.25 \end{bmatrix}^T \\ \lambda_{0\pi} &= \begin{bmatrix} 0 & 0 & 0 \end{bmatrix}^T \\ \beta_{ij} &= \alpha_{ij} - 1, \quad \eta_{ij} = \frac{\mu_{ij}}{\sigma_{ij}^2}, \quad \nu_{ij} = -\frac{1}{2\sigma_{ij}^2} \end{aligned}$$

where α_{ij} was agent i ’s posterior Dirichlet variational parameter for cluster j , and μ_{ij}/σ_{ij}^2 were agent i ’s posterior normal variational parameter for cluster j . The objective was optimized approximately over the 3×3 permutation matrices P_i by proposing swaps of two rows in P_i , accepting swaps that increased J_{AMPS} , and terminating when no possible swaps increased J_{AMPS} .

The individual posteriors for 3 of the learning agents are shown in Figure 5, while the decentralized posterior over all the agents is shown in Figure 6 alongside its symmetrization (for comparison to the true posterior – this final symmetrization is not required in practice). The AMPS posterior is a much better approximation than the naïve decentralized posterior shown in Figure 2b; this is because the AMPS posterior accounts for parameter permutation symmetry in the model prior to combining the individual posteriors. It may be noted that the decentralized posterior has slightly more uncertainty in it than the batch posterior, but this is to be expected when each learning agent individually receives little information (as demonstrated by the uncertainty in the individual posteriors shown in Figure 5).

¹The AMPS objective for each experiment was constructed using the log-partition function $A_j(\cdot)$ of the relevant exponential family models, which may be found in (Nielsen and Garcia, 2011).

3.2 DECENTRALIZED LATENT DIRICHLET ALLOCATION

The next experiment involved running decentralized variational inference with AMPS on the LDA document clustering model (Blei et al., 2003). The dataset in consideration was the 20 newsgroups dataset, consisting of 18,689 documents with 1,000 held out for testing, and a vocabulary of 11,175 words after removing stop words and stemming the remaining words. Algorithms were evaluated based on their approximate predictive likelihood of 10% of the words in each test document given the remaining 90%, as described in earlier literature (Wang et al., 2011). The variational inference algorithms in this experiment were initialized using smoothed statistics from randomly selected documents.

In LDA, the parameter permutation symmetry lies in the arbitrary ordering of the global word distributions for each topic. In particular, for the 20 newsgroups dataset, decentralized learning agents may learn the 20 Dirichlet distributions with a different ordering; therefore, in order to combine the local posteriors, we use AMPS with the following objective to reorder each agent’s global topics:

$$J_{\text{AMPS}} = \sum_{k=1}^K J_{\text{AMPS},k} = \sum_{k=1}^K \sum_{w=1}^W \log \Gamma(\alpha_{kw}) - \log \Gamma \left(\sum_{w=1}^W \alpha_{kw} \right) \quad (15)$$

$$\alpha = (1 - N)\alpha_0 + \sum_{i=1}^N P_i \alpha_i, \quad \alpha, \alpha_i \in \mathbb{R}^{K \times W}$$

$$\alpha_{0kw} = \frac{10}{W} \quad K = 20, \quad W = 11,175$$

where α_{ikw} is agent i ’s posterior Dirichlet variational parameter for topic k and word w , and the optimization is over $K \times K$ permutation matrices $P_i, i = 1, \dots, N$. For the LDA model, the AMPS objective J_{AMPS} is additive over the topics k ; therefore, J_{AMPS} can be optimized approximately by iteratively solving maximum-weight bipartite matching problems as follows:

1. Initialize the decentralized posterior parameter $\alpha \leftarrow (1 - N)\alpha_0 + \sum_{i=1}^N P_i \alpha_i$ with a set of P_i matrices
2. For each agent i until J_{AMPS} stops increasing:
 - (a) Deassign agent i ’s posterior: $\alpha \leftarrow \alpha - P_i \alpha_i$
 - (b) Form a bipartite graph with decentralized topics k on one side, agent i ’s topics k' on the other, and edge weights $w_{kk'}$ equal to $J_{\text{AMPS},k}$ if agent i ’s topic k' is assigned to the decentralized topic k
 - (c) $P_i \leftarrow$ Maximum weight assignment of agent i ’s topics
 - (d) Reassign agent i ’s posterior: $\alpha \leftarrow \alpha + P_i \alpha_i$

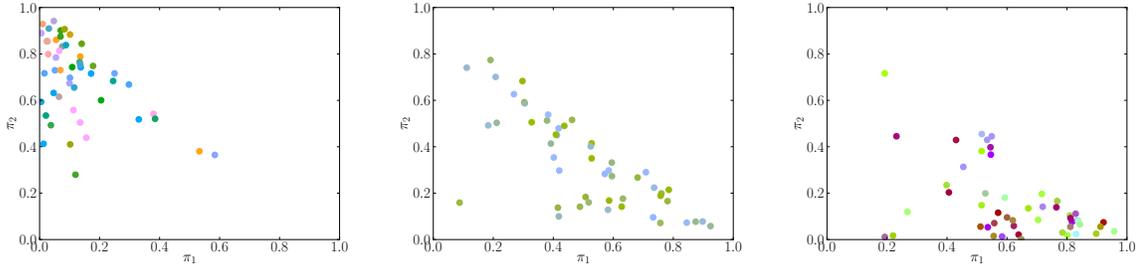

Figure 5: Samples from the individual posterior distributions from variational Bayesian inference for 3 of the learning agents. Note the high level of uncertainty in both the weights (position) and cluster locations (colour) in each posterior.

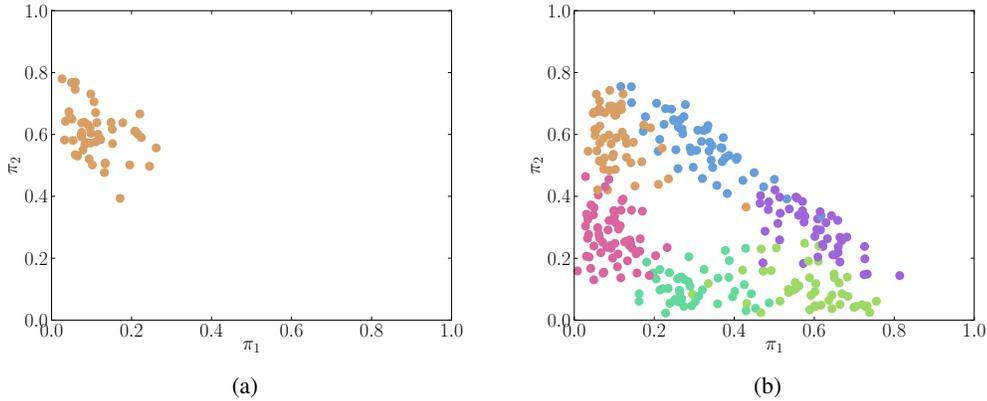

Figure 6: (6a): Samples from the decentralized posterior output by AMPS. Comparison to Figure 5 shows that the AMPS posterior merging procedure improves the posterior possessed by each agent significantly. (6b): Samples from the symmetrized decentralized posterior. This final symmetrization step is not performed in practice; it is simply done here for comparison with Figure 2a.

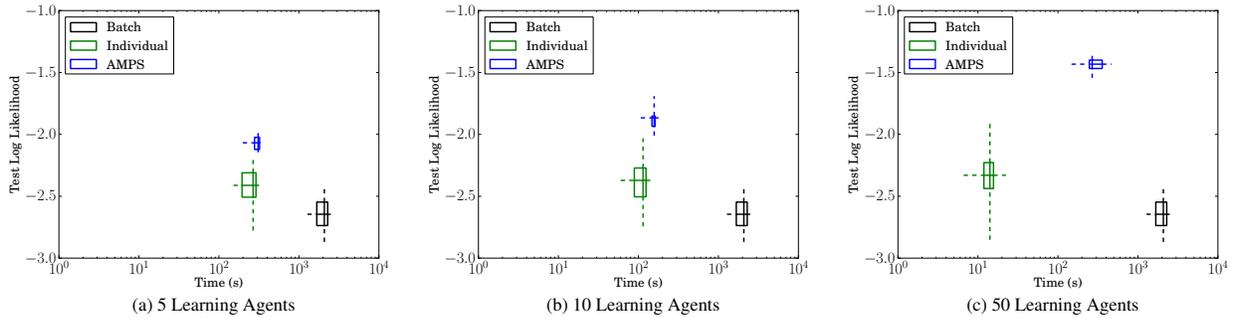

Figure 7: Plots of log likelihood on the test data for 5 (7a), 10 (7b), and 50 (7c) learning agents. The boxes bound the 25th and 75th percentiles of the data with medians shown in the interior, and whiskers show the maximum and minimum values.

First, the performance of decentralized LDA with AMPS was compared to the batch approximate LDA posterior with a varying number of learning agents. Figure 7 shows the test data log likelihood and computation time over 20 trials for the batch posterior, the AMPS decentralized posterior, and each individual agent’s posterior for 5, 10, and 50 learning agents. The results mimic those of the synthetic experiment – the posterior output by AMPS significantly outperforms each individual agent’s posterior, and the effect is magnified as the number of agents increases. Further, there is a much lower variance in the AMPS posterior test log likelihood than for each individual agent. The

batch method tends to get stuck in poor local optima in the variational objective, leading to relatively poor performance, while the decentralized method avoids these pitfalls by solving a number of smaller optimizations and combining the results afterwards with AMPS. Finally, as the number of agents increases, the amount of time required to solve the AMPS optimization increases; reducing this computation time is a potential future goal for research on this inference scheme.

The next test compared the performance of AMPS to SDA-Bayes (Broderick et al., 2013), a recent streaming, dis-

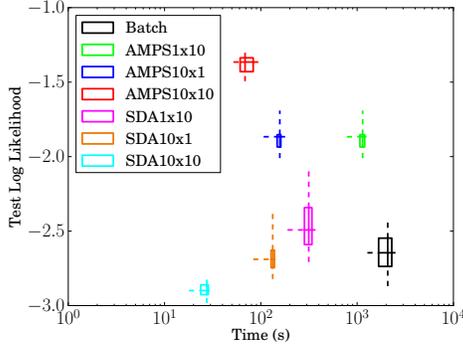

Figure 8: Comparison with SDA-Bayes. The $A \times B$ in the legend names refer to using A learning agents, where each splits their individual batches of data into B subbatches.

tributed variational inference algorithm. The algorithms were tested on 20 trials of each of three settings: one with 1 agent and 10 subbatches of data per agent; one with 10 agents and 1 subbatch of data per agent; and finally, one with 10 agents and 10 subbatches of data per agent. Each agent processed its subbatches in serial. For SDA-Bayes, each agent updated a single distributed posterior after each subbatch. For the decentralized method, each agent used AMPS to combine the posteriors from its own subbatches, and then used AMPS again to combine each agent’s resulting posterior.

Figure 8 shows the results from this procedure. AMPS outperforms SDA-Bayes in terms of test log likelihood, and is competitive in terms of the amount of time it takes to perform inference and then optimize the AMPS objective. This occurs because AMPS takes into account the arbitrary ordering of the topics, while SDA-Bayes ignores this when combining posteriors. An interesting note is that the AMPS10x10 result took less time to compute than the time for 50 agents in Figure 7c, despite the fact that it effectively merged 100 posterior distributions; this hints that developing a hierarchical optimization scheme for AMPS is a good avenue for further exploration. A final note is that using AMPS as described above is not truly a streaming procedure; however, one can rectify this by periodically merging posteriors using AMPS to form the prior for inference on subsequent batches.

3.3 DECENTRALIZED LATENT FEATURE ASSIGNMENT

The last experiment involved running decentralized variational inference with AMPS on a finite latent feature assignment model (Griffiths and Ghahramani, 2005). In this model, a set of K feature vectors $\mu_k \in \mathbb{R}^D$ are sampled from a Gaussian prior $\mu_k \sim \mathcal{N}(0, \sigma_0^2 I)$, and a set of feature inclusion probabilities are sampled from a beta prior $\pi_k \sim \text{Beta}(\alpha_k, \beta_k)$. Finally, for each image i , a set of features z_i are sampled independently from the weights $z_{ik} \sim \text{Be}(\pi_k)$, and the image $y_i \in \mathbb{R}^D$ is sampled from

a Gaussian likelihood $y_i \sim \mathcal{N}(\sum_k \mu_k z_{ik}, \sigma^2 I)$.

Two datasets were used in this experiment. The first was a synthetic dataset with $K = 5$ randomly generated $D = 10$ -dimensional binary feature vectors, feature weights sampled uniformly, and 1300 observations sampled with variance $\sigma^2 = 0.04$, with 300 held out for testing. For this dataset, algorithms were evaluated based on the error between the means of the feature posteriors and the true set of latent features, and based on their approximate predictive likelihoods of a random component in each test observation vector given the other 9 components. The second dataset was a combination of the Yale (Belhumeur et al., 1997) and Caltech² faces datasets, with 581 32×32 frontal images of faces, where 50 were held out for testing. The number of latent features was set to $K = 10$. For this dataset, algorithms were evaluated based on their approximate predictive likelihood of 10% of the pixels in each test image given the remaining 90%, and the inference algorithms were initialized using smoothed statistics from randomly selected images.

The parameter permutation symmetry in the posterior of the latent feature model lies in the ordering of the features μ_k and weights π_k . Therefore, to combine the local posteriors, we use AMPS with the following objective to reorder each agent’s set of features and weights:

$$J_{\text{AMPS}} = \sum_{k=1}^K J_{\text{AMPS},k} = \sum_{k=1}^K \log \Gamma(\alpha_k) + \log \Gamma(\beta_k) - \log \Gamma(\alpha_k + \beta_k) \quad (16)$$

$$- \frac{\eta_k^T \eta_k}{4\nu_k} - \frac{D}{2} \log(-2\nu_k)$$

where $\alpha, \beta \in \mathbb{R}^K$ are the combined posterior beta natural parameters, and $\eta \in \mathbb{R}^{D \times K}, \nu \in \mathbb{R}^K$ are the combined posterior normal natural parameters (combined using the $(1 - N) * 0 + \sum_i P_i * i$ rule as described in the foregoing). The priors were $\alpha_{k0} = \beta_{k0} = 1, \eta_{k0} = 0 \in \mathbb{R}^D$, and ν_{k0} was estimated from the data. As in the LDA model, the AMPS objective for the latent feature model is additive over the features k ; therefore the optimization was performed using iterative maximum-weight bipartite matchings as described in Section 3.2.

Figure 9 shows the results from the two datasets using batch learning and decentralized learning. For the decentralized results, the posteriors of 5 learning agents were combined using AMPS or the naïve approach (equivalent to SDA5x1 in the notation of Figure 8). Figure 9a shows that AMPS discovers the true set of latent features with a lower 2-norm

²Available online: <http://www.vision.caltech.edu/html-files/archive.html>

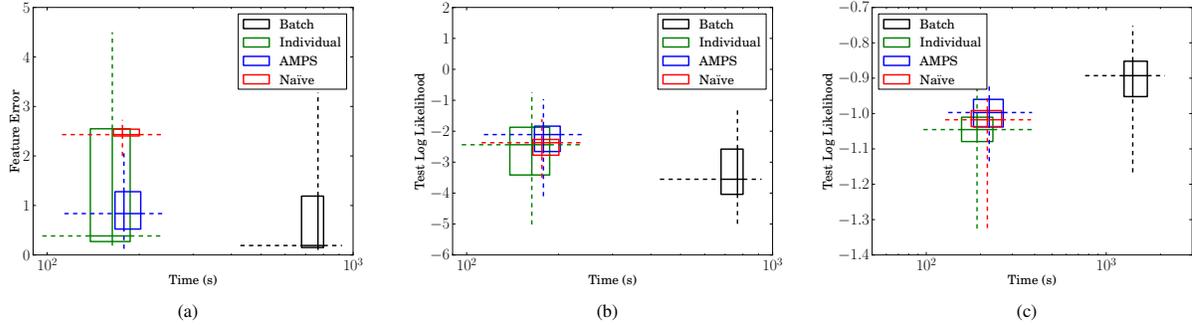

Figure 9: (9a): 2-norm error between the discovered features and the true set for the synthetic dataset. (9b): Test log likelihood for the synthetic dataset. (9c): Test log likelihood on the faces dataset. All distributed/decentralized results were generated using 5 learning agents.

error than both the naïve posterior combination and the individual learning agents, with a comparable error to the batch learning case. However, as shown in Figures 9b (synthetic) and 9c (faces), AMPS only outperforms the naïve approach in terms of predictive log likelihoods on the held-out test set by a small margin. This is due to the flexibility of the latent feature assignment model, in that there are many sets of latent features that explain the observations well.

4 DISCUSSION

This work introduced the Approximate Merging of Posteriors with Symmetry (AMPS) algorithm for approximate decentralized variational inference. AMPS may be used in ad-hoc, asynchronous, and dynamic networks. Experiments demonstrated the modelling and computational advantages of AMPS with respect to batch and distributed learning. Motivated by the examples in Section 3, there is certainly room for improvement of the AMPS algorithm. For example, it may be possible to reduce the computational cost of AMPS by using a hierarchical optimization scheme, rather than the monolithic approach used in most of the examples presented in the foregoing. Further, extending AMPS for use with Bayesian nonparametric models is of interest for cases when the number of latent parameters is unknown a priori, or when there is the possibility that agents learn disparate sets of latent parameters that are not well-combined by optimizing over permutations. Finally, while the approximate optimization algorithms presented herein work well in practice, it would be of interest to find bounds on the performance of such algorithms with respect to the true AMPS optimal solution.

Abstract

One of the goals of probabilistic inference is to decide whether an empirically observed distribution is compatible with a candidate Bayesian network. However, Bayesian networks with hidden variables give rise to highly non-trivial constraints on the observed distribution. Here, we propose an information-theoretic approach, based on the insight that conditions on *entropies* of Bayesian networks take the form of simple linear inequalities. We describe an algorithm for deriving entropic tests for latent structures. The well-known conditional independence tests appear as a special case. While the approach applies for generic Bayesian networks, we presently adopt the causal view, and show the versatility of the framework by treating several relevant problems from that domain: detecting common ancestors, quantifying the strength of causal influence, and inferring the direction of causation from two-variable marginals.

1 Introduction

Inferring causal relationships from empirical data is one of the prime goals of science. A common scenario reads as follows: Given n random variables X_1, \dots, X_n , infer their causal relations from a list of n -tuples i.i.d. drawn from $P(X_1, \dots, X_n)$. To formalize causal relations, it has become popular to use directed acyclic graphs (DAGs) with random variables as nodes (c.f. Fig. 1) and arrows meaning direct causal influence [23, 28]. Such causal models have been called *causal* Bayesian networks [23], as opposed to traditional Bayesian networks that formalize conditional independence relations without having necessarily a causal interpretation. One of the tasks of causal infer-

ence is to decide which causal Bayesian networks are compatible with empirically observed data.

The most common way to infer the set of possible DAGs from observations is based on the *Markov condition* (c.f. Sect. 2) stating which conditional statistical independencies are implied by the graph structure, and the *faithfulness assumption* stating that the joint distribution is generic for the DAG in the sense that no additional independencies hold [28, 23]. Causal inference via Markov condition and faithfulness has been well-studied for the case where all variables are observable, but some work also refers to latent structures where only a subset is observable [23, 27, 1]. In that case, we are faced with the problem of characterizing the set of *marginal distributions* a given Bayesian network can give rise to. If an observed distribution lies outside the set of marginals of a candidate network, then that model can be rejected as an explanation of the data. Unfortunately, it is widely appreciated that Bayesian networks involving latent variables impose highly non-trivial constraints on the distributions compatible with it [31, 33, 20, 21].

These technical difficulties stem from the fact that the conditional independencies amount to non-trivial algebraic conditions on probabilities. More precisely, the marginal regions are semi-algebraic sets that can, in principle, be characterized by a finite number of polynomial equalities and inequalities [14]. However, it seems that in practice, algebraic statistics is still limited to very simple models.

In order to circumvent this problem, we propose an information-theoretic approach for causal inference. It is based on an entropic framework for treating marginal problems that, perhaps surprisingly, has recently been introduced in the context of Bell's Theorem and the foundations of quantum mechanics [12, 7]. The basic insight is that the *algebraic* condition $p(x, y) = p_1(x)p_2(y)$ for independence becomes a *linear* relation $H(X, Y) = H(X) + H(Y)$ on the level of entropies. This opens up the possibility of us-

ing computational tools such as linear programming to find marginal constraints – which contrasts pleasantly with the complexity of algebraic methods that would otherwise be necessary.

1.1 Results

Our main message is that a significant amount of information about causation is contained in the entropies of observable variables and that there are relatively simple and systematic ways of unlocking that information. We will make that case by discussing a great variety of applications, which we briefly summarize here.

After introducing the geometric and algorithmic framework in Sections 2 & 3, we start with the applications in Section 4.1 which treats instrumentality tests. There, we argue that the non-linear nature of entropy, together with the fact that it is agnostic about the number of outcomes of a random variable, can greatly reduce the complexity of causal tests.

Two points are made in Sec. 4.2, treating an example where the direction of causation between a set of variables is to be inferred. Firstly, that marginal entropies of few variables can carry non-trivial information about conditional independencies encoded in a larger number of variables. This may have practical and statistical advantages. Secondly, we point out applications to tests for quantum non-locality.

In Sec. 4.3 we consider the problem of distinguishing between different hidden common ancestors causal structures. While most of the entropic tests in this paper have been derived using automated linear programming algorithms, this section presents analytic proofs valid for any number of variables.

Finally, Sec. 4.4 details three conceptually important realizations: (1) The framework can be employed to derive quantitative lower bounds on the strength of causation between variables. (2) The degree of violation of entropic inequalities carries an operational meaning. (3) Under some assumptions, we can exhibit novel conditions for distinguishing dependencies created through common ancestors from direct causation.

2 The information-theoretic description of Bayesian networks

In this section we introduce the basic technical concepts that are required to make the present paper self-contained. More details can be found in [23, 12, 7].

2.1 Bayesian networks

Here and in the following, we will consider n jointly distributed discrete random variables (X_1, \dots, X_n) . Uppercase letters label random variables while lowercase label the values taken by these variables, e.g. $p(X_i = x_i, X_j = x_j) \equiv p(x_i, x_j)$.

Choose a *directed acyclic graph* (DAG) which has the X_i 's as its vertices. The X_i 's form a *Bayesian network* with respect to the graph if every variable can be expressed as a function of its parents PA_i and an unobserved noise term N_i , such that the N_i 's are jointly independent. That is the case if and only if the distribution is of the form

$$p(x) = \prod_{i=1}^n p(x_i | pa_i).$$

Importantly, this is equivalent to demanding that the X_i fulfill the *local Markov property*: Every X_i is conditionally independent of its non-descendants ND_i given its parents PA_i : $X_i \perp\!\!\!\perp ND_i | PA_i$.

We allow some of the nodes in the DAG to stand for *hidden variables* that are not directly observable. Thus, the marginal distribution of the observed variables becomes

$$p(v) = \sum_u \prod_{i=1, \dots, m} p(v_i | pa_i) \prod_{j=1, \dots, n-m} p(u_j | pa_j), \quad (1)$$

where $V = (V_1, \dots, V_m)$ are the observable variables and $U = (U_1, \dots, U_{n-m})$ the hidden ones.

2.2 Shannon Entropy cones

Again, we consider a collection of n discrete random variables X_1, \dots, X_n . We denote the set of indices of the random variables by $[n] = \{1, \dots, n\}$ and its power set (i.e., the set of subsets) by $2^{[n]}$. For every subset $S \in 2^{[n]}$ of indices, let X_S be the random vector $(X_i)_{i \in S}$ and denote by $H(S) := H(X_S)$ the associated Shannon entropy given by $H(X_S) = -\sum_{x_s} p(x_s) \log_2 p(x_s)$. With this convention, entropy becomes a function

$$H : 2^{[n]} \rightarrow \mathbb{R}, \quad S \mapsto H(S)$$

on the power set. The linear space of all set functions will be denoted by R_n . For every function $h \in R_n$ and $S \in 2^{[n]}$, we use the notations $h(S)$ and h_S interchangeably.

The region

$$\{h \in R_n \mid h_S = H(S) \text{ for some entropy function } H\}$$

of vectors in R_n that correspond to entropies has been studied extensively in information theory [35]. Its closure is known to be a convex cone, but a tight and

explicit description is unknown. However, there is a standard outer approximation which is the basis of our work: the *Shannon cone* Γ_n . The Shannon cone is the polyhedral closed convex cone of set functions h that respect the following set of linear inequalities:

$$\begin{aligned} h([n] \setminus \{i\}) &\leq h([n]) \\ h(S) + h(S \cup \{i, j\}) &\leq h(S \cup \{i\}) + h(S \cup \{j\}) \\ h(\emptyset) &= 0 \end{aligned} \quad (2)$$

for all $S \subset [n] \setminus \{i, j\}$, $i \neq j$ and $i, j \in [n]$. These inequalities hold for entropy: The first relation – known as *monotonicity* – states that the uncertainty about a set of variables should always be larger than or equal to the uncertainty about any subset of it. The second inequality is the *sub-modularity* condition which is equivalent to the positivity of the conditional mutual information $I(X_i : X_j | X_S) = H(X_{S \cup i}) + H(X_{S \cup j}) - H(X_{S \cup \{i, j\}}) - H(X_S) \geq 0$. The inequalities above are known as the *elementary inequalities* in information theory or the *polymatroidal axioms* in combinatorial optimization. An inequality that follows from the elementary ones is said to be of *Shannon-type*.

The elementary inequalities encode the constraints that the entropies of *any* set of random variables are subject to. If one further demands that the random variables are a Bayesian network with respect to some given DAG, additional relations between their entropies will ensue. Indeed, it is a straight-forward but central realization for the program pursued here, that CI relations faithfully translate to homogeneous linear constraints on entropy:

$$X \perp\!\!\!\perp Y | Z \quad \Leftrightarrow \quad I(X : Y | Z) = 0. \quad (3)$$

The conditional independencies (CI) given by the local Markov condition are sufficient to characterize distributions that form a Bayesian network w.r.t. some fixed DAG. Any such distribution exhibits further CI relations, which can be algorithmically enumerated using the so-called *d-separation criterion* [23]. Let Γ_c be the subspace of R_n defined by the equality (3) for all such conditional independencies. In that language, *the joint distribution of a set of random variables obeys the Markov property w.r.t. to Bayesian network if and only if its entropy vector lies in the polyhedral convex cone $\Gamma_n^c := \Gamma_n \cap \Gamma_c$, that is, the distribution defines a valid entropy vector (obeying (2)) that is contained in Γ_c . The rest of this paper is concerned with the information that can be extracted from this convex polyhedron.*

We remark that this framework can easily be generalized in various directions. E.g., it is simple to incorporate certain quantitative bounds on causal influence. Indeed, small deviations of conditional independence can be expressed as $I(X : Y | Z) \leq \epsilon$ for some

$\epsilon > 0$. This is a (non-homogeneous) linear inequality on R_n . One can add any number of such inequalities to the definition of Γ_n^c while still retaining a convex polyhedron (if no longer a cone). The linear programming algorithm presented below will be equally applicable to these objects. (In contrast to entropies, the set of probability distributions subject to quantitative bounds on various mutual informations seems to be computationally and analytically intractable).

Another generalization would be to replace Shannon entropies by other, non-statistical, information measures. To measure similarities of strings, for instance, one can replace H with Kolmogorov complexity, which (essentially) also satisfies the polymatroidal axioms (2). Then, the conditional mutual information measures conditional algorithmic dependence. Due to the algorithmic Markov condition, postulated in [19], causal structures in nature also imply algorithmic independencies in analogy to the statistical case. We refer the reader to Ref. [30] for further information measures satisfying the polymatroidal axioms.

2.3 Marginal Scenarios

We are mainly interested in situations where not all joint distributions are accessible. Most commonly, this is because the variables X_1, \dots, X_n can be divided into observable ones V_1, \dots, V_m (e.g. medical symptoms) and hidden ones U_1, \dots, U_{n-m} (e.g. putative genetic factors). In that case, it is natural to assume that any subset of observable variables can be *jointly* observed. There are, however, more subtle situations (c.f. Sec. 4.2). In quantum mechanics, e.g., position and momentum of a particle are individually measurable, as is any combination of position and momentum of two distinct particles – however, there is no way to consistently assign a joint distribution to both position and momentum of the same particle [4].

This motivates the following definition: Given a set of variables X_1, \dots, X_n , a *marginal scenario* \mathcal{M} is the collection of those subsets of X_1, \dots, X_n that are assumed to be jointly measurable.

Below, we analyze the Shannon-type inequalities that result from a given Bayesian network and constrain the entropies accessible in a marginal scenario \mathcal{M} .

3 Algorithm for the entropic characterization of any DAG

Given a DAG consisting of n random variables and a marginal scenario \mathcal{M} , the following steps will produce all Shannon-type inequalities for the marginals:

Step 1: *Construct a description of the unconstrained*

Shannon cone. This means enumerating all $n + \binom{n}{2}2^{n-2}$ elementary inequalities given in (2).

Step 2: Add causal constraints presented as in (3). This corresponds to employing the d -separation criterion to construct all conditional independence relations implied by the DAG.

Step 3: *Marginalization.* Lastly, one has to eliminate all joint entropies not contained in \mathcal{M} .

The first two steps have been described in Sec. 2. We thus briefly discuss the marginalization, first from a geometric, then from an algorithmic perspective.

Given a set function $h : 2^{[n]} \rightarrow \mathbb{R}$, its restriction $h|_{\mathcal{M}} : \mathcal{M} \rightarrow \mathbb{R}$ is trivial to compute: If h is expressed as a vector in \mathbb{R}^n , we just drop all coordinates of h which are indexed by sets outside of \mathcal{M} . Geometrically, this amounts to a projection $P_{\mathcal{M}} : \mathbb{R}^{2^n} \rightarrow \mathbb{R}^{|\mathcal{M}|}$. The image of the constrained cone Γ_n^c under the projection $P_{\mathcal{M}}$ is again a convex cone, which we will refer to as $\Gamma^{\mathcal{M}}$. Recall that there are two dual ways of representing a polyhedral convex cone: in terms of either its extremal rays, or in terms of the inequalities describing its facets [2]. To determine the projection $\Gamma^{\mathcal{M}}$, a natural possibility would be to calculate the extremal rays of Γ_n^c and remove the irrelevant coordinates of each of them. This would result in a set of rays generating $\Gamma^{\mathcal{M}}$. However, Steps 1 & 2 above give a representation of Γ_n^c in terms of inequalities. Also, in order to obtain readily applicable tests, we would prefer an inequality presentation of $\Gamma^{\mathcal{M}}$. Thus, we have chosen an algorithmically more direct (if geometrically more opaque) procedure by employing Fourier-Motzkin elimination – a standard linear programming algorithm for eliminating variables from systems of inequalities [34].

In the remainder of the paper, we will discuss applications of inequalities resulting from this procedure to causal inference.

4 Applications

4.1 Conditions for Instrumentality

An instrument Z is a random variable that under certain assumptions helps identifying the causal effect of a variable X on another variable Y [16, 22, 5]. The simplest example is given by the instrumentality DAG in Fig. 1 (a), where Z is an instrumental variable and the following independencies are implied: (i) $I(Z : Y|X, U) = 0$ and (ii) $I(Z : U) = 0$. The variable U represents all possible factors (observed and unobserved) that may effect X and Y . Because conditions (i) and (ii) involve an unobservable variable U , the use of an instrument Z can only be justified if the observed

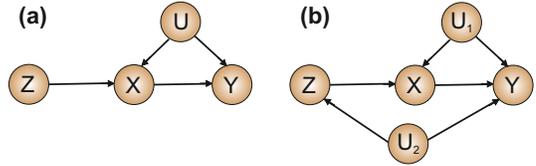

Figure 1: DAG (a) represents the instrumental scenario. DAG (b) allows for a common ancestor between Z and Y : unless some extra constraint is imposed (e.g. $I(Y, U_2) \leq \epsilon$) this DAG is compatible with any probability distribution for the variables X, Y and Z .

distribution falls inside the compatibility region implied by the instrumentality DAG. The distributions compatible with this scenario can be written as

$$p(x, y|z) = \sum_u p(u)p(y|x, u)p(x|z, u) \quad (4)$$

Note that (4) can be seen as a convex combination of deterministic functions assigning the values of X and Y [22, 5, 25]. Thus, the region of compatibility associated with $p(x, y|z)$ is a polytope and all the probability inequalities characterizing it can in principle be determined using linear programming. However, as the number of values taken by the variables increases, this approach becomes intractable [5] (see below for further comments). Moreover, if we allow for variations in the causal relations, e.g. the one shown in DAG (b) of Fig. 1, the compatibility region is not a polytope anymore and computationally challenging algebraic methods would have to be used [15]. For instance, the quantifier elimination method in [15] is unable to deal with the instrumentality DAG even in the simplest case of binary variables. We will show next how our framework can easily circumvent such problems.

Proceeding with the algorithm described in Sec. 3, one can see that after marginalizing over the latent variable U , the only non-trivial entropic inequality constraining the instrumental scenario is given by

$$I(Y : Z|X) + I(X : Z) \leq H(X). \quad (5)$$

By “non-trivial”, we mean that (5) is not implied by monotonicity and sub-modularity for the observable variables. The causal interpretation of (5) can be stated as follows: Since Z influence Y only through X , if the dependency between X and Z is large, then necessarily the dependency between Y and Z conditioned on knowing X should be small.

We highlight the fact that, irrespective of how many values the variables X, Y and Z may take (as long as they are discrete), (5) is the only non-trivial entropic

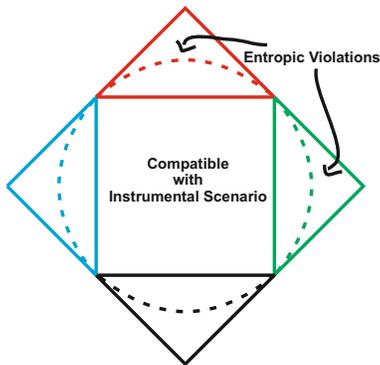

Figure 2: A comparison between the entropic and the probabilistic approach. The squares represent the polytope of distributions compatible with the instrumental DAG. Each facet in the square corresponds to one of the 4 non-trivial inequalities valid for binary variables [22, 5]. The triangles over the squares represent probability distributions that fail to be compatible with the instrumental constraints. Distributions outside the dashed curve are detected by the entropic inequality (5). Due to its non-linearity in terms of probabilities, (5) detects the non-compatibility associated with different probability inequalities. See [8] for more details.

constraint bounding the distributions compatible with the instrumentality test. This is in stark contrast with the probabilistic approach, for which the number of linear inequalities increases exponentially with the number of outcomes of the variables [5]. There is, of course, a price to pay for this concise description: There are distributions that are not compatible with the instrumental constraints, but fail to violate (5). In this sense, an entropic inequality is a necessary but not sufficient criterion for compatibility. However, it is still surprising that a single entropic inequality can carry information about causation that is in principle contained only in exponentially many probabilistic ones. This effect stems from the non-linear nature of entropy¹ and is illustrated in Fig. 2.

Assume now that some given distribution $p(x, y|z)$ is incompatible with the instrumental DAG. That could be due to some dependencies between Y and Z mediated by a common hidden variable U_2 as shown in DAG (b) of Fig. 1. Clearly, this DAG can explain any

¹We remark that the reduction of descriptive complexity resulting from the use of non-linear inequalities occurs for other convex bodies as well. The simplest example along these lines is the Euclidean unit ball B . It requires infinitely many linear inequalities to be defined (namely $B = \{x \mid (x, y) \leq 1 \forall y, \|y\|_2 \leq 1\}$). These can, of course, all be subsumed by the single non-linear condition $\|x\|_2 \leq 1$.

distribution $p(x, y|z)$ and therefore is not very informative. Notwithstanding, with our approach we can for instance put a quantitative lower bound on how dependent Y and U_2 need to be. Following the algorithm in Sec. 3, one can see that the only non-trivial constraint on the dependency between Y and U_2 is given by $I(Y : U_2) \leq H(Y|X)$. This inequality imposes a kind of *monogamy of correlations*: if the uncertainty about Y is small given X , their dependency is large, implying that Y is only slightly correlated with U_2 , since the latter is statistically independent of X .

4.2 Inferring direction of causation

As mentioned before, if all variables in the DAG are observed, the conditional independencies implied by the graphical model completely characterize the possible probability distributions [24]. For example, the DAGs displayed in Fig. 3 display a different set of CIs. For both DAGs we have $I(X : Z|Y, W) = 0$, however for DAG (a), it holds that $I(Y : W|X) = 0$ while for DAG (b) $I(Y : W|Z) = 0$. Hence, if the joint distributions of (Y, W, X) and (Y, W, Z) are accessible, then CI information can distinguish between the two networks and thus reveal the “direction of causation”.

In this section, we will show that the same is possible even if only two variables are jointly accessible at any time. We feel this is relevant for three reasons.

First – and somewhat subjectively – we believe the insight to be interesting from a fundamental point of view. Inferring the direction of causation between two variables is a notoriously thorny issue, hence it is far from trivial that it can be done from information about several pairwise distributions.

The second reason is that there are situations where joint distributions of many variables are unavailable due to practical or fundamental reasons. We have already mentioned quantum mechanics as one such example – and indeed, the present DAGs can be related to tests for quantum non-locality. We will briefly discuss the details below. But also purely classical situations are conceivable. For instance, Mendelian randomization is a good example where the joint distribution on all variables is often unavailable [10].

Thirdly, the “smoothing effect” of marginalizing may simplify the statistical analysis when only few samples are available. Conditioning on many variables or on variables that attain many different values often amounts to conditioning on events that happened only once. Common χ^2 -tests for CI [32] involve divisions by empirical estimates of variance, which lead to nonsensical results if no variance is observed. Testing for CI in those situations requires strong assumptions (like smoothness of dependencies) and remains

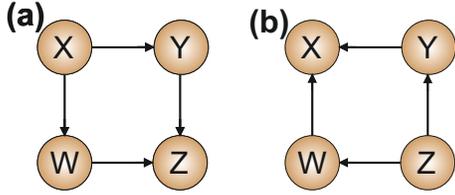

Figure 3: DAGs with no hidden variables and opposite causation directions. The DAGs can be distinguished based on the CIs induced by them. However, if only pairwise information is available one must resort to the marginalization procedure described in Sec. 3.

a challenging research topic [13, 36]. Two-variable marginals, while containing strictly less information than three-variable ones, show less fluctuations and might thus be practically easier to handle. This benefit may not sound spectacular as long as it refers to 2- versus 3-variable marginals. However, in general, our formalism can provide inequality constraints for k -variable marginals from equality constraints that involve ℓ -variable marginals for $\ell \gg k$.

We note that causal inference schemes using only pairwise mutual information is already known for trees, i.e., DAGs containing no undirected cycles. The data processing inequality implies that for every node, the mutual information to a direct neighbor cannot be smaller than the one with the neighbor of this neighbor. Hence one can find adjacencies based on pairwise mutual information only. This has been used e.g. for phylogenetic trees [17, 9]. In that sense, our results generalize these ideas to DAGs with cycles.

The non-trivial constraints on two-variable entropies given by our algorithm for the DAG (a) of Fig. 3 are:

$$\begin{aligned}
 H_Y - H_X - H_{YW} + H_{XW} &\leq 0 & (6) \\
 H_W - H_X - H_{YW} + H_{XY} &\leq 0 \\
 H_{WZ} - H_{YW} - H_{XZ} + H_{XY} &\leq 0 \\
 H_{YZ} - H_{YW} - H_{XZ} + H_{XW} &\leq 0 \\
 H_Y - H_X + H_W - H_{WZ} - H_{YZ} + H_{XZ} &\leq 0 \\
 H_Z - H_X - H_{YW} - H_{XZ} + H_{XW} + H_{XY} &\leq 0 \\
 H_Z + H_X \\
 + H_{YW} + H_{XZ} - H_{XW} - H_{XY} - H_{WZ} - H_{YZ} &\leq 0.
 \end{aligned}$$

The ones for DAG (b) are obtained by the substitution $X \leftrightarrow Z$. Invariant under this, the final inequality is valid for both scenarios. In contrast, the first six inequalities can be used to distinguish the DAGs.

As an example, one can consider the following structural equations compatible only with the DAG (b): Z is a uniformly distributed m -valued random variable,

$Y = W = Z$, and $X = Y \oplus W$ (addition modulo m). A direct calculation shows that the first inequality in (6) is violated, thus allowing one to infer the correct direction of the arrows in the DAG.

As alluded to before, we close this section by mentioning a connection to quantum non-locality [4]. Using the linear programming algorithm, one finds that the final inequality in (6) is actually valid for *any* distribution of four random variables, not only those that constitute Bayesian networks w.r.t. the DAGs in Fig. 3. In that sense it seems redundant, or, at best, a sanity check for consistency of data. It turns out, however, that it can be put to non-trivial use. While the purpose of causal inference is to check compatibility of data with a presumed causal structure, the task of quantum non-locality is to devise tests of compatibility with classical probability theory as a whole. Thus, if said inequality is violated in a quantum experiment, it follows that there is no way to construct a joint distribution of all four variables that is consistent with the observed two-variable marginals – and therefore that classical concepts are insufficient to explain the experiment.

While not every inequality which is valid for all classical distributions can be violated in quantum experiments, the constraints in (6) do give rise to tests with that property. To see this, we further marginalize over $H(X, Z)$ and $H(Y, W)$ to obtain

$$H_{XY} + H_{XW} + H_{YZ} - H_{WZ} - H_Y - H_X \leq 0 \quad (7)$$

(and permutations thereof). These relations have been studied as the “entropic version of the CHSH Bell inequality” in the physics literature [6, 12, 7], where it is shown that (7) can be employed to witness that certain measurements on quantum systems do not allow for a classical model.

4.3 Inference of common ancestors in semi-Markovian models

In this section, we re-visit in greater generality the problem considered in [29]: using entropic conditions to distinguish between hidden common ancestors.

Any distribution of a set of n random variables can be achieved if there is one latent parent (or *ancestor*) common to all of them [23]. However, if the dependencies can also be obtained from a less expressive DAG – e.g. one where at most two of the observed variables share an ancestor – then Occam’s Razor would suggest that this model is preferable. The question is then: what is the simplest common ancestor causal structure explaining a given set of observations?

One should note that unless we are able to intervene in the system under investigation, in general it may

be not possible to distinguish direct causation from a common cause. For instance, consider the DAGs (a) and (c) displayed in Fig. 4. Both DAGs are compatible with any distribution and thus it is not possible to distinguish between them from passive observations alone. For this reason and also for simplicity, we restrict our attention to semi-Markovian models where all the observable variables are assumed to have no direct causation on each other or on the hidden variables. Also, the hidden variables are assumed to be mutually independent. It is clear then that all dependencies between the observed quantities can only be mediated by their hidden common ancestors. We refer to such models as common ancestors (CM) DAGs. We reinforce, however, that our framework can also be applied in the most general case. As will be explained in more details in Sec. 4.4, in some cases, common causes can be distinguished from direct causation. Our framework can also be readily applied in these situations.

We begin by considering the simplest non-trivial case, consisting of three observed variables [29, 11, 7]. If no conditional independencies between the variables occur, then the graphs in Fig. 4 (a) and (b) represent the only compatible CM DAGs. Applying the algorithm described in Sec. 3 to the model (b), we find that one non-trivial class of constraints is given by

$$I(V_1 : V_2) + I(V_1 : V_3) \leq H(V_1) \quad (8)$$

and permutations thereof [11, 7].

It is instructive to pause and interpret (8). It states, for example, that if the dependency between V_1 and V_2 is maximal ($I(V_1 : V_2) = H(V_1)$) then there should be no dependency at all between V_1 and V_3 ($I(V_1 : V_3) = 0$). Note that $I(V_1 : V_2) = H(V_1)$ is only possible if V_1 is a deterministic function of the common ancestor U_{12} alone. But if V_1 is independent of U_{13} , it cannot depend on V_3 and thus $I(V_1 : V_3) = 0$.

Consider for instance a distribution given by

$$p(v_1, v_2, v_3) = \begin{cases} 1/2 & , \text{ if } v_1 = v_2 = v_3 \\ 0 & , \text{ otherwise} \end{cases} \quad (9)$$

This stands for a perfect correlation between all the three variables and clearly cannot be obtained by pairwise common ancestors. This incompatibility is detected by the violation of (8).

We now establish the following generalization of (8) to an arbitrary number of observables:

Theorem 1 *For any distribution that can be explained by a CM DAG where each of the latent ancestors influences at most m of the observed variables,*

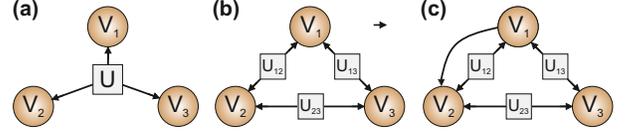

Figure 4: Models (a) and (b) are CM DAGs for three observable variables V_1, V_2, V_3 . Unlike (b), DAG (a) is compatible with any observable distribution. DAG (c) involves a direct causal influence between the observable variable V_1 and V_2 .

we have

$$\sum_{\substack{i=1, \dots, n \\ i \neq j}} I(V_i : V_j) \leq (m-1)H(V_j). \quad (10)$$

We present the proof for the case $m = 2$ while the general proof can be found in the supplemental material.

Lemma 1 *In the setting of Thm. 1 for $m = 2$:*

$$\sum_{i=2}^n H(V_j U_{ji}) \geq (N-2)H(V_j) + H(V_j \bigcup_{i=2}^N U_{ji}). \quad (11)$$

Proof. (By induction) We treat the case $j = 1$ w.l.o.g. For $n = 2$ equality holds trivially. Now assuming the validity of the inequality for any n :

$$\sum_{i=2}^{n+1} H(V_1 U_{1i}) \geq (n-2)H(V_1) \quad (12)$$

$$+ H(V_1 \bigcup_{i=2}^n U_{1i}) + H(V_1 U_{1(n+1)}) \\ \geq [(n+1) - 2]H(V_1) + H(V_1 \bigcup_{i=2}^{n+1} U_{1i}). \quad (13)$$

From (12) to (13) we have used sub-modularity. \square

Proof of Theorem 1. Apply the data processing inequality to the left-hand side of (10) to obtain

$$\sum_{i=2}^n I(A_1 : A_i) \leq \sum_{i=2}^n I(A_1 : U_{1i}) \\ = (n-1)H(A_1) + \sum_{i=2}^n H(\lambda_{1i}) - \sum_{i=2}^n H(A_1 \lambda_{1i}).$$

With Lemma 1, we get

$$\sum_{i=2}^n I(V_1 : V_i) \leq (n-1)H(V_1) + \sum_{i=2}^n H(U_{1i}) \\ - [(n-2)H(V_1) + H(V_1 \bigcup_{i=2}^n U_{1i})].$$

The mutual independence of hidden variables yields $\sum_{i=2}^n H(U_{1i}) = H(\bigcup_{i=2}^n U_{1i})$ implying that

$$\sum_{i=2}^n I(V_1 : V_i) \leq H(V_1) - H(V_1 | \bigcup_{i=2}^n U_{1i}) \leq H(V_1).$$

\square

We highlight the fact that Ineq. (10) involves only pairwise distributions – the discussion in Sec. 4.2 applies. Following our approach, one can derive further entropic inequalities, in particular involving the joint entropy of all observed variables. A more complete theory will be presented elsewhere.

4.4 Quantifying causal influences

Unlike conditional independence, mutual information captures dependencies in a quantitative way. In this section, we show that our framework allows one to derive non-trivial bounds on the strength of causal links. We then go on to present two corollaries of this result: First, it follows that the degree of violation of an entropic inequality often carries an operational meaning. Second, under some assumptions, the finding will allow us to introduce a novel way of distinguishing dependence created through common ancestors from direct causal influence.

Various measures of causal influence have been studied in the literature. Of particular interest to us is the one recently introduced in [18]. The main idea is that the causal strength $\mathcal{C}_{X \rightarrow Y}$ between a variable X on another variable Y should measure the impact of an intervention that removes the arrow between them. Ref. [18] draws up a list of reasonable postulates that a measure of causal strength should fulfill. Of special relevance to our information-theoretic framework is the axiom stating that

$$\mathcal{C}_{X \rightarrow Y} \geq I(X : Y | \text{PA}_Y^X), \quad (14)$$

where PA_Y^X stands for the parents of variable Y other than X . We focus on this property, as the quantity $I(X : Y | \text{PA}_Y^X)$ appears naturally in our description and thus allows us to bound any measure of causal strength $\mathcal{C}_{X \rightarrow Y}$ for which (14) is valid.

To see how this works in practice, we start by augmenting the common ancestor scenario considered in the previous section. Assume that now we do allow for direct causal influence between two variables, in addition to pairwise common ancestors – c.f. Fig. 4 (c). Then (14) becomes $\mathcal{C}_{V_1 \rightarrow V_2} \geq I(V_1 : V_2 | U_{12}, U_{13})$. We thus re-run our algorithm, this time with the unobservable quantity $I(V_1 : V_2 | U_{12}, U_{13})$ included in the marginal scenario. The result is

$$I(V_1 : V_2 | U_{12}, U_{13}) \geq I(V_1 : V_2) + I(V_1 : V_3) - H(V_1), \quad (15)$$

which lower-bounds the causal strength in terms of observable entropies.

The same method yields a particularly concise and relevant result when applied to the instrumental test of Sec. 4.1. The instrumental DAG may stand, for example, for a clinical study about the efficacy of some

drug where Z would label the treatment assigned, X the treatment received, Y the observed response and U for any observed or unobserved factors affecting X and Y . In this case we would be interested not only in checking the compatibility with the presumed causal relations but also the direct causal influence of the drug on the expected observed response, that is, $\mathcal{C}_{Z \rightarrow Y}$. After the proper marginalization we conclude that $\mathcal{C}_{Z \rightarrow Y} \geq I(Y : Z) + I(X : Z) - H(X)$, a strikingly simple, but non-trivial bound that can be computed from the observed quantities alone. Likewise, if one allows the instrumental DAG to have an arrow connecting Z and Y , one finds

$$\mathcal{C}_{Z \rightarrow Y} \geq I(Y : Z | X) + I(X : Z) - H(X). \quad (16)$$

The findings presented here can be re-interpreted in two ways:

First, note that the right hand side of the lower bound (15) is nothing but Ineq. (8), a constraint on distributions compatible with DAG 3 (b). Similarly, the r.h.s. of (16) is just the degree of violation of the entropic instrumental inequality (5).

We thus arrive at the conceptually important realization that the entropic conditions proposed here offer more than just binary tests. To the contrary, their degree of violation is seen to carry a quantitative meaning in terms of strengths of causal influence.

Second, one can interpret the results of this sections as providing a novel way to distinguish between DAGs (a) and (c) in Fig. 4 without experimental data. Assume that we have some information about the physical process that could facilitate direct causal influence from V_1 to V_2 in (c), and that we can use that prior information to put a quantitative upper bound on $\mathcal{C}_{V_1 \rightarrow V_2}$. Then we must reject the direct causation model (c) in favor of a common ancestor explanation (a), as soon as the observed dependencies violate the bound (15). As an illustration, the perfect correlations exhibited by the distribution (9) is incompatible with DAG (c), as long as $\mathcal{C}_{V_1 \rightarrow V_2}$ is known to be smaller than 1.

5 Statistical Tests

In this section, we briefly make the point that inequality-based criteria immediately suggest test statistics which can be used for testing hypotheses about causal structures. While a thorough treatment of statistical issues is the subject of ongoing research [3, 26], it should become plain that the framework allows to derive non-trivial tests in a simple way.

Consider an inequality $I := \sum_{S \subset 2^{[n]}} c_S H(S) \leq 0$ for suitable coefficients c_S . Natural candidates for test

statistics derived from it would be $T_I := \sum_S c_S \hat{H}(S)$ or $T'_I := \frac{T_I}{\sqrt{\text{var}(T_I)}}$, where $\hat{H}(S)$ is the entropy of the empirical distribution of X_S , and var is some consistent estimator of variance (e.g. a bootstrap estimator). If the inequality I is fulfilled for some DAG G , then a test with null hypothesis “data is compatible with G ” can be designed by testing $T_I \leq t$ or $T'_I \leq t$, for some critical value $t > 0$. In an asymptotic regime, there could be reasonable hope to analytically characterize the distribution of T'_I . However, in the more relevant small sample regime, one will probably have to resort to Monte Carlo simulations in order to determine t for a desired confidence level. In that case, we prefer to use T_I , by virtue of being “less non-linear” in the data.

We have performed a preliminary numerical study using the DAG given in Fig. 4 (b) together with Ineq. (8). We have simulated experiments that draw 50 samples from various distributions of three binary random variables V_1, V_2, V_3 and compute the test statistic T_I . To test at the 5%-level, we must choose t large enough such that for all distributions p compatible with 4(b), we have a type-I error rate $\Pr_p[T_I > t]$ below 5%. We have employed the following heuristics for finding t : (1) It is plausible that the highest type-I error rate occurs for distributions p that reach equality $\mathbb{E}_p[\hat{I}] = 0$; (2) This occurs only if V_1 is a deterministic function of V_2 and V_3 . From there, it follows that V_1 must be a function of one of V_2 or V_3 and we have used a Monte Carlo simulation with (V_2, V_3) uniformly random and $V_1 = V_2$ to find $t = .0578$. Numerical checks failed to identify distributions with higher type-I rate (though we have no proof). Fig. 5 illustrates the resulting test.

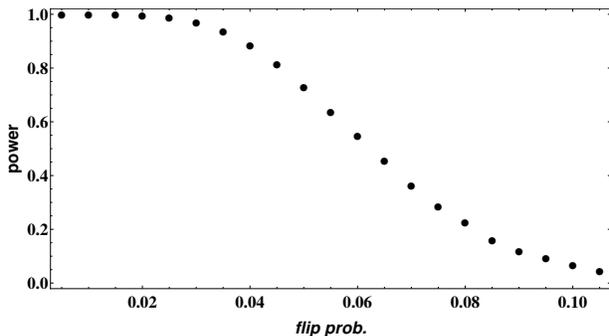

Figure 5: Power (1 minus type-II error) of the test $T_I \geq t$ for the DAG Fig. 4(b) derived from Ineq. (8) using 50 samples. The test was run on a distribution obtained by starting with three perfectly correlated binary random variables as in (9) and then inverting each of the variables independently with a given “flip probability” (x axis). Every data point is the result of 10000 Monte Carlo simulations.

6 Conclusions

Hidden variables imply nontrivial constraints on observable distributions. While we cannot give a complete characterization of these constraints, we show that a number of nontrivial constraints can be elegantly formulated in terms of entropies of subsets of variables. These constraints are linear (in)equalities, which lend themselves well to algorithmic implementation.

Remarkably, our approach only requires the polymatroidal axioms, and thus also applies to various information measures other than Shannon entropy. Some of these may well be relevant to causal inference and structure learning and may constitute an interesting topic for future research.

Abstract

We consider adaptive pool-based active learning in a Bayesian setting. We first analyze two commonly used greedy active learning criteria: the maximum entropy criterion, which selects the example with the highest entropy, and the least confidence criterion, which selects the example whose most probable label has the least probability value. We show that unlike the non-adaptive case, the maximum entropy criterion is not able to achieve an approximation that is within a constant factor of optimal policy entropy. For the least confidence criterion, we show that it is able to achieve a constant factor approximation to the optimal version space reduction in a worst-case setting, where the probability of labelings that have not been eliminated is considered as the version space. We consider a third greedy active learning criterion, the Gibbs error criterion, and generalize it to handle arbitrary loss functions between labelings. We analyze the properties of the generalization and its variants, and show that they perform well in practice.

1 INTRODUCTION

We study pool-based active learning (McCallum and Nigam, 1998) where the training data are sequentially selected and labeled from a pool of unlabeled examples, with the aim of having good performance after only a small number of examples are labeled. In practice, the selection of the next example to be labeled is usually done by greedy optimization of some appropriate objective function.

In this paper, we consider adaptive algorithms for pool-based active learning with a budget of k queries in a Bayesian setting. We examine three commonly used greedy criteria and their performance guarantees. We also generalize one of the criteria, study its properties and show that it performs well in practice.

One of the most commonly used criteria is the *maximum entropy criterion*: select the example with maximum label entropy given the observed labels (Settles, 2010). In the non-adaptive case where the set of examples must be selected before any label is observed, the analogue of this greedy criterion selects the example that maximally increases the label entropy of the selected set. This greedy criterion in the non-adaptive case is well-known to be near-optimal: the label entropy of the selected examples is at least $(1 - 1/e)$ of the optimal set. This follows from a property satisfied by the entropy function called *submodularity*. Selecting a set with large label entropy is desirable, as the chain rule of entropy implies that maximizing the label entropy of the selected set will minimize the conditional label entropy of the remaining examples. It would be desirable to have a similar near-optimal performance guarantee for the adaptive case where the label is provided after every example is selected. Whether the greedy maximum entropy criterion provides such a guarantee was not known (Cuong et al., 2013), although it was suspected that it does not. In this paper, we show that the greedy algorithm, indeed, does not provide a constant factor approximation in the adaptive case.

Another commonly used greedy criterion is the *least confidence criterion*: select the example whose most likely label has the smallest probability (Lewis and Gale, 1994; Culotta and McCallum, 2005). In this paper, we show that this criterion provides a near-optimal adaptive algorithm for maximizing the worst-case version space reduction, where the version space is the probability of labelings that are consistent with the observed labels. This will be derived as the consequence of a more general result which shows such near-optimal approximation holds for utility functions that satisfy *pointwise submodularity* and *minimal dependency*. Pointwise submodular functions were previously studied in (Guillory and Bilmes, 2010) for active learning, but with a different objective function which focuses on identifying the true function.

The *Gibbs error criterion* was proposed in (Cuong et al., 2013) as an alternative uncertainty measure suitable for ac-

Table 1: Theoretical Properties of Greedy Criteria for Adaptive Active Learning

Criterion	Objective	Near-optimality	Property
Maximum entropy	Policy entropy	No constant factor approximation (this paper)	
Least confidence	Worst-case version space reduction	(1-1/e) factor approximation (this paper)	Pointwise monotone submodular
Maximum Gibbs error	Policy Gibbs error (expected version space reduction)	(1-1/e) factor approximation (Cuong et al., 2013)	Adaptive monotone submodular

tive learning. The criterion selects the example with the largest Gibbs error for labeling. The Gibbs error is the expected error of the Gibbs classifier, which predicts the label by sampling from the current label distribution. Gibbs error is a special case of Tsallis entropy, introduced in statistical mechanics (Tsallis and Brigatti, 2004) as a generalization of the Shannon entropy (which is used in the maximum entropy criterion). In (Cuong et al., 2013), Gibbs error was used as a lower bound to the Shannon entropy and was maximized in order to minimize the posterior conditional entropy. It was shown in (Cuong et al., 2013) that using the Gibbs error criterion achieves at least $(1 - 1/e)$ of the optimal policy Gibbs error, a performance measure for this criterion, given k queries in the adaptive case. This relies on the property that the version space reduction function is *adaptive submodular* (Golovin and Krause, 2011).

The results for the three commonly used greedy criteria are shown in Table 1.

The Gibbs error criterion can be seen as a greedy algorithm for sequentially maximizing the Gibbs error over the dataset. The Gibbs error of the dataset is the expected error of a Gibbs classifier that predicts using an entire labeling sampled from the prior label distribution for the entire dataset. Here, a labeling is considered incorrect if any example is incorrectly labeled by the Gibbs classifier. Predicting an entirely correct labeling of all examples is often unrealistic in practice, particularly after only a few examples are labeled. This motivates us to generalize the Gibbs error to handle different loss functions between labelings, e.g. Hamming loss which measures the Hamming distance between two labelings. We call the greedy criterion that uses general loss functions the *average generalized Gibbs error* criterion.

The corresponding performance measure for the average generalized Gibbs error criterion is the generalized policy Gibbs error, which is the expected value of the generalized version space reduction function. The generalized version space reduction function is an extension of the version space reduction function with general loss functions. We investigate whether the generalized version space reduction

function is adaptive submodular, as this property would provide a constant factor approximation for the average generalized Gibbs error criterion. Unfortunately, we can show that the generalized version space reduction function is not necessarily adaptive submodular, although it is adaptive submodular for the special case of the version space reduction function. Despite that, we show in our experiments that the average generalized Gibbs error criterion can perform well in practice, even when we do not know whether the corresponding utility function is adaptive submodular.

As in the case for the least confidence criterion, we also consider a worst-case setting for the generalized Gibbs error. The worst case against a target labeling can be severe, so we consider a variant: the total generalized version space reduction function. This function targets the sum of the remaining losses over all the remaining labelings, rather than against a single worst-case labeling. We call the corresponding greedy criterion the *worst-case generalized Gibbs error* criterion. It selects the example with maximum worst-case total generalized version space reduction as the next query. As the total generalized version space reduction function is pointwise submodular and satisfies the minimal dependency property, the method is guaranteed to be near-optimal. Our experiments show that the worst-case generalized Gibbs error criterion performs well in practice. For binary problems, the maximum entropy, least confidence, and Gibbs error criteria are all equivalent, and the worst-case generalized Gibbs error criterion outperforms them for most problems in our experiments.

2 PRELIMINARIES

Let \mathcal{X} be a finite set of items (or examples), and let \mathcal{Y} be a finite set of labels (or states). A *labeling* of \mathcal{X} is a function from \mathcal{X} to \mathcal{Y} , and a *partial labeling* is a partial function from \mathcal{X} to \mathcal{Y} . Each labeling of \mathcal{X} can be considered as a hypothesis in the hypothesis space $\mathcal{H} = \mathcal{Y}^{\mathcal{X}}$. In the Bayesian setting, there is a prior probability $p_0[h]$ on \mathcal{H} , and an unknown true hypothesis h_{true} is initially drawn from $p_0[h]$. After observing a labeled set (i.e. a partial labeling) \mathcal{D} ,

we can obtain the posterior $p_{\mathcal{D}}[h] = p_0[h|\mathcal{D}]$ using Bayes' rule.

For any $S \subseteq \mathcal{X}$ and any distribution p on \mathcal{H} , we write $p[\mathbf{y}; S]$ to denote the probability that a randomly drawn hypothesis from p assigns labels in the sequence \mathbf{y} to items in the sequence S . That is, $p[\mathbf{y}; S] \stackrel{\text{def}}{=} \sum_{h \in \mathcal{H}} p[h] \mathbb{P}[h(S) = \mathbf{y}|h]$, where we use the notation $h(S)$ to denote the sequence $(h(x_1), \dots, h(x_i))$ whenever S is a sequentially constructed set (x_1, \dots, x_i) , or simply the set $\{h(x) : x \in S\}$ if the items in S are not ordered. In our setting, h is a deterministic hypothesis, so $\mathbb{P}[h(S) = \mathbf{y}|h] = \mathbf{1}(h(S) = \mathbf{y})$, where $\mathbf{1}(\cdot)$ is the indicator function. Note that $p[\cdot; S]$ is a probability distribution on the set of all label sequences \mathbf{y} of S . For $x \in \mathcal{X}$ and $y \in \mathcal{Y}$, we also write $p[y; x]$ for $p[\{y\}; \{x\}]$.

In practice, we often consider probabilistic models (like the naive Bayes models) which are used to generate labels for examples, and a prior is imposed on these models instead of on the labelings. In this case, we can follow the construction in the supplementary material of (Cuong et al., 2013) to construct an equivalent prior on the labelings and work with this induced prior.

We consider pool-based active learning with a fixed budget: given a budget of k queries, we aim to adaptively select from the pool \mathcal{X} the best k examples with respect to some objective function.¹ A pool-based active learning algorithm corresponds to a policy for choosing training examples from \mathcal{X} . A *policy* is a mapping from a partial labeling to the next unlabeled example to query. When the active learning policy chooses an unlabeled example, its label according to h_{true} will be revealed.

A policy can be represented by a policy tree in which each node corresponds to an unlabeled example to query, and edges below a node correspond to its labels. In this paper, we use policy and policy tree interchangeably. A policy can be non-adaptive or adaptive. In a non-adaptive policy, the observed labels are not taken into account when the policy chooses the next example. An adaptive policy, on the other hand, can use the observed labels to determine the next example to query. We will focus on adaptive policies in this paper.

Let Π_k be the set of policy trees of height k . Note that $\Pi_{|\mathcal{X}|}$ contains full policy trees, while Π_k with $k < |\mathcal{X}|$ contains partial policy trees. Following the insight in (Cuong et al., 2013), for any (full or partial) policy π , we define a probability distribution $p_0^\pi[\cdot]$ over the paths from the root to a leaf of π . Intuitively, $p_0^\pi[\rho]$ is the probability that the policy π follows the path ρ during its execution. This probability distribution is induced by the randomness of h_{true} and is

¹ In our setting, the usual objective of determining the true hypothesis h_{true} is infeasible unless the support of p_0 is small. When $p_0[h] > 0$ for all h , we need to query the whole pool \mathcal{X} in order to determine h_{true} .

defined as $p_0^\pi[\rho] \stackrel{\text{def}}{=} p_0[y_\rho; x_\rho]$, where x_ρ (resp. y_ρ) is the sequence of examples (resp. labels) along path ρ . Some objective functions for pool-based active learning can be defined using this probability distribution.

3 SUBMODULARITY

Our objective in active learning can often be stated as maximizing some average or worst-case performance with respect to some utility function $f(S)$ in the non-adaptive case, or $f(S, h)$ in the adaptive case, where S is the set of chosen examples. When $f(S)$ is submodular or $f(S, h)$ is adaptive submodular, greedy algorithms are known to be near-optimal (Nemhauser et al., 1978; Golovin and Krause, 2011). We shall briefly summarize some results about greedy optimization of submodular functions and adaptive submodular functions, then prove a new result about the worst-case near-optimality of a greedy algorithm for maximizing a pointwise submodular function.²

3.1 NEAR-OPTIMALITY OF SUBMODULAR MAXIMIZATION

A set function $f : 2^{\mathcal{X}} \rightarrow \mathbb{R}$ is *submodular* if it satisfies the following diminishing return property: for all $A \subseteq B \subseteq \mathcal{X}$ and $x \in \mathcal{X} \setminus B$,

$$f(A \cup \{x\}) - f(A) \geq f(B \cup \{x\}) - f(B).$$

The function f is called *monotone* if $f(A) \leq f(B)$ for all $A \subseteq B$.

To select a set of size k that maximizes a monotone submodular function, one greedy strategy is to iteratively select the next example x^* that satisfies

$$x^* = \arg \max_x \{f(S \cup \{x\}) - f(S)\}, \quad (1)$$

where S is the previously selected examples. The following theorem by Nemhauser et al. (1978) states the near-optimality of this greedy algorithm when maximizing a monotone submodular function.

Theorem 1 (Nemhauser et al. 1978). *Let f be a monotone submodular function such that $f(\emptyset) = 0$, and let S_k be the set of examples selected up to iteration k using the greedy criterion in Equation (1). Then for all $k > 0$, we have $f(S_k) \geq (1 - 1/e) \max_{|S|=k} f(S)$.*

3.2 NEAR-OPTIMALITY OF ADAPTIVE SUBMODULAR MAXIMIZATION

Adaptive submodularity (Golovin and Krause, 2011) is an extension of submodularity to the adaptive setting. For a partial labeling \mathcal{D} and a full labeling h , we write $h \sim \mathcal{D}$ to

² Note that our result can also be applied to settings other than active learning.

denote that \mathcal{D} is consistent with h . That is, $\mathcal{D} \subseteq h$ when we view a labeling as a set of (x, y) pairs. For two partial labelings \mathcal{D} and \mathcal{D}' , we call \mathcal{D} a sub-labeling of \mathcal{D}' , if $\mathcal{D} \subseteq \mathcal{D}'$.

We consider a utility function $f : 2^{\mathcal{X}} \times \mathcal{Y}^{\mathcal{X}} \rightarrow \mathbb{R}_{\geq 0}$ which depends on the examples selected and the true labeling of \mathcal{X} . For a partial labeling \mathcal{D} and an example x , we define $\Delta(x|\mathcal{D}) \stackrel{\text{def}}{=} \mathbb{E}_h [f(\text{dom}(\mathcal{D}) \cup \{x\}, h) - f(\text{dom}(\mathcal{D}), h) | h \sim \mathcal{D}]$, where the expectation is with respect to $p_0[h \sim \mathcal{D}]$ and $\text{dom}(\mathcal{D})$ is the domain of \mathcal{D} .

From the definitions in (Golovin and Krause, 2011), f is *adaptive submodular* with respect to p_0 if for all \mathcal{D} and \mathcal{D}' such that $\mathcal{D} \subseteq \mathcal{D}'$, and for all $x \in \mathcal{X} \setminus \text{dom}(\mathcal{D}')$, we have $\Delta(x|\mathcal{D}) \geq \Delta(x|\mathcal{D}')$. Furthermore, f is *adaptive monotone* with respect to p_0 if for all \mathcal{D} with $p_0[h \sim \mathcal{D}] > 0$ and for all $x \in \mathcal{X}$, we have $\Delta(x|\mathcal{D}) \geq 0$.

Let π be a policy for selecting the examples and x_h^π be the set of examples selected by π under the true labeling h . We define the expected utility of π as $f_{\text{avg}}(\pi) \stackrel{\text{def}}{=} \mathbb{E}[f(x_h^\pi, h)]$, where the expectation is with respect to $p_0[h]$. To adaptively select a set of size k that maximizes f_{avg} , one greedy strategy is to iteratively select the next example x^* that satisfies

$$x^* = \arg \max_x \Delta(x|\mathcal{D}), \quad (2)$$

where \mathcal{D} is the partial labeling that has already been observed. The following theorem by Golovin and Krause (2011) states the near-optimality of this greedy policy when f is adaptive monotone submodular.

Theorem 2 (Golovin and Krause 2011). *Let f be an adaptive monotone submodular function with respect to p_0 , π be the adaptive policy selecting k examples using Equation (2), and π^* be the optimal policy with respect to f_{avg} that selects k examples. Then for all $k > 0$, we have $f_{\text{avg}}(\pi) > (1 - 1/e)f_{\text{avg}}(\pi^*)$.*

3.3 NEAR-OPTIMALITY OF POINTWISE SUBMODULAR MAXIMIZATION

Theorem 2 gives near-optimal average-case performance guarantee for greedily optimizing an adaptive monotone submodular function. We now give a new near-optimal worst-case performance guarantee for greedily optimizing a pointwise monotone submodular function. A utility function $f : 2^{\mathcal{X}} \times \mathcal{Y}^{\mathcal{X}} \rightarrow \mathbb{R}_{\geq 0}$ is said to be *pointwise submodular* if the set function $f_h(S) \stackrel{\text{def}}{=} f(S, h)$ is submodular for all h . Similarly, f is *pointwise monotone* if $f_h(S)$ is monotone for all h .

When f is pointwise monotone submodular, the average utility $f_{\text{avg}}(S) = \mathbb{E}_{h \sim p_0}[f(S, h)]$ is monotone submodular, and thus the non-adaptive greedy algorithm is a near-optimal non-adaptive policy for maximizing $f_{\text{avg}}(S)$

(Golovin and Krause, 2011). However, we are more interested in the adaptive policies in this section.

For any partial labeling \mathcal{D} , any $x \in \mathcal{X} \setminus \text{dom}(\mathcal{D})$, and any $y \in \mathcal{Y}$, we write $\mathcal{D} \cup \{(x, y)\}$ to denote the partial labeling \mathcal{D} with an additional mapping from x to y .

We assume that for any $S \subseteq \mathcal{X}$ and any labeling h , the value of $f(S, h)$ does not depend on the labels of examples in $\mathcal{X} \setminus S$. We call this the *minimal dependency* property. Let us extend the definition of f so that its second parameter can be a partial labeling. The minimal dependency property implies that for any partial labeling \mathcal{D} and any labeling $h \sim \mathcal{D}$, we have $f(\text{dom}(\mathcal{D}), h) = f(\text{dom}(\mathcal{D}), \mathcal{D})$. Without this minimal dependency property, the theorem in this section may not hold. We will see some examples of functions that satisfy or do not satisfy the minimal dependency property in Section 4 and 5.

For a partial labeling \mathcal{D} and an example x , define

$$\delta(x|\mathcal{D}) \stackrel{\text{def}}{=} \min_{y \in \mathcal{Y}} \{f(\text{dom}(\mathcal{D}) \cup \{x\}, \mathcal{D} \cup \{(x, y)\}) - f(\text{dom}(\mathcal{D}), \mathcal{D})\}.$$

We consider the adaptive greedy strategy that iteratively selects the next example x^* satisfying

$$x^* = \arg \max_x \delta(x|\mathcal{D}), \quad (3)$$

where \mathcal{D} is the partial labeling that has already been observed. For any policy π , let $f_{\text{worst}}(\pi) \stackrel{\text{def}}{=} \min_h f(x_h^\pi, h)$ be the worst-case objective function. The following theorem states the near-optimality of the above greedy policy with respect to f_{worst} when f is pointwise monotone submodular.³

Theorem 3. *Let f be a pointwise monotone submodular function such that $f(\emptyset, h) = 0$ for all h , and f satisfies the minimal dependency property. Let π be the adaptive policy selecting k examples using Equation (3), and π^* be the optimal policy with respect to f_{worst} that selects k examples. Then for all $k > 0$, we have $f_{\text{worst}}(\pi) > (1 - 1/e)f_{\text{worst}}(\pi^*)$.*

The main idea in proving this theorem is to show that at every step, the greedy policy can cover at least $(1/k)$ -fraction of the optimal remaining utility. This property can be proven by replacing the current greedy step with the optimal policy and considering the adversary's path for this optimal policy. See Appendix A for a proof of this theorem.

We note that in the worst-case setting, Golovin and Krause (2011) also considered the problem of minimizing the number of queries needed to achieve a target utility value. However, their results mainly rely on the condition that the

³ Note that in the definition of $f_{\text{worst}}(\pi)$, h has to range over the set $\mathcal{Y}^{\mathcal{X}}$ of all possible labelings. Otherwise, Theorem 3 does not necessarily hold.

utility function is adaptive submodular, not the pointwise submodular condition considered in this section. It is also worth noting that our new greedy criterion in Equation (3) is different from the greedy criterion considered by Golovin and Krause (2011), which is essentially Equation (2). Thus, our result does not follow from their result and is developed using a different argument.

4 PROPERTIES OF GREEDY ACTIVE LEARNING CRITERIA

We now briefly introduce three greedy criteria that have been used for active learning: maximum entropy, maximum Gibbs error, and least confidence. These criteria are equivalent in the binary-class case (i.e. they all choose the same examples to query), but they are different in the multi-class case. We will prove some new properties of the maximum entropy and the least confidence criteria.

4.1 MAXIMUM ENTROPY

The maximum entropy criterion chooses the next example whose posterior label distribution has the maximum Shannon entropy (Settles, 2010). Formally, this criterion chooses the next example x^* that satisfies

$$x^* = \arg \max_x \mathbb{E}_{y \sim p_{\mathcal{D}}[y;x]}[-\ln p_{\mathcal{D}}[y;x]], \quad (4)$$

where $p_{\mathcal{D}}$ is the posterior obtained after observing the partial labeling \mathcal{D} . From (Cuong et al., 2013), it is desirable to maximize the policy entropy

$$H_{\text{ent}}(\pi) \stackrel{\text{def}}{=} \mathbb{E}_{\rho \sim p_0^\pi}[-\ln p_0^\pi[\rho]],$$

where the expectation is over all the paths in the policy tree of π , as maximizing the policy entropy will minimize the expected label entropy given the observations. Criterion (4) can be viewed as a greedy algorithm for maximizing the policy entropy.

Due to the monotonicity and submodularity of Shannon entropy (Fujishige, 1978), we can construct a non-adaptive greedy policy that achieves near-optimality with respect to the objective function H_{ent} in the non-adaptive setting. In the adaptive setting, however, it was previously unknown whether the maximum entropy criterion is near-optimal with respect to H_{ent} (Cuong et al., 2013).

We now show that, in general, the maximum entropy criterion may not be near-optimal with respect to the objective function H_{ent} (Theorem 4).

Theorem 4. *Let π be the adaptive policy in Π_k selecting examples using Equation (4), and π^* be the optimal adaptive policy in Π_k with respect to H_{ent} . For any $0 < \alpha < 1$, there exists a problem where $H_{\text{ent}}(\pi)/H_{\text{ent}}(\pi^*) < \alpha$.*

The main idea in proving this theorem is to construct a set of independent distractor examples that have highest entropy but provide no information about the true hypothesis. The greedy criterion is tricked to choose only these distractor examples. On the other hand, there is an identifier example which gives the identity of the true hypothesis but has a lower entropy than the distractor examples. Once the label of the identifier example is revealed, there will be a number of high entropy examples to query, so that the policy entropy achieved is higher than that of the greedy algorithm. See the supplement for a proof of this theorem.

4.2 MAXIMUM GIBBS ERROR

The maximum Gibbs error criterion chooses the next example whose posterior label distribution has the maximum Gibbs error (Cuong et al., 2013). Formally, this criterion chooses the next example x^* that satisfies

$$x^* = \arg \max_x \mathbb{E}_{y \sim p_{\mathcal{D}}[y;x]}[1 - p_{\mathcal{D}}[y;x]]. \quad (5)$$

This criterion attempts to greedily maximize the policy Gibbs error

$$H_{\text{gibbs}}(\pi) \stackrel{\text{def}}{=} \mathbb{E}_{\rho \sim p_0^\pi}[1 - p_0^\pi[\rho]],$$

which is a lower-bound of the policy entropy $H_{\text{ent}}(\pi)$.

It has been shown by Cuong et al. (2013, sup.) that the policy Gibbs error H_{gibbs} corresponds to the expected version space reduction in \mathcal{H} . Furthermore, the maximum Gibbs error criterion in Equation (5) corresponds to the algorithm that greedily maximizes the expected version space reduction. For $S \subseteq \mathcal{X}$ and $h \in \mathcal{H}$, the version space reduction function is defined as $f(S, h) \stackrel{\text{def}}{=} 1 - p_0[h(S); S]$.

Since the version space reduction function is adaptive monotone submodular (Golovin and Krause, 2011), the maximum Gibbs error criterion is near-optimal with respect to the objective function H_{gibbs} in both the non-adaptive and adaptive settings. That is, the greedy policy using Equation (5) has the policy Gibbs error within a factor $(1 - 1/e)$ of the optimal policy (Cuong et al., 2013).

4.3 LEAST CONFIDENCE

The least confidence criterion chooses the next example whose most likely label has minimal posterior probability (Lewis and Gale, 1994; Culotta and McCallum, 2005). Formally, this criterion chooses the next examples x^* that satisfies

$$x^* = \arg \min_x \{\max_{y \in \mathcal{Y}} p_{\mathcal{D}}[y;x]\}. \quad (6)$$

Note that $x^* = \arg \max_x \{1 - \max_y p_{\mathcal{D}}[y;x]\}$. Thus, the least confidence criterion greedily optimizes the error rate of the Bayes classifier on the distribution $p_{\mathcal{D}}[\cdot; x]$. In this section, we use the result in Section 3.3 to prove that

the least confidence criterion near-optimally maximizes the worst-case version space reduction.

For a policy π , we define the worst-case version space reduction objective as

$$H_{lc}(\pi) \stackrel{\text{def}}{=} \min_h f(x_h^\pi, h)$$

where f is the version space reduction function defined in Section 4.2. We note that f satisfies the minimal dependency property. It can also be shown that f is pointwise monotone submodular, and the least confidence criterion is equivalent to the criterion in Equation (3). Thus, it follows from Theorem 3 that the least confidence criterion is near-optimal with respect to the objective function H_{lc} (Theorem 5). See the supplement for a proof.

Theorem 5. *Let π be the adaptive policy in Π_k selecting examples using Equation (6), and π^* be the optimal adaptive policy in Π_k with respect to H_{lc} . For all $k > 0$, we have $H_{lc}(\pi) > (1 - 1/e)H_{lc}(\pi^*)$.*

5 ACTIVE LEARNING WITH GENERAL LOSS

In this section, let us focus on the maximum Gibbs error criterion in Section 4.2. The policy Gibbs error objective H_{gibbs} can be written as $H_{\text{gibbs}}(\pi) = \mathbb{E}_{h \sim p_0} [f(x_h^\pi, h)]$, where f is the version space reduction function (Cuong et al., 2013, sup.). Note that $f(x_h^\pi, h)$ is the expected 0-1 loss that a random labeling drawn from p_0 differs from h on x_h^π . Because of the nature of 0-1 loss, even if the random labeling only differs from h on one element of x_h^π , it is counted as an error.

To overcome this disadvantage, we formulate a new objective function that can handle an arbitrary general loss function $L : \mathcal{Y}^{\mathcal{X}} \times \mathcal{Y}^{\mathcal{X}} \rightarrow \mathbb{R}_{\geq 0}$ satisfying the following two properties: $L(h, h') = L(h', h)$ for any two labelings h and h' of \mathcal{X} , and if $h = h'$ then $L(h, h') = 0$. For $S \subseteq \mathcal{X}$ and $h \in \mathcal{H}$, we define the *generalized version space reduction function*

$$f_L(S, h) \stackrel{\text{def}}{=} \mathbb{E}_{h' \sim p_0} [L(h, h') \mathbf{1}(h(S) \neq h'(S))].$$

Note that $f_L(S, h) = \sum_{h': h(S) \neq h'(S)} p_0[h'] L(h, h')$, which can be written as

$$\sum_{h'} p_0[h'] L(h, h') - \sum_{h': h(S) = h'(S)} p_0[h'] L(h, h').$$

If L is the 0-1 loss, i.e. $L(h, h') = \mathbf{1}(h \neq h')$, we have $f_{0-1}(S, h) = \sum_{h': h(S) \neq h'(S)} p_0[h']$, which is equal to the version space reduction function $f(S, h)$.

Our new objective is to maximize the expected value of the generalized version space reduction

$$H_L^{\text{avg}}(\pi) \stackrel{\text{def}}{=} \mathbb{E}_{h \sim p_0} [f_L(x_h^\pi, h)].$$

When L is the 0-1 loss, this objective function is equal to the policy Gibbs error $H_{\text{gibbs}}(\pi)$. Thus, we call $H_L^{\text{avg}}(\pi)$ the *generalized policy Gibbs error*.

5.1 AVERAGE-CASE CRITERION

To maximize $H_L^{\text{avg}}(\pi)$, a natural algorithm is to greedily maximize f_L at each step. Let \mathcal{D} be the previously observed partial labeling, this greedy criterion chooses the next example x^* that satisfies

$$x^* = \arg \max_x \mathbb{E}_{h \sim p_{\mathcal{D}}} [f_L(\text{dom}(\mathcal{D}) \cup \{x\}, h) - f_L(\text{dom}(\mathcal{D}), h)] \quad (7)$$

We call this criterion the *average generalized Gibbs error criterion*.

From the result in Section 3.2, if f_L is adaptive monotone submodular, then using the average generalized Gibbs error criterion is near-optimal. Theorem 6 below states this result, which is a direct consequence of Theorem 2.

Theorem 6. *Let π_L^{avg} be the adaptive policy in Π_k selecting examples using Equation (7), and π^* be the optimal adaptive policy in Π_k with respect to H_L^{avg} . If f_L is adaptive monotone submodular with respect to the prior p_0 , then $H_L^{\text{avg}}(\pi_L^{\text{avg}}) > (1 - 1/e)H_L^{\text{avg}}(\pi^*)$.*

Note that if L is 0-1 loss, then f_L is adaptive monotone submodular with respect to any prior. Unfortunately, in general, f_L may not be adaptive submodular with respect to a prior p_0 (Theorem 7). See the supplement for a proof.

Theorem 7. *Let p_0 be a prior with $p_0[h] > 0$ for all h . There exists a loss function L such that f_L is not adaptive submodular with respect to p_0 .*

In the supplementary material, we also discuss a sufficient condition for f_L to be adaptive monotone submodular with respect to p_0 , and hence satisfy the precondition in Theorem 6. However, it remains open whether this sufficient condition is true for any interesting loss function other than 0-1 loss.

5.2 WORST-CASE CRITERION

We have shown in Theorem 7 that f_L may not be adaptive submodular, and thus we may not always have a theoretical guarantee for the average generalized Gibbs error criterion. In this section, we will reconsider our objective in the worst case instead of the average case.

In the worst case, we may want to maximize the objective function $H_L^{\text{worst}}(\pi) \stackrel{\text{def}}{=} \min_h f_L(x_h^\pi, h)$. However, using this objective function may be too conservative since the generalized version space reduction is computed only from the losses between the surviving labelings⁴ and the worst-

⁴ The surviving labelings in $f_L(S, h)$ are the labelings consistent with h on S .

case labeling. Instead, we propose a less conservative objective function based on the losses among all the surviving labelings. Formally, we define the following *total generalized version space reduction* function

$$t_L(S, h) \stackrel{\text{def}}{=} \sum_{h'} \sum_{h''} p_0[h'] L(h', h'') p_0[h''] - \sum_{h': h'(S)=h(S)} \sum_{h'': h''(S)=h(S)} p_0[h'] L(h', h'') p_0[h''].$$

Our new objective is to maximize the following function called the *worst-case total generalized policy Gibbs error*

$$T_L^{\text{worst}}(\pi) \stackrel{\text{def}}{=} \min_h t_L(x_h^\pi, h).$$

To maximize T_L^{worst} , we propose a greedy algorithm that maximizes the worst-case total generalized version space reduction at every step. Note that $t_L(S, h)$ satisfies the minimal dependency property, i.e. its value does not depend on the labels of $\mathcal{X} \setminus S$ in h . So, for a partial labeling \mathcal{D} , we have $t_L(\text{dom}(\mathcal{D}), h) = t_L(\text{dom}(\mathcal{D}), \mathcal{D})$ for any $h \sim \mathcal{D}$. Using this notation, the greedy criterion for choosing the next example x^* can be written as

$$x^* = \arg \max_x \{ \min_{y \in \mathcal{Y}} [t_L(\text{dom}(\mathcal{D}) \cup \{x\}, \mathcal{D} \cup \{(x, y)\}) - t_L(\text{dom}(\mathcal{D}), \mathcal{D})] \} \quad (8)$$

where \mathcal{D} is the previously observed partial labeling. We call this criterion the *worst-case generalized Gibbs error* criterion. It can be shown that t_L is pointwise monotone submodular and satisfies the minimal dependency property for any loss function L . Furthermore, the criterion in Equation (8) is equivalent to the criterion in Equation (3). Thus, it follows from Theorem 3 that this greedy criterion is near-optimal with respect to the objective function $T_L^{\text{worst}}(\pi)$ (Theorem 8). See the supplement for a proof.

Theorem 8. *Let π_L^{worst} be the adaptive policy in Π_k selecting examples using Equation (8), and π^* be the optimal adaptive policy in Π_k with respect to T_L^{worst} . We have $T_L^{\text{worst}}(\pi_L^{\text{worst}}) > (1 - 1/e) T_L^{\text{worst}}(\pi^*)$.*

It is worth noting that, like t_L , the function f_L is also pointwise submodular for any loss function L . The proof for the pointwise submodularity of f_L is essentially similar to the proofs that f and t_L are pointwise submodular in Theorem 5 and Theorem 8 (see the supplement for a proof of this claim). However, f_L does not satisfy the minimal dependency property. Besides, Theorem 7 also shows that f_L may not be adaptive submodular. Thus, this is an example that a pointwise submodular function is not necessarily adaptive submodular, and we may not be able to use Golovin and Krause (2011)'s result to obtain a result in the average case for pointwise submodular functions.

5.3 COMPUTING THE CRITERIA

In this section, we discuss the computations of the criteria in Equation (7) and Equation (8). First, we give two

propositions below regarding these equations. See the supplement for proofs.

Proposition 1. *The selected example x^* in Equation (7) is equal to*

$$\arg \min_x \sum_y \mathbb{E}_{h, h' \sim p_{\mathcal{D}}} [L(h, h') \mathbf{1}(h(x) = h'(x) = y)].$$

Proposition 2. *The selected example x^* in Equation (8) is equal to*

$$\arg \min_x \{ \max_y \mathbb{E}_{h, h' \sim p_{\mathcal{D}}} [L(h, h') \mathbf{1}(h(x) = h'(x) = y)] \}.$$

From these two propositions, we can compute Equation (7) and Equation (8) by estimating the expectation $\mathbb{E}_{h, h' \sim p_{\mathcal{D}}} [L(h, h') \mathbf{1}(h(x) = h'(x) = y)]$ for each $y \in \mathcal{Y}$. This estimation can be done by sampling from the posterior.

We can sample directly from $p_{\mathcal{D}}$ two sets H and H' which contain samples of h and h' respectively. Then, the expectation $\mathbb{E}_{h, h' \sim p_{\mathcal{D}}} [L(h, h') \mathbf{1}(h(x) = h'(x) = y)]$ can be approximated by

$$\frac{1}{|H| \times |H'|} \sum_{h \in H} \sum_{h' \in H'} L(h, h') \mathbf{1}(h(x) = h'(x) = y).$$

Note that this approximation only requires samples of the labelings from the posterior, and we do not need to explicitly maintain the set of all labelings which may be exponentially large. In the case when the labelings are generated by probabilistic models following some prior distribution, sampling from $p_{\mathcal{D}}$ may be difficult. A simple approximation is to sample H and H' from the MAP model.

6 EXPERIMENTS

Experimental tests comparing the maximum entropy criterion, the maximum Gibbs error criterion, and the least confidence criterion were reported in (Cuong et al., 2013). In this section, we only focus on the active learning criteria with general loss functions, and conduct experiments with two common loss functions used in practice: the Hamming loss and the F_1 loss. For two labelings h and h' (viewing them as label vectors), the Hamming loss is the Hamming distance between them, and the F_1 loss is $1 - F_1(h, h')$ where $F_1(h, h') \in [0, 1]$ is the F_1 score between h and h' .

We experiment with various binary-class tasks from the UCI repository (Bache and Lichman, 2013) and the 20Newsgroups dataset (Joachims, 1996). We use the binary-class logistic regression as our model, and compare the active learners using the greedy criteria in Section 5.1 and 5.2 with the passive learner (Pass) and the maximum Gibbs error active learner (Gibbs). The maximum Gibbs error criterion is estimated from Equation (5) using the MAP

Table 2: AUC for Accuracy and F_1 on UCI Datasets

Dataset	Accuracy				F_1

hypothesis. Note that the maximum Gibbs error criterion is equivalent to the maximum entropy and the least confidence criteria in this case since the tasks are binary-class.

We estimate the average-case criteria (AvgH and AvgF) in Section 5.1 and the worst-case criteria (WorstH and WorstF) in Section 5.2 using the approximation in Section 5.3 with the MAP hypothesis. AvgH and WorstH use the Hamming loss, while AvgF and WorstF use the F_1 loss. We compare the AUCs (area under the curve) for the accuracy scores of Pass, Gibbs, AvgH, and WorstH. We also compare the AUCs for the F_1 scores of Pass, Gibbs, AvgF, and WorstF.

The AUCs are computed from the first 150 examples and normalized so that their ranges are from 0 to 100. We randomly choose the first 10 examples as a seed set. We use the same seed set for all the algorithms.

The detailed procedure to compute the AUCs for our experiments is as follows. We sequentially choose 10 (seed size), 11, ..., 150 training examples using active learning or passive learning. Then for each training size, we train a model and compute its score (accuracy or F_1) on a separate test set. Using these scores, we can compute the AUCs. We

use the AUC scores because we want to compare the whole learning curves from choosing 10 to 150 training examples, not just the scores at any single point (e.g. 150 examples). This is consistent with previous works such as (Settles and Craven, 2008) and (Cuong et al., 2013).

The results for the UCI datasets are given in Table 2. From Table 2, all the active learning algorithms perform better than passive learning in terms of accuracy. On average, WorstH and AvgH perform slightly better than Gibbs, and WorstH achieves the best average AUC for accuracy. In addition, all the active learning algorithms also perform better than passive learning in terms of F_1 score. On average, WorstF and AvgF also perform slightly better than Gibbs, and AvgF achieves the best average AUC for F_1 score.

The results for the 20Newsgroups dataset are given in Table 3. From Table 3, all the active learning algorithms are better than passive learning in terms of accuracy. WorstH and AvgH are slightly better than Gibbs on average. Overall, WorstH achieves the best average AUC for accuracy. In addition, the active learning algorithms are also better than passive learning in terms of F_1 score. WorstF and AvgF are also slightly better than Gibbs, and AvgF has the best average AUC for F_1 score.

In both datasets, using the Hamming loss or F_1 loss is better than using the 0-1 loss (the Gibbs criterion). Furthermore, the worst-case criterion with Hamming loss achieves the best average scores in terms of accuracy, while the average-case criterion with F_1 loss achieves the best average scores in terms of F_1 .

7 CONCLUSION

We have discussed several theoretical properties of greedy algorithms for active learning. In particular, we proved a negative result for the maximum entropy criterion and a near-optimality result for the least confidence criterion in the worst case. We also considered active learning with general losses and proposed two greedy algorithms, one of which is for the average case and the other is for the worst case. Our experiments show that the new algorithms perform well in practice.

A APPENDIX: PROOF OF THEOREM 3

Let π and π^* be the policies as in the statement of Theorem 3. Let $h_\pi = \arg \min_h f(x_h^\pi, h)$. Then we have $f_{\text{worst}}(\pi) = f(x_{h_\pi}^\pi, h_\pi)$. Note that h_π corresponds to a path from the root to a leaf of the policy tree of π . Let the examples and labels along the path h_π (from the root of the tree to a leaf) be: $h_\pi \stackrel{\text{def}}{=} \{(x_1, y_1), (x_2, y_2), \dots, (x_k, y_k)\}$.

Since f satisfies the minimal dependency property, let us abuse the notation and write $f(\{x_t\}_{t=1}^i, \{y_t\}_{t=1}^i)$ to denote $f(\{x_t\}_{t=1}^i, h_\pi)$. Define

$$u_i \stackrel{\text{def}}{=} f(\{x_t\}_{t=1}^i, \{y_t\}_{t=1}^i) - f(\{x_t\}_{t=1}^{i-1}, \{y_t\}_{t=1}^{i-1})$$

$$v_i \stackrel{\text{def}}{=} \sum_{t=1}^i u_t \quad \text{and} \quad z_i \stackrel{\text{def}}{=} f_{\text{worst}}(\pi^*) - v_i.$$

We prove the following claims.

Claim 1. For all i , we have $u_{i+1} \geq z_i/k$.

Proof. Consider the case that after observing $(x_1, y_1), \dots, (x_i, y_i)$, we run the policy π^* from its root and only follow the paths consistent with $(x_1, y_1), \dots, (x_i, y_i)$ down to a leaf. In this case, all the paths of the policy π^* must obtain a value at least $z_i = f_{\text{worst}}(\pi^*) - v_i$, because running π^* without any observation would obtain at least $f_{\text{worst}}(\pi^*)$ and the observations $(x_1, y_1), \dots, (x_i, y_i)$ cover a value v_i .

Now we consider the adversary's path of the policy π^* in this scenario which is defined as

$$h^{\text{adv}} \stackrel{\text{def}}{=} \{(x_1^{\text{adv}}, y_1^{\text{adv}}), (x_2^{\text{adv}}, y_2^{\text{adv}}), \dots, (x_k^{\text{adv}}, y_k^{\text{adv}})\},$$

where $y_j^{\text{adv}} = \arg \min_y \{f(\{x_t\}_{t=1}^i \cup \{x_t^{\text{adv}}\}_{t=1}^{j-1} \cup \{x_j^{\text{adv}}\}, \{y_t\}_{t=1}^i \cup \{y_t^{\text{adv}}\}_{t=1}^{j-1} \cup \{y_j\}) - f(\{x_t\}_{t=1}^i \cup \{x_t^{\text{adv}}\}_{t=1}^{j-1}, \{y_t\}_{t=1}^i \cup \{y_t^{\text{adv}}\}_{t=1}^{j-1})\}$

if x_j^{adv} has not appeared in $\{x_1, \dots, x_i\}$. Otherwise, if $x_j^{\text{adv}} = x_t$ for some $t \in \{1, \dots, i\}$, then $y_j^{\text{adv}} = y_t$. From the previous discussion, h^{adv} covers a value of at least z_i in k steps. Thus, one of its steps must cover a value of at least z_i/k .

Hence, what remains is to show that doing the greedy step in π after observing $(x_1, y_1), \dots, (x_i, y_i)$ is better than any single step along h^{adv} . In the trivial case where $(x_j^{\text{adv}}, y_j^{\text{adv}}) \in \{(x_1, y_1), \dots, (x_i, y_i)\}$, we obtain nothing in this step since $(x_j^{\text{adv}}, y_j^{\text{adv}})$ has already been observed. Thus, the above is true in this case. In the non-trivial case,

$$\begin{aligned} & u_{i+1} \\ &= f(\{x_t\}_{t=1}^{i+1}, \{y_t\}_{t=1}^{i+1}) - f(\{x_t\}_{t=1}^i, \{y_t\}_{t=1}^i) \\ &\geq \min_y \{f(\{x_t\}_{t=1}^i \cup \{x_{i+1}\}, \{y_t\}_{t=1}^i \cup \{y\}) \\ &\quad - f(\{x_t\}_{t=1}^i, \{y_t\}_{t=1}^i)\} \\ &\geq \min_y \{f(\{x_t\}_{t=1}^i \cup \{x_j^{\text{adv}}\}, \{y_t\}_{t=1}^i \cup \{y\}) \\ &\quad - f(\{x_t\}_{t=1}^i, \{y_t\}_{t=1}^i)\} \\ &\geq \min_y \{f(\{x_t\}_{t=1}^i \cup \{x_t^{\text{adv}}\}_{t=1}^{j-1} \cup \{x_j^{\text{adv}}\}, \\ &\quad \{y_t\}_{t=1}^i \cup \{y_t^{\text{adv}}\}_{t=1}^{j-1} \cup \{y_j\}) \\ &\quad - f(\{x_t\}_{t=1}^i \cup \{x_t^{\text{adv}}\}_{t=1}^{j-1}, \{y_t\}_{t=1}^i \cup \{y_t^{\text{adv}}\}_{t=1}^{j-1})\} \\ &= f(\{x_t\}_{t=1}^i \cup \{x_t^{\text{adv}}\}_{t=1}^{j-1} \cup \{x_j^{\text{adv}}\}, \\ &\quad \{y_t\}_{t=1}^i \cup \{y_t^{\text{adv}}\}_{t=1}^{j-1} \cup \{y_j^{\text{adv}}\}) \\ &\quad - f(\{x_t\}_{t=1}^i \cup \{x_t^{\text{adv}}\}_{t=1}^{j-1}, \{y_t\}_{t=1}^i \cup \{y_t^{\text{adv}}\}_{t=1}^{j-1}). \end{aligned}$$

Note that the second inequality is due to the greedy criterion, and the third inequality is due to the submodularity of f on the adversary path. Therefore, this claim is true. \square

Claim 2. For all $i \geq 0$, we have $z_i \leq (1 - \frac{1}{k})^i f_{\text{worst}}(\pi^*)$.

Proof. We prove this claim by induction. For $i = 0$, this holds because $z_0 = f_{\text{worst}}(\pi^*)$ by definition. Assume that $z_i \leq (1 - \frac{1}{k})^i f_{\text{worst}}(\pi^*)$, then due to Claim 1,

$$\begin{aligned} z_{i+1} &= f_{\text{worst}}(\pi^*) - v_{i+1} = f_{\text{worst}}(\pi^*) - v_i - u_{i+1} \\ &= z_i - u_{i+1} \leq z_i - \frac{z_i}{k} = (1 - \frac{1}{k})z_i \\ &\leq (1 - \frac{1}{k})^{i+1} f_{\text{worst}}(\pi^*). \end{aligned}$$

Therefore, this claim is true. \square

To prove Theorem 3, we apply Claim 2 with $i = k$ and have $z_k \leq (1 - \frac{1}{k})^k f_{\text{worst}}(\pi^*) < \frac{1}{e} f_{\text{worst}}(\pi^*)$. Hence, $f_{\text{worst}}(\pi) = v_k = f_{\text{worst}}(\pi^*) - z_k > (1 - \frac{1}{e}) f_{\text{worst}}(\pi^*)$.

Abstract

Determining conditional independence (CI) relationships between random variables is a challenging but important task for problems such as Bayesian network learning and causal discovery. We propose a new kernel CI test that uses a single, learned permutation to convert the CI test problem into an easier two-sample test problem. The learned permutation leaves the joint distribution unchanged if and only if the null hypothesis of CI holds. Then, a kernel two-sample test, which has been studied extensively in prior work, can be applied to a permuted and an unpermuted sample to test for CI. We demonstrate that the test (1) easily allows the incorporation of prior knowledge during the permutation step, (2) has power competitive with state-of-the-art kernel CI tests, and (3) accurately estimates the null distribution of the test statistic, even as the dimensionality of the conditioning variable grows.

1 INTRODUCTION

A distribution P_{xyz} over variables X , Y , and Z satisfies a *conditional independence* relationship $X \perp\!\!\!\perp Y \mid Z$ (“ X is conditionally independent of Y given Z ”) when the joint distribution factorizes as $P_{xyz} = P_{x|z} P_{y|z} P_z$, assuming the existence of conditional density functions. There are several other equivalent characterizations of conditional independence (Dawid, 1979). Determining whether such conditional independence relationships hold between variables is important for problems such as Bayesian network learning, causal discovery, and counterfactual analysis. Using a conditional independence test as a subroutine, the PC algorithm (Spirtes, Glymour, and Scheines, 2000), for example, can be used to determine a set of causal graphs based on the conditional independence relationships between variables. Moreover, counterfactual analysis often requires assumptions of ignorability, which involve

conditional independences among counterfactual variables (Rosenbaum and Rubin, 1983).

Numerous approaches exist to measure conditional dependence or test for conditional independence. For example, under the assumption of Gaussian variables with linear dependence relationships, *partial correlation* can be used to test for conditional independence (Baba, Shibata, and Sibuya, 2004). Another characterization of conditional independence is that $P_{x|yz} = P_{x|z}$. Some tests use this characterization to determine conditional independence by measuring the distance between estimates of these conditional densities (Su and White, 2008). When the conditioning variable is discrete, $X \perp\!\!\!\perp Y \mid Z$ if and only if $X \perp\!\!\!\perp Y \mid Z = z_i$ for every possible value z_i that Z takes. Permutation-based tests have been successfully applied to conditional independence testing in this discrete-variable case (Tsamardinos and Borboudakis, 2010). Other tests use this characterization by *discretizing* continuous conditioning variables and testing for independence within each discrete “bin” of Z (Margaritis, 2005).

Generally, conditional independence testing is a challenging problem (Bergsma, 2004). The “curse of dimensionality” in terms of the dimensionality of the conditioning variable Z can make the problem even more difficult to solve. To see why, first consider the case when Z takes a finite number of values $\{z_1, \dots, z_k\}$; then $X \perp\!\!\!\perp Y \mid Z$ if and only if $X \perp\!\!\!\perp Y \mid Z = z_i$ for each value z_i . Given a sample of size n , even if the data points are evenly distributed across values of Z , we must show independence within every subset of the sample with identical Z values using only approximately n/k points within each subset. When Z is real-valued and P_z is continuous, the observed values of Z are almost surely unique. To extend the procedure to the continuous case, we must infer conditional independence using nonidentical but nearby values of Z , where “nearby” must be quantified with some distance metric. Finding nearby points becomes difficult (without additional assumptions) as the dimensionality of Z grows. To guarantee that conditional independence reduces to unconditional independence between X and Y within each subset,

we need a large number of subsets of Z . On the other hand, with many subsets, in each subset one may not have enough points to assess independence.

Recently, kernel-based tests have also been proposed for conditional as well as unconditional independence testing (see Section 3 for a more detailed discussion). Kernel functions can be used to implicitly map objects from an input space into a “feature space,” or reproducing kernel Hilbert space (RKHS) (Aizerman, Braverman, and Rozoner, 1964; Schölkopf and Smola, 2002). Some tests use the kernel mean embedding, which is an embedding of distributions into an RKHS (Berlinet and Thomas-Agnan, 2004; Smola et al., 2007; Sriperumbudur et al., 2010). When the kernel used is *characteristic*, the embeddings of two distributions are equal (under the distance metric imposed by the RKHS norm) if and only if the distributions are identical. For example, all *universal* kernels such as the radial basis function (RBF) kernel are characteristic (Sriperumbudur et al., 2010). The Hilbert–Schmidt independence criterion (HSIC) is an unconditional independence test that measures the distance in the RKHS between the embedding of a joint distribution and the embedding of the product of its marginal distributions. The HSIC can also be interpreted as the Hilbert–Schmidt norm of a cross-covariance operator, a generalization of the covariance matrix, between the RKHSs corresponding to the marginal distributions (Gretton et al., 2008). The intuition behind the test is that a joint distribution P_{xy} is equal to the product of its marginals if and only if $X \perp\!\!\!\perp Y$. The HSIC has been extended to the conditional independence setting using the norm of the conditional cross-covariance operator to measure conditional dependence (Fukumizu et al., 2008). However, this approach also degrades as the dimensionality of the conditioning variable increases. A more recent approach, the kernel conditional independence test (KCIT), proposed by Zhang et al. (2011), uses a characterization of conditional independence defined in terms of the partial association under all square-integrable functions relating the variables X , Y , and Z (Daudin, 1980). The test relaxes this characterization to use a smaller, but sufficiently rich class of functions from some universal RKHS. For this test, the distribution of the test statistic is known and can be estimated efficiently. However, as the dimensionality of the conditioning variable grows larger or the relationships between the variables grow more complex, the distribution of the KCIT test statistic under the null distribution becomes harder to accurately estimate in practice.

In contrast to a conditional independence test, a kernel two-sample test (Gretton et al., 2006, 2009, 2012a) merely tests whether two samples have been drawn from the same distribution. The two-sample problem is conceptually simpler than testing for conditional independence, and has been studied extensively in prior work. Thus, the behavior of the null distributions for two-sample test statistics are well-

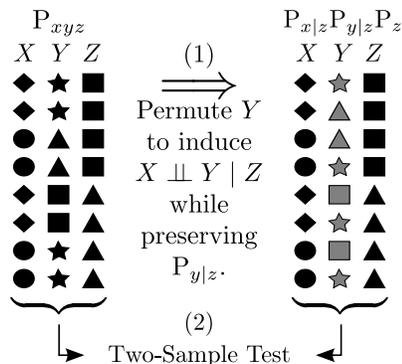

Figure 1: An overview of the proposed approach. First, we observe a sample from the joint distribution (left), and permute the sample to simulate a sample from the factorized distribution (right). The permutation is chosen to induce conditional independence while preserving $P_{x|z}$, $P_{y|z}$, and P_z . Then, a two-sample test is used to compare the permuted sample to an independent, unpermuted sample from the joint distribution.

understood.

We propose a new approach to test for conditional independence that uses a permutation to reduce the problem to a two-sample test. An overview of the approach is illustrated in Figure 1. First, a single, carefully chosen permutation is applied to a sample to simulate a sample from the factorized distribution $P_{x|z}P_{y|z}P_z$, which equals the underlying joint distribution if and only if the null hypothesis holds. Then, a kernel two-sample test (Gretton et al., 2012a) is performed between the permuted sample and an independent, unpermuted sample from the original distribution to determine whether the null hypothesis of conditional independence should be rejected. The approach permits various strategies for “learning” an appropriate permutation given prior knowledge about relationships between X , Y , and Z . The p -values for our test can be accurately, efficiently approximated using the approaches studied previously for kernel two-sample tests. We show using synthetic datasets that the proposed test has power competitive with state-of-the-art approaches, and can accurately estimate the distribution of the test statistic under the null hypothesis as the dimensionality of Z grows to produce a well-calibrated test. We also illustrate using a real-world dataset the practicability of the test for inferring conditional independence relationships.

2 DESCRIPTION OF THE TEST

In testing for *unconditional* independence, we observe an independent and identically distributed (i.i.d.) sample $\Omega = \{(x_i, y_i)\}_{i=1}^n$ drawn from P_{xy} . The variables X and Y are independent if and only if the joint distribution factorizes as

$P_{xy} = P_x P_y$. Here, P denotes a density function, but we use the same notation to represent the distribution itself. If we managed to draw a sample Ω' from $P_x P_y$, we could use a two-sample test between Ω and Ω' to determine whether to reject the null hypothesis $\mathcal{H}_0 : X \perp\!\!\!\perp Y$. Since we do not have access to the underlying joint distribution, but only a sample Ω , we must “simulate” a sample from the factorized distribution. By the i.i.d. assumption, the joint distribution of $(X_1, Y_1), \dots, (X_n, Y_n)$ is a product of identical factors $P_{xy}(X_i, Y_i)$. Hence for all i , X_i and Y_i have the same marginals P_x and P_y , respectively. Moreover, for $i \neq j$, we have $X_i \perp\!\!\!\perp Y_j$. If π is a permutation satisfying $\pi(i) \neq i$, we thus have $X_i \perp\!\!\!\perp Y_{\pi(i)}$, and the distribution of $(X_i, Y_{\pi(i)})$ must be $P_x(X_i) P_y(Y_{\pi(i)})$. Therefore, the permuted sample $(x_i, y_{\pi(i)})_{i=1}^n$ approximately simulates an i.i.d. sample from $P_x P_y$.¹

Below, we first discuss a way to extend the use of permutations to the conditional independence setting. Then, we show how to apply a kernel two-sample test to a permuted and an unpermuted sample to test for conditional independence. We describe how bootstrapping can be used to improve the power of the test. Given the two-sample test, we describe a kernel-based approach for learning an appropriate permutation.

2.1 PERMUTING FOR CONDITIONAL INDEPENDENCE

In this paper, for a joint distribution P_{xyz} over the variables X , Y , and Z , we are interested in determining whether $X \perp\!\!\!\perp Y \mid Z$, which occurs if and only if $P_{xyz} = P_{x|z} P_{y|z} P_z$. We observe an i.i.d. sample $\Omega = \{(x_i, y_i, z_i)\}_{i=1}^n$ drawn according to P_{xyz} . As above, if we were able to draw an independent sample Ω' from the factorized distribution $P_{x|z} P_{y|z} P_z$, we could use a two-sample test between Ω and Ω' to determine whether to reject the null hypothesis $\mathcal{H}_0 : X \perp\!\!\!\perp Y \mid Z$. Given the distributions $P_{x|z}$, $P_{y|z}$, and P_z , we could sample from the factorized distribution by first drawing $z_i \sim P_z$, and then $x_i \sim P_{x|z_i}$ and $y_i \sim P_{y|z_i}$. However, since we are given only a sample, we must “simulate” a sample from $P_{x|z} P_{y|z} P_z$. If the null hypothesis holds, one can consider each x_i and y_i in Ω as independently drawn from the conditional distributions $P_{x|z_i}$ and $P_{y|z_i}$, respectively. Suppose for some $i \neq j$, we find that $z_i = z_j$. In that case, we can proceed analogously to the unconditional case: we can swap the corresponding values y_i and y_j , breaking the dependence between X and Y , to obtain a joint observations

¹In the finite sample setting, this is only an approximation: while the permutation removes the dependence between X and its corresponding Y , it introduces a dependence to one of the other Y variables. In the limit $n \rightarrow \infty$, this becomes negligible (Janzing et al., 2013); moreover, in the limit we could waive the constraint $\pi(i) \neq i$ which we do not do in the present work since it is easy to implement.

(x_i, y_j, z_i) (and, likewise, (x_j, y_i, z_j)) drawn from the distribution $P_{x|z} P_{y|z} P_z$. Therefore, if we were able to (non-trivially) permute every y_i value so that the same permutation leaves the values of z_i in the sample invariant, then this would simulate i.i.d. draws from $P_{x|z} P_{y|z} P_z$. Unfortunately, when Z is continuous, the observed values of Z in Ω will be almost surely unique. In this case, we must “approximately” simulate a sample from $P_{x|z} P_{y|z} P_z$.

The procedure described above can be formalized as follows. Let the sample be expressed as $\Omega = (\mathbf{x}, \mathbf{y}, \mathbf{z})$, where \mathbf{x} , \mathbf{y} , and \mathbf{z} denote tuples of length n holding the sample elements for each of the variables (which might be multivariate), with ranges \mathcal{X} , \mathcal{Y} , and \mathcal{Z} . For the moment, we assume that \mathcal{X} , \mathcal{Y} , and \mathcal{Z} are equipped with addition and scalar multiplication. When we introduce the kernelization of the sample in Section 2.2, this assumption holds even when the sample elements are nonvectorial structured objects. Let \mathbf{P} be a linear transformation, represented as a matrix with nonnegative entries, that is defined to act on a sample as in: $\mathbf{P}\Omega \triangleq (\mathbf{x}, \mathbf{P}\mathbf{y}, \mathbf{z})$, where $\mathbf{P}\mathbf{y}$ is a tuple whose i^{th} element contains $\sum_j \mathbf{P}_{ij} y_j$. To preserve statistical properties of the sample, we cannot use a general linear transformation \mathbf{P} ; it must be a permutation matrix:

Proposition 1. *Let \mathcal{T} be the set of transformation such that for any $\mathbf{P} \in \mathcal{T}$ and sample \mathbf{y} of size n , $\text{mean}(\mathbf{P}\mathbf{y}) = \text{mean}(\mathbf{y})$ and $\|\text{var}(\mathbf{P}\mathbf{y})\|_{\text{HS}} = \|\text{var}(\mathbf{y})\|_{\text{HS}}$. Then \mathcal{T} is a set of permutation matrices of size n .²*

Essentially, the matrix \mathbf{P} must be stochastic to preserve the mean and orthogonal to preserve the variance, and these properties combined imply that it is a permutation. Given that \mathbf{P} is a permutation, we additionally require that $\text{Tr}(\mathbf{P}) = 0$, so that no element in the sample \mathbf{y} is permuted with itself (i.e., left unchanged). Otherwise, some dependence between x_i and y_i might remain. We use \mathcal{P} to denote the set of zero-trace permutations.

Ideally, we would further constrain \mathcal{P} so that all $\mathbf{P} \in \mathcal{P}$ satisfy $\mathbf{z} = \mathbf{P}\mathbf{z}$; that is, the values of \mathbf{z} are invariant under each permutation \mathbf{P} , or equivalently, we only permute the values of y_i that correspond to the same value of z_i . In the unconditional case, we can consider Z to be some constant variable, in which case any permutation is permitted. However, in the conditional case, this requirement is too restrictive so that the set of valid permutations is empty because each value of Z appears only once almost surely in the sample with continuous Z . Accordingly, we relax the problem to finding a permutation that enforces $\mathbf{z} \approx \mathbf{P}\mathbf{z}$. In particular, given some *distortion measure* $\delta : \mathcal{Z}^n \times \mathcal{Z}^n \rightarrow [0, \infty)$ that quantifies the discrepancy between permuted and unpermuted values of Z , we seek to optimize $\min_{\mathbf{P} \in \mathcal{P}} \delta(\mathbf{z}, \mathbf{P}\mathbf{z})$. For general classes of distortion measures, this optimiza-

²A proof can be found in the supplementary materials, available at http://enr.case.edu/doran_gary/publications.html.

tion problem is straightforward to solve. For example, let $d(z_i, z_j)$ be any symmetric pairwise distortion measure (e.g., a distance metric) and $\delta(\mathbf{z}, \mathbf{Pz}) = \sum_i d(z_i, (\mathbf{Pz})_i)$. Let \mathbf{D} be a matrix of pairwise distances between sample elements ($\mathbf{D}_{ij} = d(z_i, z_j)$). Since $\mathbf{P}_{ij} = 1$ if and only if z_i is permuted to z_j , $\delta(\mathbf{z}, \mathbf{Pz}) = \sum_{ij} \mathbf{P}_{ij} \mathbf{D}_{ij} = \text{Tr}(\mathbf{PD})$ and the distortion measure can be minimized using:

$$\min_{\mathbf{P} \in \mathcal{P}} \text{Tr}(\mathbf{PD}). \quad (1)$$

Relaxing \mathcal{P} to the set of doubly stochastic matrices (matrices whose rows and columns sum to one) with zero trace, the feasible region becomes the convex hull of permutation matrices, by the Birkhoff–von Neumann theorem (Birkhoff, 1946; von Neumann, 1953), subject to a linear constraint. Therefore, the simplex algorithm applied to Equation 1 returns a solution corresponding to a vertex of the feasible region, which is a permutation. The formulation in Equation 1 gives a general approach to permuting a sample, where the choice of distance metric d can encode some assumptions about the properties of the distributions $P_{x|z}$ or $P_{y|z}$. Below we discuss using \mathbf{P} to construct the test statistic and possible choices for d .

2.2 TEST STATISTIC AND NULL DISTRIBUTION

After learning an appropriate permutation, a two-sample test between a permuted and an unpermuted sample can be used to test the null hypothesis of conditional independence. A well-studied kernel-based two-sample test uses the maximum mean discrepancy (MMD) test statistic (Gretton et al., 2012a). The MMD employs *mean embeddings* of the two samples into some RKHS. Before describing the mean embedding, we introduce the notation used to “kernelize” the sample. Given the ranges \mathcal{X} , \mathcal{Y} , and \mathcal{Z} of the random variables X , Y , and Z , let $k_x(\cdot, \cdot)$, $k_y(\cdot, \cdot)$, and $k_z(\cdot, \cdot)$ be positive-definite *kernel* functions defined on these spaces ($k_x : \mathcal{X} \times \mathcal{X} \rightarrow \mathbb{R}$, etc.). Corresponding to each kernel k_x is some *feature map* $\phi_x : \mathcal{X} \rightarrow \mathcal{H}_x$ such that $k_x(x, x') = \langle \phi_x(x), \phi_x(x') \rangle$, where \mathcal{H}_x is the RKHS or *feature space* of k_x . We use a product of individual kernels to define the kernel on joint spaces; e.g., $k_{xyz}((x, y, z), (x', y', z')) = k_x(x, x')k_y(y, y')k_z(z, z')$ is a kernel over $\mathcal{X} \times \mathcal{Y} \times \mathcal{Z}$ with feature map $\phi_x \otimes \phi_y \otimes \phi_z$, where \otimes denotes the tensor product. Given that k_x , k_y , and k_z are translation-invariant characteristic kernels, the product kernel is also characteristic under mild assumptions (Sriperumbudur et al., 2010).

By mapping our sample into a feature space as $\{(\phi_x(x_i), \phi_y(y_i), \phi_z(z_i))\}_{i=1}^n$, we can treat each sample element as a vector (which is infinite-dimensional for the characteristic kernels used below), even when the underlying distribution over X , Y , and Z is over arbitrary sets of objects on which kernels are defined. In matrix notation, we can express the mapped sample as $(\Phi_x(\mathbf{x}), \Phi_y(\mathbf{y}), \Phi_z(\mathbf{z}))$, and the permuted sample in the

feature space as $\mathbf{P}\Omega = (\Phi_x(\mathbf{x}), \mathbf{P}\Phi_y(\mathbf{y}), \Phi_z(\mathbf{z}))$ with the i^{th} element of $\mathbf{P}\Phi_y(\mathbf{y})$ equal to $\sum_j \mathbf{P}_{ij} \phi_y(y_j)$. The conditions on \mathbf{P} in Proposition 1 are still necessary, since the linear kernel with feature map $\phi_y : \mathcal{Y} \rightarrow \mathcal{H}_y$ is a special case to which Proposition 1 applies. In prior work (Sriperumbudur et al., 2010), $\text{mean}(\Phi_y(\mathbf{y}))$ is called the *empirical kernel mean embedding*, and is expressed with the notation $\hat{\mu}(\mathbf{y}) = \frac{1}{n} \sum_{y \in \mathbf{y}} \phi_y(y)$. Given the constraints on \mathbf{P} , $\Phi_y(\mathbf{P}\mathbf{y}) = \mathbf{P}\Phi_y(\mathbf{y})$ for any Φ_y , and the mean embedding is invariant under \mathbf{P} : $\hat{\mu}(\mathbf{y}) = \hat{\mu}(\mathbf{P}\mathbf{y})$. The notation $\hat{\mu}(\Omega)$ will be used to denote the mean embedding of an entire sample using the product kernel defined on the joint space.

Given the kernelization of the sample, the test statistic is computed as follows. The original sample Ω of n elements is randomly split in half to form the samples $\Omega^{(1)}$ and $\Omega^{(2)}$, to ensure independence between the permuted and unpermuted samples (a condition required by the two-sample test). Using the formulation in Equation 1, we learn a permutation that induces conditional independence in the second subsample $\Omega^{(2)}$. Finally, we compute the (biased) MMD test statistic as follows:

$$\begin{aligned} \text{MMD}(\Omega^{(1)}, \mathbf{P}\Omega^{(2)}) &= \left\| \hat{\mu}(\Omega^{(1)}) - \hat{\mu}(\mathbf{P}\Omega^{(2)}) \right\|_{\mathcal{H}}^2 \quad (2) \\ &= \frac{4}{n^2} \mathbf{1}^\top (\mathbf{K}^{(1)} + \mathbf{K}^{(2)} - 2\mathbf{K}^{(12)}) \mathbf{1}. \end{aligned}$$

Here, $\mathbf{1}$ is a vector of ones of an appropriate size, the matrices $\mathbf{K}^{(1)}$ and $\mathbf{K}^{(2)}$ are pairwise kernel matrices within the permuted and unpermuted samples, respectively, and $\mathbf{K}^{(12)}$ is the “cross” kernel matrix between the unpermuted and permuted samples. Since we use product kernels, the matrices can be expressed in terms of a Hadamard product between the original kernel matrices for each variable:

$$\begin{aligned} \mathbf{K}^{(1)} &= \mathbf{K}_x^{(1)} \odot \mathbf{K}_y^{(1)} \odot \mathbf{K}_z^{(1)} \\ \mathbf{K}^{(2)} &= \mathbf{K}_x^{(2)} \odot (\mathbf{P}\mathbf{K}_y^{(2)}\mathbf{P}^\top) \odot \mathbf{K}_z^{(2)} \\ \mathbf{K}^{(12)} &= \mathbf{K}_x^{(12)} \odot (\mathbf{K}_y^{(12)}\mathbf{P}^\top) \odot \mathbf{K}_z^{(12)}, \end{aligned}$$

where $(\mathbf{K}_x)_{ij} = k_x(x_i, x_j)$, and likewise for \mathbf{K}_y and \mathbf{K}_z .

The behavior of the MMD test statistic has been extensively studied in prior work (Gretton et al., 2006, 2009, 2012a), and there are numerous approaches to estimating the null distribution and computing a p -value for the test statistic. For example, the null distribution can be estimated via a bootstrapping approach in which (1) $\Omega^{(1)}$ and $\mathbf{P}\Omega^{(2)}$ are randomly shuffled together and then split into two again, and then (2) the test statistic is recomputed between the shuffled samples (Gretton et al., 2009). Steps (1) and (2) are repeated b times to obtain an empirical estimate of the null distribution. The null distribution can also be approximated using a Gamma distribution. This estimate is computationally more efficient to obtain, but can also be less accurate in some scenarios (Gretton et al., 2009). As we are interested in the small-sample case, we choose to use the more robust bootstrap estimate at the expense of more computation.

Algorithm 1 KCIPT: Kernel Conditional Independence Permutation Test

Require: Sample $\Omega = (\mathbf{x}, \mathbf{y}, \mathbf{z})$, Distortion measure δ , Significant level α , Outer bootstrap iterations B , Inner bootstrap iterations b , Monte Carlo iterations M

- 1: **for** Outer Bootstrap $1 \leq i \leq B$ **do**
- 2: Split sample evenly into $\Omega^{(1)}, \Omega^{(2)}$
- 3: Find permutation matrix \mathbf{P} for $\Omega^{(2)}$ using δ to compute \mathbf{D} and solving Equation 1.
- 4: $\text{MMD}[i] \leftarrow \text{MMD}(\Omega^{(1)}, \mathbf{P}\Omega^{(2)})$
- 5: **for** Inner Bootstrap $1 \leq j \leq b$ **do**
- 6: Shuffle, re-split $\Omega^{(1)}, \mathbf{P}\Omega^{(2)}$ to Ω', Ω'' .
- 7: $\text{inner_null}[i, j] \leftarrow \text{MMD}(\Omega', \Omega'')$
- 8: **end for**
- 9: **end for**
- 10: $\text{statistic} \leftarrow \text{mean}_{1 \leq i \leq B}(\text{MMD}[i])$
- 11: **for** Monte Carlo Iteration $1 \leq k \leq M$ **do**
- 12: **for** Outer Bootstrap $1 \leq i \leq B$ **do**

- 15: **end for**
- 16: $\text{outer_null}[k] \leftarrow \text{mean}_{1 \leq i \leq B}(\text{samples}[i])$
- 17: **end for**
- 18: $p\text{-value} \leftarrow 1 - \text{percentile}(\text{statistic}, \text{outer_null})$
- 19: **if** $p\text{-value} \geq \alpha$ **then**
- 20: Fail to Reject $\mathcal{H}_0 (X \perp\!\!\!\perp Y \mid Z)$
- 21: **else**
- 22: Reject \mathcal{H}_0 , Conclude $X \not\perp\!\!\!\perp Y \mid Z$
- 23: **end if**

A characteristic kernel must be used to ensure that the MMD test statistic is consistent (convergent to zero if and only if the two samples are drawn from the same distribution). A kernel k_{xyz} is said to be *characteristic* if the corresponding mean map is injective (Sriperumbudur et al., 2010). Several popular kernels are characteristic, including the Gaussian RBF kernel $k(x, x') = \exp(-\|x - x'\|_2^2 / 2\sigma^2)$, with bandwidth parameter σ . Given that the RBF kernel is used for the test, there is still a question of how to select the bandwidth parameter. We set σ to be the median pairwise distance between sample elements, which prior work shows to be an effective heuristic (Gretton et al., 2012a). Other strategies existing for selecting σ to improve the power of the test statistic (Sriperumbudur et al., 2009; Gretton et al., 2012b).

2.3 BOOTSTRAPPING THE TEST STATISTIC

As defined above, the test statistic relies on splitting a sample randomly in half, which reduces the power of the two-sample test. However, if we randomly split the sample many times to compute many test statistics, we can bootstrap the MMD statistic itself to recover some of the power lost due to splitting. An overview of the test with bootstrapping is given in Algorithm 1.

Let $\{(\Omega_i^{(1)}, \Omega_i^{(2)})\}_{i=1}^B$ be a set of random splits of the dataset, where B denotes the number of random splits. The bootstrapped test statistic is the average of individual MMD test statistics for each split: $\text{MMD}_{\text{boot}}(\Omega) = \frac{1}{B} \sum_{i=1}^B \text{MMD}(\Omega_i^{(1)}, \mathbf{P}_i \Omega_i^{(2)})$, where \mathbf{P}_i is the permutation learned for the i^{th} split. The null distribution of MMD_{boot} can be estimated via a Monte Carlo simulation by repeatedly averaging together the draws from each individual test statistic’s null distribution. Specifically, the null distribution N_i is first estimated for each test statistic $\text{MMD}_b(\Omega_i^{(1)}, \mathbf{P}_i \Omega_i^{(2)})$. Then, M points are drawn from each of the B null distributions: $s_{ij} \sim N_i$, for $1 \leq i \leq B$, $1 \leq j \leq M$. The points are averaged so that the resulting sample $\{\frac{1}{B} \sum_{i=1}^B s_{ij}\}_{j=1}^M$ is used to estimate the null distribution of $\text{MMD}_{\text{boot}}(\Omega)$.

Since we are combining many tests, any systematic error in estimating the null distribution will be compounded. Accordingly, we choose to use the robust bootstrapping approach described in Section 2.2 with a large number of draws b to estimate each null distribution N_i . Note that the statistic bootstrapping procedure (the “outer” bootstrap) is separate from the bootstrapping used to estimate the null hypothesis (the “inner” bootstrap). In the first case, a new permutation is learned for each split to compute the test statistic. In the second case, the learned permutation for the given split is left fixed, and the permuted and unpermuted subsamples are shuffled together randomly to simulate the null hypothesis. Since each N_i is an empirical estimate using a set of observed test statistics, we draw from N_i by sampling with replacement from the underlying set. If desired, the inner bootstrap shown in Algorithm 1 can be replaced with some other estimate of the null distribution of each MMD test statistic.

2.4 LEARNING THE PERMUTATION

Given the description of our test procedure, we now return to the issue of learning a permutation. Intuitively, since the test statistic uses an RKHS distance between samples, we would like our distortion measure to also utilize the RKHS distance. Therefore, we choose $d(z_i, z_j) = \|\phi_z(z_i) - \phi_z(z_j)\|$. In fact, we show that minimizing Equation 1 with respect to the RKHS distortion measure leads to a consistent test statistic when the distortion converges to zero. That is, we would like for the MMD between permuted and unpermuted samples to converge to zero if and only if the null hypothesis $\mathcal{H}_0 : X \perp\!\!\!\perp Y \mid Z$ holds.

Definition 1. A test statistic is asymptotically consistent if it converges in probability to zero if and only if the null hypothesis holds.

Theorem 1. Let $\mathbf{D}_{ij}^{\text{RKHS}} = \|\phi_z(z_i) - \phi_z(z_j)\|$ be a pairwise RKHS distance matrix between Z values in a sample. The proposed test statistic (Equation 2) is asymptot-

ically consistent if the quantity $\min_{\mathbf{P} \in \mathcal{P}} \frac{1}{n} \text{Tr}(\mathbf{P}\mathbf{D}^{\text{RKHS}})$ converges in probability to zero as $n \rightarrow \infty$.

Proof. Intuitively, minimizing $\frac{1}{n} \text{Tr}(\mathbf{P}\mathbf{D}^{\text{RKHS}})$ minimizes a majorant of the MMD between the permuted and unpermuted joint samples $(\mathbf{P}\mathbf{y}, \mathbf{z})$ and (\mathbf{y}, \mathbf{z}) . When this value converges to zero in probability, then so does the MMD, which implies that the permuted sample embedding converges to the embedding of the factorized joint distribution.³ \square

The optimal choice of the distance metric $d(z_i, z_j)$ should depend on how Z influences X and Y . Consider an extreme case where all dimensions of Z except Z_1 are irrelevant to (independent from) X and Y given Z_1 . We aim to find the nearby points along Z_1 , which are not necessarily neighbors when all dimensions are included. In other words, we should exclude all those irrelevant dimensions of Z when calculating the distances between z_i . An example is shown in Figure 2, where Y is some linear function of only the first component of Z , plus some Gaussian noise. Sample elements within the “level sets” of the hyperplane (indicated in the figure) are approximately exchangeable.

Generally speaking, given prior knowledge about structure in the relationships between variables, better measures of distance can be employed when learning the permutation. For example, a well-studied assumption in causal discovery is that X and Y are continuous functions of Z plus some independent Gaussian noise (Hoyer et al., 2008). When this is true, $P_{y|z} = \mathcal{N}(f(z), \Sigma)$, where f is some continuous function relating Z and Y , and Σ is a covariance matrix. In this case, $P_{y|z_i} \approx P_{y|z_j}$ if $f(z_i) \approx f(z_j)$, so it makes sense to use the distance metric $d(z_i, z_j) = \|f(z_i) - f(z_j)\|_2$ when learning the permutation. Although f is unknown, it can be learned from the data; e.g., by using Gaussian Process (GP) regression (Rasmussen and Williams, 2006). Of course, the consistency of the test statistic when heuristics are used depends upon whether the assumptions made by the heuristics are satisfied by the underlying joint distribution. In our experimental results, described below, we find that the function-based distance heuristic adds power to the test for synthetic datasets in which X and Y are in fact noisy functions of Z .

3 RELATED WORK

A previous approach, the conditional HSIC (CHSIC), uses the Hilbert–Schmidt norm of the conditional cross-covariance operator, which is a measure of conditional covariance of the images of X and Y under functions f and g from RKHSs corresponding to some kernels defined on X and Y . When the RKHSs correspond to characteristic kernels, the operator norm is zero if and only if $X \perp\!\!\!\perp Y \mid Z$

³See supplementary materials for the full proof.

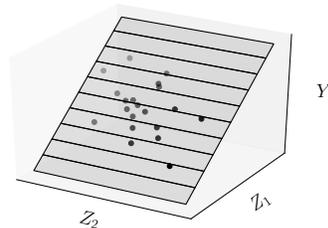

Figure 2: If Y is a function of Z plus noise, then many dimensions of Z might be irrelevant for determining conditional independence. In this example, Y is a noisy function of Z_1 , so sample elements within the level sets of the hyperplane are approximately exchangeable.

(Fukumizu et al., 2008). Since it is unknown how to analytically compute the null distribution of the CHSIC, the distribution is estimated using a bootstrapping approach. As described above for the MMD, a null distribution can be estimated by shuffling and recomputing the test statistic numerous times. In the conditional case, X and Y should only be shuffled when the corresponding Z values are near each other. Therefore, the values of Z are partitioned using a clustering algorithm, and bootstrap estimates are obtained by permuting Y values only within clusters (Fukumizu et al., 2008). Compared to our approach, the CHSIC has several disadvantages. The CHSIC requires *many* permutations to estimate the null distribution, whereas our approach only requires *one* carefully chosen permutation (per outer bootstrap iteration). Since the CHSIC clusters Z values to generate permutations, the permuted data points within each cluster have more widely varying values for Z , causing larger approximation errors. Finally, for high-dimensional datasets, finding an appropriate clustering algorithm becomes difficult, and the approximation quickly breaks down.

Other previous approaches to conditional independence testing use the partial association of regression functions relating X , Y , and Z (Huang, 2010; Zhang et al., 2011). In particular, the kernel-based KCIT (Zhang et al., 2011) is based on the following characterization of conditional independence: for any $f \in L^2_{XZ}$, and $g \in L^2_Y$, define $\tilde{f}(X, Z) = f(X, Z) - h_f(Z)$ and $\tilde{g}(Y, Z) = g(Y) - h_g(Z)$, where $h_f, h_g \in L^2_Z$ are regression functions of the values of f and g using only the variable Z . Then $X \perp\!\!\!\perp Y \mid Z$ if and only if for all $f \in L^2_{XZ}$, $g \in L^2_Y$, and \tilde{f}, \tilde{g} defined as above, $E[\tilde{f}\tilde{g}] = 0$ (Daudin, 1980). The KCIT relaxes the spaces of functions L^2_{XZ} , L^2_Y , and L^2_Z to be RKHSs corresponding to kernels defined on these variables. A universal kernel is required so that the RKHS for Z is dense in corresponding L^2_Z space. By contrast, the HSIC and our approach only require characteristic kernels, which need not be universal (Sriperumbudur et al., 2010).

4 EMPIRICAL EVALUATION

Our analysis suggests that by using a single permutation to compute the test statistic, our approach, the kernel conditional independence permutation test (KCIPT) will be more powerful than the CHSIC, which requires clustering the values of Z and many permutations in each cluster to estimate the null distribution. These permutations become difficult to find as the dimensionality of Z grows, as shown in prior work (Zhang et al., 2011). Furthermore, by using an MMD-based test statistic, the KCIPT can better estimate the null distribution than the KCIT in scenarios that require a careful choice of parameters. Finally, the outer bootstrapping procedure should improve the power of the KCIPT.

To empirically support our analysis, we implement KCIPT in MATLAB,⁴ and compare it to implementations of CHSIC and KCIT used in prior work (Zhang et al., 2011). We use two criteria for performance evaluation, type I error (the fraction of the time the null hypothesis \mathcal{H}_0 is incorrectly rejected), and power (the fraction of the time \mathcal{H}_0 is correctly rejected). Rather than choosing a specific significance level α at which to evaluate power and type I error, we record the p -values resulting from each test and analyze the behavior of the tests as α varies. For KCIPT, we use an RBF kernel $k(x, x') = \exp(-\|x - x'\|_2^2 / 2\sigma^2)$ for each variable, with bandwidth parameters σ_x , σ_y , and σ_z chosen using the “median” heuristic (Gretton et al., 2012a). For bootstrapping, we use parameters $B = 25$, $b = 10^4$, and $M = 10^4$. CHSIC and KCIT use the recommended parameters set in their implementations.

In order to characterize the power and type I error of the tests, we must evaluate the tests across many samples from the same underlying distribution. We use synthetic datasets from prior work for this purpose (Fukumizu et al., 2008; Zhang et al., 2011). Each dataset has a variant where the null hypothesis holds, for testing type I error, and where the null hypothesis does not hold, for testing power. We perform 300 tests for each condition, for each dataset described below.

Post-nonlinear Noise. The first dataset we use generates X and Y as functions of Z using a post-nonlinear noise model (Zhang and Hyvärinen, 2009; Zhang et al., 2011). In this generative process, the dimensionality of the conditioning variable Z grows, but only the first dimension Z_1 is relevant to the conditional independence of X and Y . Each of X and Y are determined using $G(F(Z_1) + E)$, where G and F are arbitrary smooth, nonlinear functions and E is a Gaussian noise variable. All dimensions of Z are i.i.d. Gaussian random variables. Since $X \perp\!\!\!\perp Y \mid Z$ by default, identical Gaussian noise is added to X and Y to produce a variant of the dataset for which $X \not\perp\!\!\!\perp Y \mid Z$. Because only

one conditioning variable is relevant to the problem, we expect that at least the KCIT and KCIPT with the function-distance distortion measure will be robust to increasing dimensionality, but that performance will degrade eventually.

Chaotic Times Series. The second dataset we use is a chaotic time series based on the Hénon map (Hénon, 1976). The two-dimensional variables $X = (X_t^{(1)}, X_t^{(2)})$ and $Y = (Y_t^{(1)}, Y_t^{(2)})$ are computed using only the values from the previous time step as follows:

$$\begin{aligned} X_t^{(1)} &= 1.4 - X_{t-1}^{(1)2} + 0.3X_{t-1}^{(2)} \\ Y_t^{(1)} &= 1.4 - \left[\gamma X_{t-1}^{(1)} Y_{t-1}^{(1)} + (1 - \gamma) Y_{t-1}^{(1)2} \right] + 0.3Y_{t-1}^{(2)} \\ X_t^{(2)} &= X_{t-1}^{(1)}, \quad Y_t^{(2)} = Y_{t-1}^{(1)}. \end{aligned}$$

The parameter γ controls the effect that previous values of X have on Y . To increase the difficulty of this task, two additional independent Gaussian noise variables with zero mean and standard deviation $\sigma = 0.5$ are concatenated to both X and Y . Here, conditional dependence and independence characterizes the causal influence from X to Y when $\gamma > 0$. Namely, in this dataset, $X_{t+1} \perp\!\!\!\perp Y_t \mid X_t$, but $Y_{t+1} \not\perp\!\!\!\perp X_t \mid Y_t$.

For each underlying joint distribution, we generate the cumulative density function (CDF) of the p -values obtained for each test across the 300 random samples. While the CDFs of the tests’ p -values are useful for understanding the global behavior of the tests,⁵ it is more succinct to summarize each curve with a single statistic. In prior work, the powers and type I errors at a particular, fixed value of α are used to summarize results (Fukumizu et al., 2008; Gretton et al., 2012a; Zhang et al., 2011). However, presenting results in this way can be misleading if one of the tests has an advantage at a particular value of α . Therefore, we use two statistics to summarize the power and type I error across values of α . When the test has high power, it correctly rejects the null hypothesis even when α is small. Therefore, the area under the CDF, or *power curve* is close to 1.0. On the other hand, when the null hypothesis is true, a *well-calibrated* test will produce uniformly-distributed p -values so that the type I error rate is equal to α . In this case, the CDF is a diagonal line with slope 1. To measure calibratedness, the Kolmogorov test can be used to quantify the difference between the empirically observed CDF and that for the uniform distribution. Since sample sizes are finite and null distributions are only approximately estimated, the null hypothesis of perfect calibratedness will likely be rejected by the Kolmogorov test after enough tests are performed. However, the relative (log) p -values corresponding to the Kolmogorov test can be used to compare calibratedness; larger p -values roughly correspond to better calibration.

⁵See the supplementary materials for details.

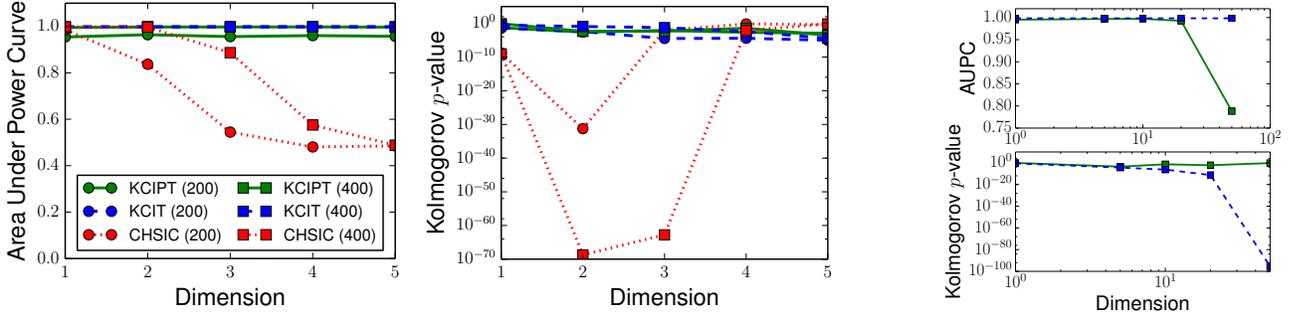

Figure 3: **(Left)** Summarized results for the post-nonlinear noise dataset. These results clearly show how the power of HSIC decreases as noise is added to the conditioning variable. **(Right)** A comparison of KCIT and KCIPT for high-dimensional datasets. The performance of the tests begin to degrade in different ways, with the power of KCIPT falling to chance levels while the KCIT becomes poorly calibrated between $D = 10$ and $D = 50$.

Figure 3 (left) shows results for the post-nonlinear noise dataset as the dimensionality D of the conditioning variable increases. Since Y is a function of Z , the function-distance distortion measure is used, as described in Section 2.4.⁶ Gaussian process regression is used to find the function f relating Z and Y . As observed in prior work (Zhang et al., 2011), the CHSIC approach is sensitive to the dimensionality of the conditioning variable, so power quickly decreases as D increases. With a dataset of size 200, KCIT is slightly more powerful than KCIPT, but the performance converges as the sample size increases to 400. Furthermore, the performance of KCIPT is preserved as dimensionality increases, since the regression-based distance effectively serves as dimensionality reduction on the conditioning variable.

Figure 3 (right) shows what happens to both KCIPT and KCIT as the dimensionality of the dataset continues to increase to $D = 50$; both tests fail by this point, but in different ways. KCIT becomes very poorly calibrated between $D = 10$ and $D = 50$, while the power of KCIPT degrades around the same dimensionality. We conjecture that the observed behavior is due to the differences in kernel parameter selection for each approach. The kernel values for KCIT are chosen heuristically depending on dataset size, but the test is only evaluated on low-dimensional datasets (Zhang et al., 2011). As dimensionality increases, the heuristic is less effective, and the test poorly estimates the null distribution. By contrast, the KCIPT uses the median heuristic, which automatically adjusts the kernel parameter as dataset size and dimensionality increase. Thus, the null distribution is correctly estimated, but the test statistic becomes less powerful on this dataset.

The results for the chaotic time series are shown in Figure 4. For this test, the RKHS distance is used as the distortion measure to learn the permutation. The behavior of the

⁶We compare this distortion measure with other choices in the supplementary materials.

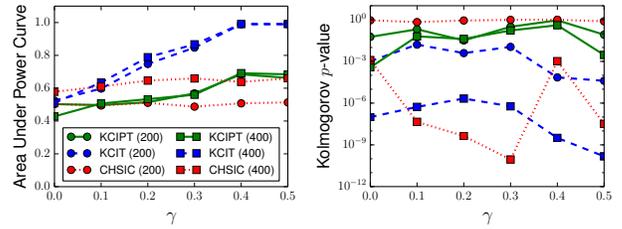

Figure 4: Results for the chaotic time series. As expected, the power of these tests increases as the conditional dependence controlled by γ increases. The KCIT is not well-calibrated on this dataset, and HSIC becomes less well-calibrated as sample size increases.

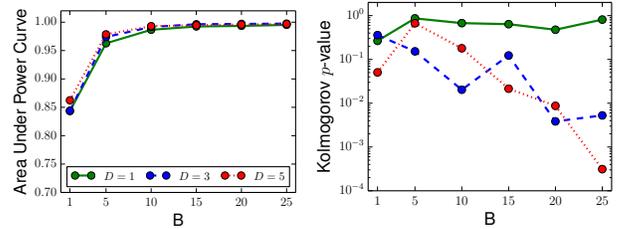

Figure 5: Effects of bootstrapping the test statistic with B iterations on the post-nonlinear noise dataset with $n = 400$. Bootstrapping increases the power of the test, but also decreases the calibration when dimensionality D of the conditioning variable increases. The observed effect is likely due to the approximation errors induced by the permutation leading to an over-rejection of the null hypothesis.

tests is shown as γ increases. In this noisy chaotic dataset, conditional dependence is more difficult to detect, and none of the techniques perform very well when γ is small. Although KCIT has the best performance in terms of power, it is poorly-calibrated as the sample size increases. In fact, both the CHSIC and KCIT become *less* well-calibrated as

sample size increases, suggesting systematic errors in null distribution estimation. For CHSIC, it appears that there are difficulties in finding permutations to estimate the null distribution, and for KCIT, the chaotic nature of the dataset might violate its assumption that variables are related by continuous, well-behaved functions.

Using the post-nonlinear noise dataset with $n = 400$, we also quantify the extent to which the outer bootstrapping procedure described in Section 2.3 improves the power of the test. Figure 5 shows the power and calibration of the test as the number of bootstraps B increases; $B = 1$ corresponds to no bootstrapping of the test statistic, and $B = 25$ is used in the previous experiments. Bootstrapping the test statistic does in fact increase power for this dataset. However, when the dimensionality of Z grows, the calibration of the test decreases. We believe that this behavior is a result of the approximation error induced by the permutation; as dimensionality increases, it becomes harder to find an appropriate permutation with a fixed sample size. However, we observe in Figure 3 (left) that the other tests also tend to be poorly calibrated on this dataset as the dimensionality of Z increases. These results do not suggest a general procedure for selecting B , but they illustrate that at least for the post-nonlinear noise data, there is a power-calibration trade-off involved in the use of bootstrapping.

Medical Data. Finally, we explore the application of the KCIPT to a real-world dataset used in prior work (Fukumizu et al., 2008). The data consists of three variables, creatinine clearance (C), digoxin clearance (D), and urine flow (U), measured on 35 patients. The ground truth, that $D \perp\!\!\!\perp U \mid C$, is known for this dataset. We try to recover this relationship using the PC algorithm (Spirtes, Glymour, and Scheines, 2000), with the KCIPT and $\alpha = 0.05$ used as a test for conditional independence. We choose $B = 10$, since it appears to be an effective setting that reduces the overall computation time (Figure 5). The output of the PC algorithm is the Markov equivalence class $D-C-U$, which contains the only causal structures (either $D \leftarrow C \leftarrow U$, $D \rightarrow C \rightarrow U$, or $D \leftarrow C \rightarrow U$) consistent with the ground truth conditional independence relationship and pairwise dependence relationships, assuming there are no unobserved confounding variables.

5 DISCUSSION

In relation to existing kernel-based conditional independence tests, a major advantage of KCIPT observed in our empirical analysis is its ability to accurately estimate the null distribution. Hence, we observe that KCIPT is well-calibrated across the synthetic datasets we study, even under the more extreme scenarios when the dimensionality of the conditioning variable is large or there are complex, nonlinear relationships between variables in the joint distribution. Our results align with those observed in

prior work, in which permutation-based conditional independence tests for datasets with discrete values were found to be well-calibrated with respect to asymptotic tests (Tsamardinos and Borboudakis, 2010). Additionally, using a well-calibrated conditional independence test produces more robust solutions in Bayesian network learning.

The need for conditional independence testing is ubiquitous in the sciences. Unfortunately, performing the test in practice is known to be very challenging. This work not only simplifies the problem, but also presents a general framework for conditional independence testing which can be extended immediately to numerous settings. Thus, there remain many interesting extensions and questions to study in future work, such as applications to non-i.i.d. data, different approaches for learning a permutation, and deciding which variable to permute in the asymmetric test statistic. Furthermore, we look forward to applying KCIPT to real-world datasets with more complex conditional dependence relationships.

6 CONCLUSION

In this work, we propose a new conditional independence test that employs a permutation to generate an artificial sample from a joint distribution for which the null hypothesis of the test holds. Effectively, we transform the conditional independence test into a two-sample test problem, which is easier to solve, well-studied, and scales to high-dimensional datasets. We use a kernel-based two sample test between an original sample and a permuted sample, which share the same distribution if and only if the conditional independence relationship holds. Prior knowledge about the joint distribution can be incorporated into the process of finding an appropriate permutation. The resulting test has power competitive with existing kernel-based approaches for conditional independence testing and better estimates the null distribution on the datasets used for evaluation. In future work, we will explore theoretical relationships between our approach and those using partial association and further investigate the use of our test for applications in causal discovery.

Abstract

The Pitman-Yor process provides an elegant way to cluster data that exhibit power law behavior, where the number of clusters is unknown or unbounded. Unfortunately, inference in Pitman-Yor process-based models is typically slow and does not scale well with dataset size. In this paper we present new auxiliary-variable representations for the Pitman-Yor process and a special case of the hierarchical Pitman-Yor process that allows us to develop parallel inference algorithms that distribute inference both on the data space and the model space. We show that our method scales well with increasing data while avoiding any degradation in estimate quality.

1 INTRODUCTION

Bayesian nonparametric priors such as the Dirichlet process allow us to create flexible probabilistic models with an unbounded number of parameters. These models are appropriate when the latent dimensionality of our data is unknown or may grow with sample size. Unfortunately, inference in such models is often unwieldy, due to the high number of instantiated parameters and the need to discover the appropriate number of parameters for a given data set.

There has been growing interest in scalable inference algorithms for Bayesian nonparametric models. Earlier attempts at distributing inference were either highly model-specific (Doshi-Velez et al., 2009), or introduced additional approximation into the inference procedure and were mostly concentrated at distributed learning on data and not on the model (Asuncion et al., 2008). More recent approaches (Williamson et al., 2013; Lovell et al., 2012; Chang and Fisher III, 2013) have used both model- and data-parallel design to infer the latent structure without introducing additional approximation.

Most previous research on scalable inference in Bayesian

nonparametrics has focused on parallel inference for Dirichlet process-based models. Dirichlet process models are not ideal for modeling language, as they do not capture the power-law behavior often found in text data (Zipf, 1935). The Pitman-Yor process (Perman et al., 1992; Pitman and Yor, 1997) is a two-parameter extension to the Dirichlet process that allows heavier-tailed distributions over partitions. It is therefore often used in text and language applications, because it more accurately matches the statistics of natural language (Goldwater et al., 2006; Teh, 2006a), and can be used to build hierarchical models for text that out-perform their Dirichlet process-based counterparts (Teh, 2006b; Wood et al., 2009; Blunsom and Cohn, 2011). However, inference remains a bottleneck.

In this paper, we address this issue using an approach pioneered for the Dirichlet process by Williamson et al. (2013) and Lovell et al. (2012): We construct an alternative representation of a nonparametric process that incorporates conditional independencies, and use these conditional independencies to divide our model (and in doing so, our data) into sub-models that can be learned in parallel.

The key to achieving this lies in the introduction of new representations for the Pitman-Yor process and a hierarchical extension, presented in Section 3. These representations afford the conditional independence structure required to develop model- and data-parallel inference algorithms, as demonstrated in Section 4. In Section 5, we perform a thorough evaluation of our inference algorithms and of the modeling assumptions made. We show that our hierarchical model, which is a special case of the hierarchical Pitman-Yor process (Teh, 2006b), is a good fit for natural language. We empirically demonstrate that we can speed up computation in Pitman-Yor process mixture models and hierarchical Pitman-Yor process models with no deterioration in performance, and show good results across a range of dataset sizes and data dimensionalities.

2 BACKGROUND

In this section, we will review the Pitman-Yor process and the hierarchical Pitman-Yor process, and discuss existing approaches for parallelization in Bayesian nonparametric models.

2.1 THE PITMAN-YOR PROCESS

The Dirichlet process (Ferguson, 1973) is a distribution over probability measures of the form $D := \sum_{k=1}^{\infty} \pi_k \delta_{\phi_k}$, parametrized by a concentration parameter $\alpha > 0$ and a probability measure H . The order statistics of the atom sizes π_k are described by the following stick-breaking distribution:

$$\begin{aligned} \pi_k &= w_k \prod_{j=1}^{k-1} (1 - w_j) \\ w_j &\sim \text{Beta}(1, \alpha) \end{aligned} \quad (1)$$

and the atom locations ϕ_k are sampled i.i.d. from H . The resulting probability measure D can be used to cluster observations; a finite number of observations will belong to a finite (but random) number of clusters.

The Pitman-Yor process (Perman et al., 1992; Pitman and Yor, 1997) is a two-parameter extension of the Dirichlet process, parametrized by a discount parameter $0 \leq d \leq 1$, a concentration parameter $\alpha > -d$, and a probability measure H . When the discount parameter is zero, we recover the Dirichlet process. As the discount parameter increases, we get increasingly heavy-tailed distributions over the atom sizes in the resulting probability measure. We can see this behavior by considering the stick-breaking process for the Pitman-Yor process:

$$\begin{aligned} \pi_k &= w_k \prod_{j=1}^{k-1} (1 - w_j) \\ w_j &\sim \text{Beta}(1 - d, \alpha + jd). \end{aligned} \quad (2)$$

As d increases, the rate of decay of the ordered atom sizes will decrease. When $d = 0$, we recover the stick-breaking construction for the Dirichlet process given in Equation 2. This behavior makes the Pitman-Yor process particularly appropriate for applications in language modeling. Natural language has long been known to exhibit power-law behavior (Zipf, 1935), and the Pitman-Yor process is able to capture this (Teh, 2006a).

We can use the Pitman-Yor process to cluster data using the following mixture model:

$$D \sim \text{PY}(\alpha, d, H) \quad \theta_i | D \sim D \quad x_i | \theta_i \sim f(\theta_i). \quad (3)$$

We can also construct a hierarchy of Pitman-Yor processes (Teh, 2006a) that allows us to jointly cluster multiple related groups of data. Each group is associated with a

Pitman-Yor process-distributed random measure, and the group-specific Pitman-Yor processes are coupled via a shared, Pitman-Yor process-distributed base measure. For M groups, each containing N_m data points, the generative process is

$$\begin{aligned} D_0 &\sim \text{PY}(\alpha, d, H) \\ D_m | D_0 &\sim \text{PY}(\gamma, c, D_0), \quad m = 1, \dots, M \\ \theta_{mi} | D_m &\sim D_m, \quad i = 1, \dots, N_m \\ x_{mi} | \theta_{mi} &\sim f(\theta_{mi}). \end{aligned} \quad (4)$$

This distribution has found a number of applications in text and language modeling (Teh, 2006b; Wood et al., 2009; Blunsom and Cohn, 2011).

2.2 PARALLEL METHODS FOR BAYESIAN NONPARAMETRICS

Bayesian nonparametric models allow an unbounded number of parameters, and can increase the number of parameters used as we see more data. This makes them appealing for large, complex, and potentially growing datasets. Unfortunately, naive implementation of Gibbs samplers, such as those developed in Ishwaran and James (2001), Neal (1998) and Teh et al. (2006), do not scale well to such datasets.

To counter issues of scalability, a number of authors have attempted to parallelize inference in Bayesian nonparametric models. Such algorithms typically rely on *data parallelization* – data is split onto multiple processors, and messages are passed between processors. Often, this involves making approximations that break long-range dependencies. For example in Asuncion et al. (2008) and Doshi-Velez et al. (2009), each processor maintains local sufficient statistics for the data stored on it, and approximates the full sufficient statistics by combining the local statistics with snapshots of the local statistics from other processors.

Such an approach typically leads to inaccuracies in the estimates of the global parameters or sufficient statistics. This is particularly true in Bayesian nonparametric models, where we have many components with a small number of observations. Combining the local statistics for these components is difficult, and Williamson et al. (2013) show that this leads to estimate deterioration in the case of Dirichlet processes and hierarchical Dirichlet processes. In models with power law behavior, this effect is likely to be more pronounced, due to the larger number of components with very few associated data points.

An alternative approach is to explicitly partition the model into sub-models that are independent or conditionally independent. Inference is performed on each sub-model independently, and the results are combined globally. We call

such algorithms *model-parallel*. Such models are typically also data-parallel, with different sub-models governing different subsets of the data. They also have the advantage that the sub-models typically have a smaller space of latent parameters than the full model.

Recent examples of algorithms that are both data-parallel and model-parallel are given by Williamson et al. (2013) and Lovell et al. (2012), who use auxiliary variable model representations for Dirichlet processes and hierarchical Dirichlet processes to obtain conditional independence. These algorithms hinge on the fact that we can write a Dirichlet process mixture model as a mixture of Dirichlet process mixture models, as follows:

$$\begin{aligned} D_j &\sim \text{DP}(\alpha_j, H_j), \\ \phi &\sim \text{Dirichlet}(\alpha_1, \dots, \alpha_P), \\ \mu_i | \phi &\sim \phi, \\ \theta_i | \mu_i, D_1, \dots, D_P &\sim D_{\mu_i}, \\ x_i &\sim f(\theta_i). \end{aligned} \quad (5)$$

The marginal distribution over the x_i s is the equal in distribution to that obtained by the Dirichlet process mixture model

$$\begin{aligned} D &\sim \text{DP}\left(\sum_j \alpha_j, \frac{\sum_j \alpha_j H_j}{\sum_j \alpha_j}\right), \\ \theta_i | D &\sim D, \\ x_i | \theta_i &\sim f(\theta_i). \end{aligned} \quad (6)$$

Conditioned on the μ_i s in Equation 5, we can split our model into conditionally independent sub-models involving disjoint subsets of the data, achieving both model- and data-parallelization.

3 AUXILIARY VARIABLE REPRESENTATIONS

In this section, we introduce new representations for the Pitman-Yor process and hierarchical Pitman-Yor process, that will allow us to develop model- and data-parallel inference algorithms.

3.1 AUXILIARY VARIABLE REPRESENTATION FOR THE PITMAN-YOR PROCESS

To obtain an auxiliary variable representation, we first show that a Pitman-Yor mixture model with positive concentration parameter α and continuous base measure H can be constructed as a finite mixture of Pitman-Yor mixture models. We start with a little-used representation of the atom sizes of the Pitman-Yor process.

Theorem 1 (Mixture model representation of a Pitman-Yor process). *Let $G_0 := \sum_k \rho_k \delta_{\theta_k} \sim \text{DP}(\alpha, H_0)$, and let*

$G_k := \sum_j \pi_{j,k} \delta_{\phi_{j,k}} \stackrel{i.i.d.}{\sim} \text{PY}(0, d, H)$, where H is a continuous probability measure (note that this is a normalized stable process with stable parameter d). Then $D = \sum_k \rho_k G_k$ is distributed according to a Pitman-Yor process with concentration parameter α , discount parameter d , and base measure H .

Proof. This is a direct consequence of Proposition 22 in Pitman and Yor (1997). \square

By extension, we can express a Pitman-Yor mixture model as a Dirichlet process mixture of normalized stable process mixture models, provided the concentration parameter α of the Pitman-Yor process is strictly positive and the base measure H is continuous.

Corollary 1. *The marginal distribution over the data ($x_i, i = 1, \dots, N$) implied by the generative procedure*

$$\begin{aligned} G &\sim \text{GEM}(\alpha) \\ D_j &\sim \text{PY}(d, 0, H) \\ t_i | G &\sim G \\ \theta_i | t_i, D_1, D_2, \dots &\sim D_{t_i} \\ x_i | \theta_i &\sim f(\theta_i) \end{aligned} \quad (7)$$

is the same as the marginal distribution over the x_i obtained using the Pitman-Yor mixture model of Equation 3.

Proof. The proof is a straightforward extension of Theorem 1. \square

We have therefore reduced a Pitman-Yor mixture model with concentration parameter $\alpha > 0$ to a Dirichlet process mixture model. This allows us to apply Equation 5 and write our Pitman-Yor mixture model as a finite Dirichlet mixture of Pitman-Yor mixture models, providing the conditional independence required to construct a model-parallel sampler.

Theorem 2 (Auxiliary variable representation for Pitman-Yor mixture models). *Provided the concentration parameter $\alpha > 0$ and the base probability measure H is continuous, we can rewrite the generative process for the Pitman-Yor mixture model given in Equation 3 as:*

$$\begin{aligned} D_j &\sim \text{PY}\left(\frac{\alpha}{P}, d, H\right), \\ \phi &\sim \text{Dirichlet}\left(\frac{\alpha}{P}, \dots, \frac{\alpha}{P}\right), \\ \mu_i | \phi &\sim \phi, \\ \theta_i | \mu_i, D_1, \dots, D_P &\sim D_{\mu_i}, \\ x_i | \theta_i &\sim f(\theta_i), \end{aligned} \quad (8)$$

for $j = 1, \dots, P$ and $i = 1, \dots, N$. The marginal distribution over the x_i remains the same.

Proof. Since we can write the Pitman-Yor mixture model as a Dirichlet process mixture model, this follows as a direct application of Equation 5. An alternative proof is given in the supplement. \square

3.2 AUXILIARY VARIABLE REPRESENTATION FOR THE HIERARCHICAL PITMAN-YOR PROCESS

The results in Section 3.1 can be extended to certain special cases of the hierarchical Pitman-Yor process described in Equation 4. Unfortunately, we can only apply Theorem 1 and Corollary 1 when the base measure of the Pitman-Yor process is continuous. For the group-level Pitman-Yor processes in Equation 4, this is not the case.

The auxiliary variable representation for the Dirichlet process given in Equation 5, however, does not require a continuous base measure. We note that the Dirichlet process is a special case of the Pitman-Yor process, with discount parameter $d = 0$. We therefore work with the following special case of the hierarchical Pitman-Yor process:

$$\begin{aligned} D_0 &\sim \text{PY}(\alpha, d, H) \\ \gamma &\sim \text{Gamma}(\alpha) \\ D_m | D_0 &\sim \text{DP}(\gamma, D_0), \quad m = 1, \dots, M \\ \theta_{mi} | D_m &\sim D_m, \quad i = 1, \dots, N_m \\ x_{mi} | \theta_{mi} &\sim f(\theta_{mi}). \end{aligned} \quad (9)$$

We will refer to this construction as a hierarchical Pitman Yor/Dirichlet process (HPY/DP). The use of a gamma dependence between the concentration parameters was first introduced by Williamson et al. (2013) in the context of the hierarchical Dirichlet process.

In Section 5, we investigate the performance of this special case of the hierarchical Pitman-Yor process on a text corpus. We find that it performs nearly as well as the more general model of Equation 4, and out-performs the hierarchical Dirichlet process (Teh et al., 2006). We therefore propose this model for large-scale text data, since it allows scalable parallel inference without significant deterioration in performance.

Theorem 3 extends the auxiliary variable representation of Theorem 2 to the hierarchical model of Equation 9.

Theorem 3 (Auxiliary variable representation for the hierarchical Pitman-Yor process). *We can rewrite the genera-*

tive process for the hierarchical model of Equation 9 as:

$$\begin{aligned} \zeta_j &\sim \text{Gamma}(\alpha/P), \\ D_{0j} &\sim \text{PY}(\alpha/P, d, H), \\ \nu_m &\sim \text{Dirichlet}(\zeta_1, \dots, \zeta_P), \\ D_{mj} | D_{0j} &\sim \text{DP}(\zeta_j, D_{0j}), \\ \mu_{mi} | \nu_m &\sim \nu_m \\ \theta_{mi} | \mu_{mi}, D_{m1}, \dots, D_{mP} &\sim D_{m\mu_{mi}} \\ x_{mi} | \theta_{mi} &\sim f(\theta_{mi}), \end{aligned} \quad (10)$$

for $j = 1, \dots, P$, $m = 1, \dots, M$, and $i = 1, \dots, N_m$. The marginal distribution over the x_i remains the same as in Equation 9.

Proof. Let $\gamma := \sum_j \zeta_j$. The normalized vector $\frac{\zeta_1, \dots, \zeta_P}{\gamma}$ is distributed according to Dirichlet $(\frac{\alpha}{P}, \dots, \frac{\alpha}{P})$, so from Theorem 1 we find that

$$D_0 := \sum_{j=1}^P \frac{\zeta_j}{\gamma} D_{0j} \sim \text{PY}(\alpha, d, H).$$

Now, for $m = 1, \dots, M$ and $j = 1, \dots, P$, let $\eta_{mj} \sim \text{Gamma}(\zeta_j)$ and $D_{mj} \sim \text{DP}(\zeta_j, D_{0j})$. The normalized vector $(\eta_{m1}, \dots, \eta_{mP}) / \sum_{j=1}^P \eta_{mj}$ is therefore distributed according to Dirichlet $(\zeta_1, \dots, \zeta_P)$. From Equation 5, we see that

$$D_m := \sum_{j=1}^P \eta_{mj} D_{mj} \sim \text{DP}(\gamma, D_0). \quad \square$$

The representation in Theorem 3 provides the conditional independence structure required to construct a data- and model-parallel inference algorithm.

4 INFERENCE

The auxiliary variable representation introduced in Theorem 2 makes the cluster allocations for data points $\{x_i : \mu_i = j\}$ conditionally independent of the cluster allocations for data points $\{x_i : \mu_i \neq j\}$. A similar conditional independence relationship for the hierarchical model is implied by Theorem 3. We can therefore split the data onto P parallel processors or cores, based on the values of μ_i (or μ_{mi} in the hierarchical case). We will henceforth call μ_i (μ_{mi}) the ‘‘processor indicator’’ for the i th data point (i th data point in the m th group).

The resulting samplers allow both model and data parallelization. Inference in Pitman-Yor mixture models and hierarchical Pitman-Yor processes scales with both the number of data points and the number of clusters. Since each

conditionally-independent sub-model only uses a subset of the data points and of the clusters, we are able to obtain significant computational advantage, as we will show empirically in Section 5.

4.1 PARALLEL INFERENCE IN THE PITMAN-YOR PROCESS

We consider first the Pitman-Yor mixture model of Equation 3. Under the auxiliary variable representation of Equation 8, each data point x_i is associated with a processor indicator μ_i and parameter θ_i . We introduce cluster indicator variables z_i , such that $z_i = z_j$ iff $\theta_i = \theta_j$. Provided the base measure H is continuous, all data points associated with a single cluster will have the same processor indicator, meaning that we can assign each cluster to one of the P processors (i.e., all data points in a single cluster are assigned to the same processor). Note that the j th processor will typically be associated with multiple clusters, corresponding to the local Pitman-Yor process D_j . Conditioned on the assignments of the processor indicators μ_i , the data points x_i in Equation 8 depend only on the local Pitman-Yor process D_{μ_i} and the associated parameters.

We can easily marginalize out the D_j and ϕ . Assume that each data point x_i is assigned to a processor $\mu_i \in \{1, \dots, P\}$, and a cluster z_i residing on that processor. We will perform *local* inference on the cluster assignments z_i , and intermittently we will perform *global* inference on the μ_i .

4.1.1 Local inference: Sampling the z_i

Conditioned on the processor assignments, the distribution over cluster assignments z_i is given by

$$P(z_i = k | \{z_j : j \neq i, \mu_j = \mu_i\}, x_i, \text{rest}) \propto \begin{cases} \frac{n_{\mu_i, k}^{-d}}{\alpha + n_{\mu_i, k}} f_k(x_i) & \text{for existing cluster } k \\ \frac{\alpha + Kd}{\alpha + n_{\mu_i, k}} f^*(x_i) & \text{new cluster } k \end{cases}$$

where $n_{j,k}$ is the number of data points in the k th cluster on processor j , $f_k(x)$ is the likelihood of data point x for the k th cluster, and $f^*(x)$ is the likelihood of data point x under a new cluster.

4.1.2 Global inference: Sampling the μ_i

Under the auxiliary variable scheme, each cluster is associated with a single processor. We jointly resample the processor allocations of all data points within a given cluster, allowing us to move an entire cluster from one processor to another. We use a Metropolis Hastings step with a proposal distribution $Q(k, j_1, j_2)$ that independently assigns cluster k from processor j_1 to processor j_2 . We discuss choices of proposal distribution $Q(k, j_1, j_2)$ in Section 4.3.

The accept/reject probability is given by $r \cdot \frac{Q(k, j_2, j_1)}{Q(k, j_1, j_2)}$ where r is the likelihood ratio

$$r = \prod_{j=1}^P \frac{\Gamma(N_j^* + \alpha/P) (\alpha/P)^{(d; K_j^* - 1)}}{\Gamma(N_j + \alpha/P) (\alpha/P)^{(d; K_j - 1)}} \frac{(\alpha/P + 1 - d)^{(1; N_j - 1)}}{(\alpha/P + 1 - d)^{(1; N_j^* - 1)}} \prod_{i=1}^{\max(N_j, N_j^*)} [(1 - d)^{(1; i - 1)}]^{(a_{ij}^* - a_{ij})} \frac{a_{ij}!}{a_{ij}^*!}, \quad (11)$$

where N_j is the number of data points on processor j , a_{ij} is the number of clusters of size i on processor j and

$$(a)^{(b;c)} = \begin{cases} 1 & \text{if } c = 0 \\ a(a+b) \dots (a+(c-1)b) & \text{for } c = 1, 2, \dots \end{cases}$$

A derivation of Equation 11 is given in the supplement. In fact, we can simplify Equation 11 further, since many of the terms in the ratio of factorials will cancel.

The reassignment of clusters can be implemented in a number of different manners. Actually transferring data from one processor to another will lead to bottlenecks, but may be appropriate if the entire data set is too large to be stored in memory on a single machine. If we can store a copy of the dataset on each machine, or we are using multiple cores on a single machine, we can simply transfer updates to lists of which data points belong to which cluster on which machine. We note that the reassignments need not occur at the same time, reducing the bandwidth required.

4.2 PARALLEL INFERENCE IN THE HIERARCHICAL PITMAN-YOR/DIRICHLET PROCESS

Again, we can assign tokens x_{mi} to one of P processors according to μ_{mi} . Conditioned on the processor assignment and the values of ζ_j , the data on each processor is distributed according to an HPY/DP. We instantiate the processor allocations μ_{mi} and the bottom-level DP parameters, plus sufficient representation to perform inference in the processor-specific HPY/DPs. We assume a Chinese restaurant franchise representation (Teh et al., 2006) – each group is represented using a “restaurant”; data points in the lower-level Dirichlet processes are clustered into “tables”; in the upper-level Pitman-Yor process, these “tables” are clustered and each cluster is assigned a “dish”.

4.2.1 Local inference: Sampling the table and dish allocations

Conditioned on the processor assignments, we simply have P independent HPY/DPs, and can use any existing inference algorithm for the hierarchical Pitman-Yor process. In our experiments, we used the Chinese restaurant franchise

sampling scheme (Teh et al., 2006; Teh, 2006a); other representations could also be used.

4.2.2 Global inference: Sampling the μ_{mi} and the ζ_j

We can represent the ζ_j as $\zeta_j := \gamma \xi_j$, where $\gamma \sim \text{Gamma}(\alpha, 1)$ and $\xi := (\xi_1, \dots, \xi_P) \sim \text{Dirichlet}(\alpha/P, \dots, \alpha/P)$. We sample ξ and the μ_{mi} jointly, and then sample γ , in order to improve the acceptance ratio of our Metropolis Hastings steps.

Again, we want to reallocate whole clusters rather than independently reallocate individual tokens. So, our proposal distribution again assigns cluster k from processor j_1 to processor j_2 with probability $Q(k, j_1, j_2)$. Note that this means that a single data point does not necessarily reside on a single processor – its tokens may be split among multiple processors. We also propose $\xi^* \sim \text{Dirichlet}(\alpha/P, \dots, \alpha/P)$, and accept the resulting state with probability $\min(1, r \frac{Q(k, j_2, j_1)}{Q(k, j_1, j_2)})$, where

$$r = \prod_{j=1}^P \frac{(\xi_j^*)^{(T_j^* + \alpha/P)} T_j^*! (\alpha/P)^{(d; U_j^* - 1)}}{((\xi_j)^{(T_j + \alpha/P)}) T_j! (\alpha/P)^{(d; U_j - 1)}} \cdot \frac{(\alpha/P + 1 - d)^{(1; T_j - 1)}}{(\alpha/P + 1 - d)^{(1; T_j^* - 1)}} \cdot \left\{ \prod_{i=1}^{\max(T_j, T_j^*)} [(1 - d)^{(1; i - 1)}]^{b_{ji}^* - b_{ji}} \frac{b_{ji}!}{b_{ji}^*!} \right\} \cdot \prod_{m=1}^M \prod_{i=1}^{\max(N_j, N_j^*)} \frac{a_{jmi}!}{a_{jmi}^*!} \quad (12)$$

Here, T_{mj} is the total number of occupied tables from the m th restaurant on processor j , U_j is the total number of unique dishes on processor j , a_{jmi} is the total number of tables in restaurant m on processor j with exactly i customers, and b_{ji} is the total number of dishes on processor j served at exactly i tables. Many of the ratios can be simplified further, reducing computational costs. A derivation of Equation 12 is given in the supplement.

As with the sampler described in Section 4.1, we can either transfer the data between machines, or simply update lists of which data points are “active” on each machine. We can resample γ after sampling ξ and the μ_{mi} using a standard Metropolis Hastings step.

4.3 CHOICE OF PROPOSAL DISTRIBUTION

There are many valid choices for the proposal distributions $Q(k, j_1, j_2)$ used to sample the μ_i and μ_{mi} in Sections 4.1 and 4.2. We tried several different proposal distributions and found we obtained good mixing when

$$Q(k, j_1, j_2) = \begin{cases} \frac{1}{P-1} s_{j_1} & \text{if } j_1 \neq j_2 \\ 1 - s_{j_1} & \text{if } j_1 = j_2 \end{cases} \quad (13)$$

where s_{j_1} is the fraction of data in processor j_1 . As discussed by Gal and Ghahramani (2013), due to cluster size imbalance inherent to the Pitman-Yor process, we do not expect to see even load balance; however this proposal distribution encourages processors with a larger proportion of the data (higher load) to transfer data to under-used data. Since at any point the fraction of points in any cluster is small it also reduces the number of transfer and hence network load. We will show in Section 5 that this not only gives good performance but also gives good load sharing among multiple processors.

5 EVALUATION

We expect the inference algorithms presented in Section 4 to yield faster inference than a non-parallel implementation. Each processor is locally performing inference in a Pitman-Yor mixture model or a hierarchical Pitman-Yor/Dirichlet process. These models only contain a subset of the total number of clusters and of the total data set. Since inference in these models scales at least linearly (depending on likelihood) with both the number of data points and the number of latent components, we expect them to converge much more quickly than a Pitman-Yor mixture model or hierarchical Pitman-Yor/Dirichlet process on the entire data set. Provided the computational cost of the global steps remains relatively low, and provided the global steps achieve sufficiently fast mixing, we expect to see overall speed-ups. Further, we expect the estimate quality to remain high, since our algorithms do not introduce approximations.

In both cases, we evaluate via comparison with non-parallel implementations of the model. We are unaware of any other parallelizable inference algorithms for the Pitman-Yor process and its extensions.

5.1 PITMAN-YOR MIXTURE OF GAUSSIANS

We first evaluate performance of the parallel sampler for the Pitman-Yor mixture model, described in Section 4.1, using synthetic data. We generated data sets of varying size N and data dimensionality D , to evaluate performance on different sized datasets. Each data set contained $N/2000$ clusters of size 500, $N/4000$ clusters of size 1000, $N/10000$ clusters of size 2500, and $N/20000$ clusters of size 5000, giving $K = 9N/10000$ clusters in total. This was designed to give many smaller clusters and fewer larger clusters. Each cluster parametrized a univariate Gaussian with unit variance and mean sampled according to a $\text{Uniform}((-K/2, K/2)^D)$ distribution.

We ran our algorithm on 90% of the resulting data sets using the algorithm described in Section 4.1, on 1,2,4 and 8 cores of a multi-core machine. Each algorithm was initialized by clustering the data into 80 clusters. We performed

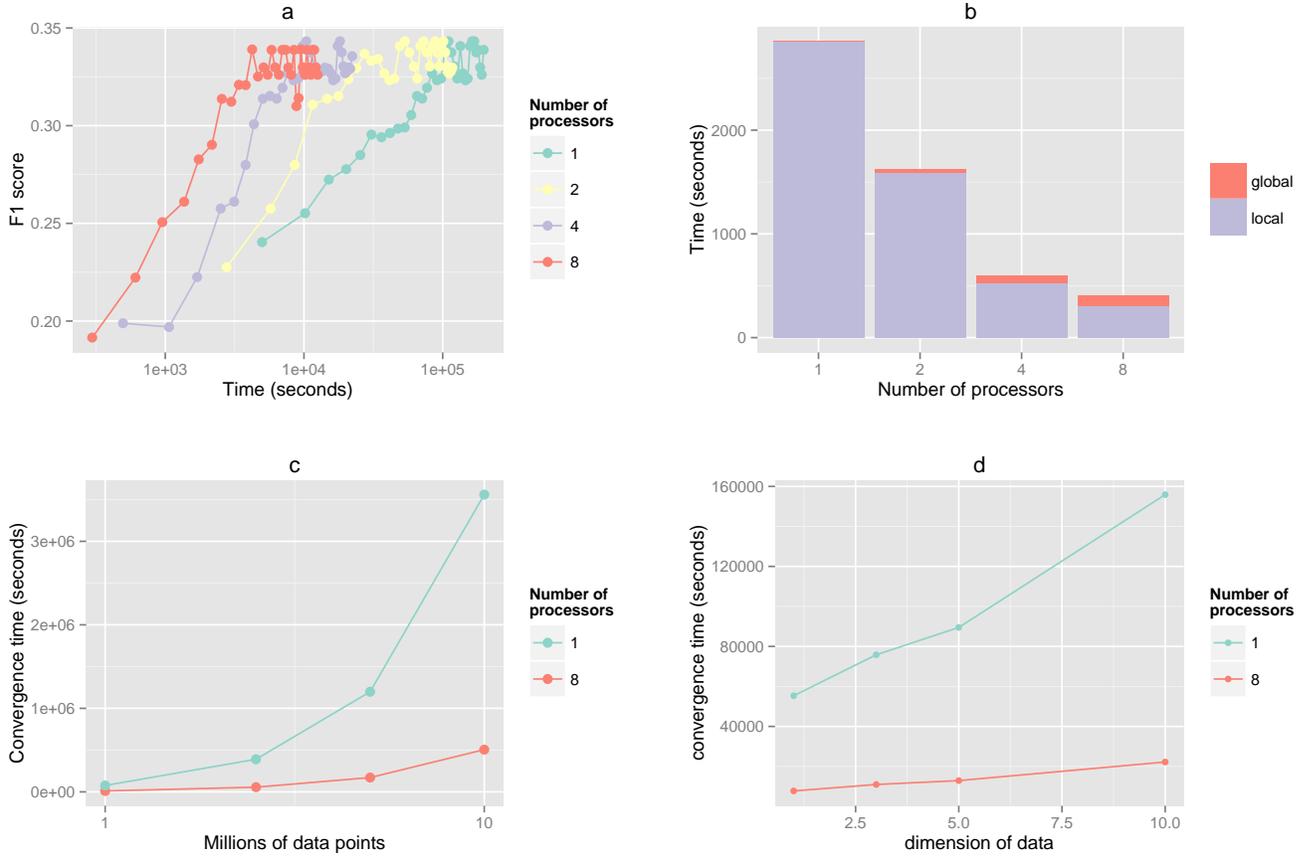

Figure 1: Evaluation on synthetic data modeled using a Pitman-Yor mixture model. a: F1 score vs run time; b: Amount of time spent on global vs local computation; c: Time taken to reach convergence ($< 0.1\%$ change in training set log likelihood) vs number of data points; d: Time taken to reach convergence vs data dimension.

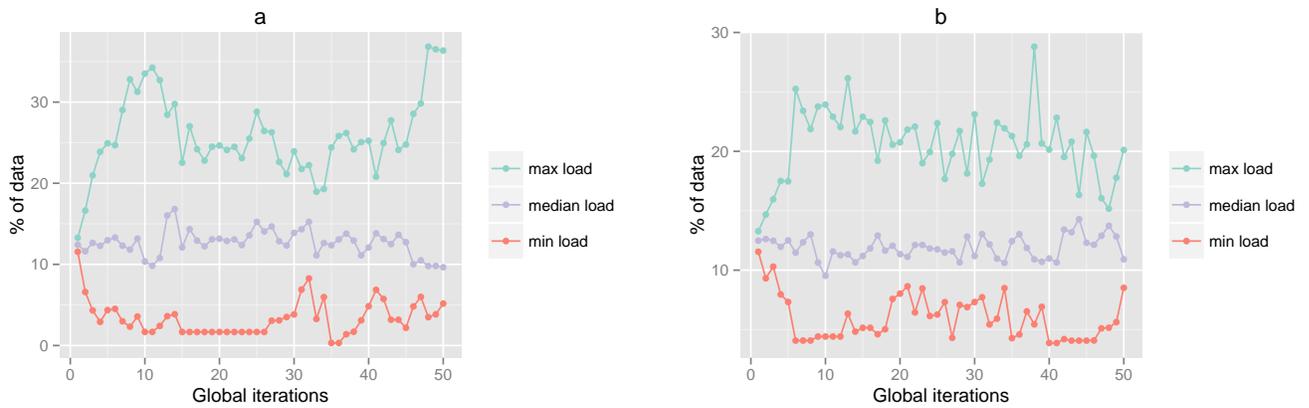

Figure 2: Maximum, median, and minimum loads per global iteration, using (a) a uniform proposal distribution; (b) the proposal distribution given in Equation 13.

100 iterations of the local inference step for each iteration of the global inference step. The concentration parameter α was set to 0.5 and d was set to 0.1; these values were selected via grid search. We evaluated by calculating the test set log likelihood for the remaining 10% of the data.

Figure 1(a) shows how the log likelihood of the test sample varies with time, for one million datapoints with $D = 3$. We see that we get good speedup by increasing the number of processors, while converging to (approximately) the same value for all experiments. Figure 1(b) shows that the amount of time spent on local computation far exceeds that

Data Size	1M	2.5M	5M	10 M
Efficiency	0.864	0.873	0.877	0.879
Dimension	1	3	5	10
Efficiency	0.893	0.864	0.866	0.877
Processors		2	4	8
Efficiency		0.880	0.865	0.864

Table 1: Efficiency with varying data size (with $D = 3$ and $P = 8$), varying data dimension (with $N = 1M$ $P = 8$) and number of processor (with $N = 1M$ and $D = 3$).

spent on global steps, explaining why we have a faster per-iteration time. Figures 1(c) and 1(d) show that the decrease in computational speed is apparent at different sizes of data set N and data dimensionality D .

Following Asuncion et al. (2008), we report the efficiency of our model. If a model running on P processor converges in time T_p while the single processor model converges in time T then the efficiency is calculated as $\frac{T}{P \cdot T_p}$. Table 1 shows how efficiency varies if we change the number of data points, the dimensionality of each data point, and the number of processors. An efficiency of 1 would indicate a linear speed-up – using P processors is P times as fast as using one processor. We get efficiency very close to the linear speedup as shown in Table 1.

Next we evaluate how evenly computation is split between the cores. Figure 2 shows the how the data is split between cores over time. Figure 2(b) shows the load distribution obtained using the proposal distribution of Equation 13, and Figure 2(a) shows the load distribution obtained using the uniform distribution used by Williamson et al. (2013). The maximum load governs the amount of time spend performing local computation (which was seen in Figure 1(b) to dominate the computation time). While, as we would expect (Gal and Ghahramani, 2013), we have uneven loads in both cases, we achieve better load balancing using the new proposal.

5.2 HIERARCHICAL PITMAN-YOR/DIRICHLET PROCESS

In this section, we evaluate the sampler described in Section 4.2 on two text data sets:

- NIPS¹: A collection of 2470 papers from the NIPS conference, collected between 1988 and 2003 which includes 14300 unique words and a total of 3, 280, 697 words.
- ENRON²: A collection of 39861 emails including 28102 unique words and a total of 6, 400, 000 words.

¹<http://ai.stanford.edu/~gal/data.html>

²<https://archive.ics.uci.edu/ml/datasets/Bag-of+Words>

Dataset	HDP	HPY/DP	HPY
NIPS	1706.52	1650.44	1621.34
ENRON	2110.98	2054.85	2018.36

Table 2: Test set perplexity for different models.

Processors	2	4	8
NIPS	0.855	0.805	0.824
ENRON	0.854	0.807	0.817

Table 3: Efficiency of the HPY/DP algorithm with varying number of processors.

In each case, we held out 10% of the data for testing, and evaluated our algorithms using perplexity on the held out test set, as calculated in Asuncion et al. (2008).

We begin by considering how much performance is gaining by restricting the lower-level stochastic processes to be Dirichlet processes, rather than Pitman-Yor processes. Table 2 compares the full hierarchical Pitman-Yor process described in Equation 4 (denoted HPY), the model implemented using our algorithm and described in Equation 9 (denoted HPY/DP), and the hierarchical Dirichlet process Teh et al. (2006) (denoted HDP).

We find that, while the full hierarchical Pitman-Yor process obtains the best perplexity, the HPY/DP model still performs better than the hierarchical Dirichlet process. Since there is not, currently, a scalable inference algorithm for the full hierarchical Pitman-Yor process, we argue that the proposed algorithm and model offer a good trade-off between scalability and performance

Having established the applicability of the model, we consider scalability. Figures 3(a) and 3(b) show how the sample test set perplexity changes with time using 1,2,4 and 8 processors on the NIPS and ENRON data sets, respectively. As with the Pitman-Yor mixture model, we see that increasing the number of processors yields improvements in computation time. Figures 3(c) and 3(d) show that, as before, this occurs because the cost of the local computations decreases as we add more processors, and remains high relative to the cost of the global computations. This is reflected in the efficiencies obtained for different numbers of processors (Table 3), which remain close to one.

6 DISCUSSION AND FUTURE WORK

In this paper, we have presented new auxiliary variable representations for certain cases of the Pitman-Yor process and the hierarchical Pitman-Yor process. These representations allowed us to make use of conditional independencies to develop inference schemes that are both data- and model-parallel.

While this paper provides a significant step forward in

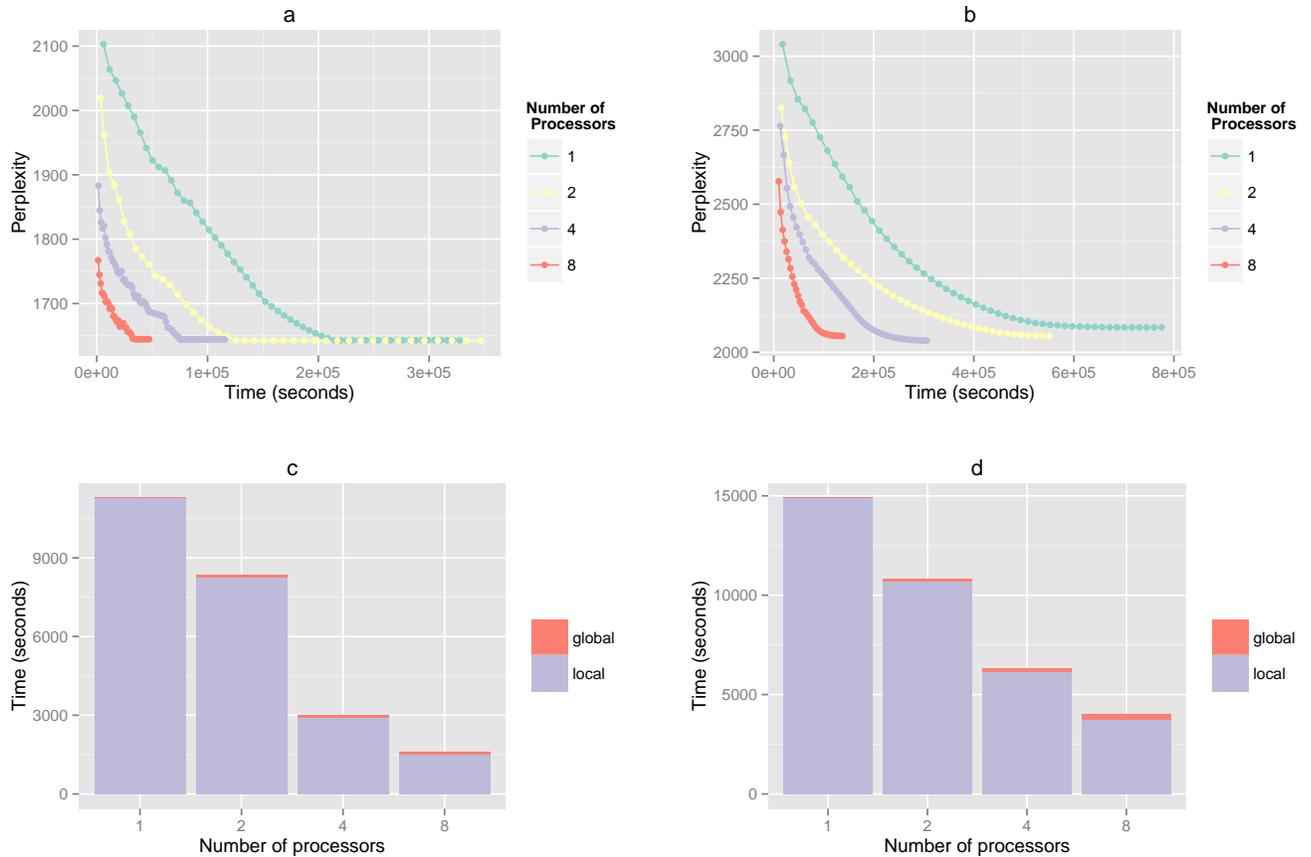

Figure 3: Evaluation on text corpora using the HPY/DP model. a: Test set perplexity vs run time (NIPS); b: Test set perplexity vs run time (ENRON); c: Amount of time spent on global vs local computation (NIPS); d: Amount of time spent on global vs local communication (ENRON).

the development of parallel inference algorithms for the Pitman-Yor process, it does not cover all algorithms of interest. The auxiliary variable representation introduced in Theorem 2 requires a positive concentration parameter. It remains an open question whether there exist alternative representations for $\alpha < 0$ that yield the desired conditional independence structure. Further, our auxiliary variable representation requires a continuous base measure H . While this is typically the case for Pitman-Yor mixture models, it is not the case for the more general hierarchical Pitman-Yor process described in Equation 4. We hope that this work inspires further research into scalable inference for models beyond the Dirichlet process, allowing parallel algorithms for this and other models.

Market Making with Decreasing Utility for Information

Abstract

We study information elicitation in cost-function-based combinatorial prediction markets when the market maker’s utility for information decreases over time. In the *sudden revelation* setting, it is known that some piece of information will be revealed to traders, and the market maker wishes to prevent guaranteed profits for trading on the sure information. In the *gradual decrease* setting, the market maker’s utility for (partial) information decreases continuously over time. We design adaptive cost functions for both settings which: (1) preserve the information previously gathered in the market; (2) eliminate (or diminish) rewards to traders for the publicly revealed information; (3) leave the reward structure unaffected for other information; and (4) maintain the market maker’s worst-case loss. Our constructions utilize mixed Bregman divergence, which matches our notion of utility for information.

1 INTRODUCTION

Prediction markets have been used to elicit information in a variety of domains, including business [6, 7, 12, 28], politics [4, 29], and entertainment [25]. In a prediction market, traders buy and sell *securities* with values that depend on some unknown future outcome. For example, a market might offer securities worth \$1 if Norway wins a gold medal in Men’s Moguls in the 2014 Winter Olympics and \$0 otherwise. Traders are given an incentive to reveal their beliefs about the outcome by buying and selling securities, e.g., if the current price of the above security is \$0.15, traders who believe that the probability of Norway winning is more than 15% are incentivized to buy and those who believe that the probability is less than 15% are incentivized to sell. The equilibrium price reflects the market consensus about the security’s expected payout (which here coincides with the probability of Norway winning the medal).

There has recently been a surge of research on the design of prediction markets operated by a centralized authority called a *market maker*, an algorithmic agent that offers to buy or sell securities at some current price that depends on the history of trades in the market. Traders in these markets can express their belief whenever it differs from the current price by either buying or selling, regardless of whether other traders are willing to act as a counterparty, because the market maker always acts as a counterparty, thus “providing the liquidity” and subsidizing the information collection. This is useful in situations when the lack of interested traders would negatively impact the efficiency in a traditional exchange. Of particular interest to us are *combinatorial prediction markets* [8–10, 17–19, 26] which offer securities on various related events such as “Norway wins a total of 4 gold medals in the 2014 Winter Olympics” and “Norway wins a gold medal in Men’s Moguls.” In combinatorial markets with large, expressive security spaces, such as an Olympics market with securities covering 88 nations participating in 98 events, the lack of an interested counterparty is a major concern. Only a single trader may be interested in trading the security associated with a specific event, but we would still like the market to incorporate this trader’s information.

Most market makers considered in the literature are implemented using a pricing function called the *cost function* [11]. While such markets have many favorable properties [1, 2], the current approaches have several drawbacks that limit their applicability in real-world settings. First, existing work implicitly assumes that the outcome is revealed all at once. When concerned about “just-in-time arbitrage,” in which traders closer to the information source make last-minute guaranteed profits by trading on the sure information before the market maker can adjust prices, the market maker can prevent such profits by closing the entire market just before the outcome is revealed. This approach is undesirable when partial information about the outcome is revealed over time, as is often the case in practice, including the Olympics market. For instance, we may learn the results of Men’s Moguls before Ladies’ Figure Skating has taken place. Closing a large combinatorial market when

ever a small portion of the outcome is determined seems to be an unreasonably large intervention.

Second, in real markets, the information captured by the market’s consensus prices often becomes less useful as the revelation of the outcome approaches. Consider a market over the event “Unemployment in the U.S. falls below 5.8% by the end of 2015.” Although there may be a particular moment when the unemployment rate is publicly revealed, this information becomes gradually less useful as that moment approaches; the government may be less able to act on the information as the end of the year draws near. In the Olympics market, the outcome of a particular competition is often more certain as the final announcement approaches, e.g., if one team is far ahead by the half-time of a hockey game, market forecasts become less interesting. Existing market makers fail to take this diminishing utility for information into account, with the strength of the market incentives remaining constant over time.

To address these two shortcomings of existing markets, we consider two settings:

- a *sudden revelation* setting in which it is known that some piece of information (such as the winner of Men’s Moguls) will be publicly revealed at a particular time, driving the market maker’s utility for this information to zero; crucially, in this setting we assume that the market maker *does not* have direct access to this information at the time it is revealed, which is realistic in the case of the Olympics where a human might not be available to input winners for all 98 events in real time;
- a *gradual decrease* setting in which the market maker has a diminishing utility for a piece of information (such as the unemployment rate for 2015) over time and therefore is increasingly unwilling to pay for this information even while other information remains valuable.

The sudden revelation setting can be viewed as a special case of the gradual decrease setting. In both cases, we model the relevant information as a variable X , representing a partly determined outcome such as the identity of the gold medal winner in a single sports event.

We consider cost-function-based market makers in which the cost function switches one or many times, and aim to design switching strategies such that: (1) information previously gathered in the market is not lost at the time of the switch, (2) a trader who knows the value of X but has no additional information is unable to profit after the switch (for the sudden revelation setting) or is able to profit less and less over time (in the gradual decrease setting), and (3) the market maker maintains the same reward structure for any other information that traders may have. To formalize these objectives, we define the notion of the market maker’s utility (Sec. 2) and show how it corresponds to the *mixed Bregman divergence* [13, 15] (Sec. 2.5).

For the sudden revelation setting (Sec. 3), we introduce a generic cost function switching technique which in many cases removes the rewards for “just-in-time arbitragers” who know only the value of X , while allowing traders with other information to profit, satisfying our objectives.

For the gradual decrease setting (Sec. 4), we focus on *linearly constrained market makers* (LCMMs) [13], proposing a time-sensitive market maker that gradually decreases liquidity by employing the cost function of a different LCMM at each point in time, again meeting our objectives.

Others have considered the design of cost-function-based markets with adaptive liquidity [3, 21–24]. That line of research has typically focused on the goal of slowing down price movement as more money enters the market. In contrast, we adjust liquidity to reflect the current market maker’s utility which can be viewed as something external to trading in the market. Additionally, we change liquidity only in the “low-utility” parts of the market, whereas previous work considered market-wide liquidity shifts. Brahma et al. [5] designed a Bayesian market maker that adapts to perceived increases in available information. Our market maker does not try to infer high information periods, but assumes that a schedule of public revelations is given a priori. Our market makers have guaranteed bounds on worst-case loss whereas those of Brahma et al. [5] do not.

2 SETTING AND DESIDERATA

We begin by reviewing cost-function-based market making before describing our desiderata. Here and throughout the paper we make use of many standard results from convex analysis, summarized in Appendix A. All of the proofs in this paper are relegated to the appendix.¹

2.1 COST-FUNCTION-BASED MARKET MAKING

Let Ω denote the *outcome space*, a finite set of mutually exclusive and exhaustive states of the world. We are interested in the design of cost-function-based market makers operating over a set of K securities on Ω specified by a *payoff function* $\rho : \Omega \rightarrow \mathbb{R}^K$, where $\rho(\omega)$ denotes the vector of security payoffs if the outcome $\omega \in \Omega$ occurs. Traders may purchase *bundles* $\mathbf{r} \in \mathbb{R}^K$ of securities from the market maker, with r_i denoting the quantity of security i that the trader would like to purchase; negative values of r_i are permitted and represent short selling. A trader who purchases a bundle \mathbf{r} of securities pays a specified cost for this bundle up front and receives a (possibly negative) payoff of $\rho(\omega) \cdot \mathbf{r}$ if the outcome $\omega \in \Omega$ occurs.

Following Chen and Pennock [11] and Abernethy et al. [1, 2], we assume that the market maker initially prices securities using a convex potential function $C : \mathbb{R}^K \rightarrow \mathbb{R}$,

¹The full version of this paper on arXiv includes the appendix.

called the *cost function*. The current state of the market is summarized by a vector $\mathbf{q} \in \mathbb{R}^K$, where q_i denotes the total number of shares of security i that have been bought or sold so far. If the market state is \mathbf{q} and a trader purchases the bundle \mathbf{r} , he must pay the market maker $C(\mathbf{q} + \mathbf{r}) - C(\mathbf{q})$. The new market state is then $\mathbf{q} + \mathbf{r}$. The *instantaneous price* of security i is $\partial C(\mathbf{q})/\partial q_i$ whenever well-defined; this is the price per share of an infinitesimally small quantity of security i , and is frequently interpreted as the traders' collective belief about the expected payoff of this security. Any expected payoff must lie in the convex hull of the set $\{\rho(\omega)\}_{\omega \in \Omega}$, called *price space*, denoted \mathcal{M} .

While our cost function might not be differentiable at all states \mathbf{q} , it is always *subdifferentiable* thanks to convexity, i.e., its subdifferential $\partial C(\mathbf{q})$ is non-empty for each \mathbf{q} and, if it is a singleton, it coincides with the gradient. Let $\mathbf{p}(\mathbf{q}) := \partial C(\mathbf{q})$ be called the *price map*. The set $\mathbf{p}(\mathbf{q})$ is always convex and can be viewed as a multi-dimensional version of the "bid-ask spread". In a state \mathbf{q} , a trader can make an expected profit if and only if he believes that $\mathbb{E}[\rho(\omega)] \notin \mathbf{p}(\mathbf{q})$. If C is differentiable at \mathbf{q} , we slightly abuse notation and also use $\mathbf{p}(\mathbf{q}) := \nabla C(\mathbf{q})$.

We assume that the cost function satisfies two standard properties: *no arbitrage* and *bounded loss*. The former means that as long as all outcomes ω are possible, there are no market transactions with a guaranteed profit for a trader. The latter means that the worst-case loss of the market maker is a priori bounded by a constant. Together, they imply that the cost function C can be written in the form $C(\mathbf{q}) = \sup_{\mu \in \mathcal{M}} [\mu \cdot \mathbf{q} - R(\mu)]$, where R is the convex conjugate of C , with $\text{dom } R = \mathcal{M}$. See Abernethy et al. [1, 2] for an analysis of the properties of such markets.

Example 1. *Logarithmic market-scoring rule (LMSR).* The LMSR of Hanson [18, 19] is a cost function for a *complete market* where traders can express any probability distribution over Ω . Here, for any $K \geq 1$, $\Omega = [K] := \{1, \dots, K\}$ and $\rho_i(\omega) = \mathbf{1}[i = \omega]$ where $\mathbf{1}[\cdot]$ is a 0/1 indicator, i.e., the security i pays out \$1 if the outcome i occurs and \$0 otherwise. The price space \mathcal{M} is the simplex of probability distributions in K dimensions. The cost function is $C(\mathbf{q}) = \ln(\sum_{i=1}^K e^{q_i})$, which is differentiable and generates prices $p_i(\mathbf{q}) = e^{q_i}/(\sum_{j=1}^K e^{q_j})$. Here R is the negative entropy function, $R(\mu) = \sum_{i=1}^K \mu_i \ln \mu_i$.

Example 2. *Square.* The square market consists of two independent securities ($K = 2$) each paying out either \$0 or \$1. This can be encoded as $\Omega = \{0, 1\}^2$ with $\rho_i(\omega) = \omega_i$ for $i = 1, 2$. The price space is the unit square $\mathcal{M} = [0, 1]^2$. Consider the cost function $C(\mathbf{q}) = \ln(1 + e^{q_1}) + \ln(1 + e^{q_2})$, which is differentiable and generates prices $p_i(\mathbf{q}) = e^{q_i}/(1 + e^{q_i})$ for $i = 1, 2$. Using this cost function is equivalent to running two independent binary markets, each with an LMSR cost function. We have $R(\mu) = \sum_{i=1}^2 \mu_i \ln \mu_i + (1 - \mu_i) \ln(1 - \mu_i)$.

PROTOCOL 1: Sudden Revelation Market Makers

Input: initial cost function C , initial state \mathbf{s}^{ini} , switch time t , update functions $\text{NewCost}(\mathbf{q})$, $\text{NewState}(\mathbf{q})$

Until time t :
 sell bundles $\mathbf{r}^1, \dots, \mathbf{r}^N$ priced using C
 for the total cost $C(\mathbf{s}^{\text{ini}} + \mathbf{r}) - C(\mathbf{s}^{\text{ini}})$ where $\mathbf{r} = \sum_{i=1}^N \mathbf{r}^i$
 let $\mathbf{s} = \mathbf{s}^{\text{ini}} + \mathbf{r}$

At time t :
 $\tilde{C} \leftarrow \text{NewCost}(\mathbf{s})$
 $\tilde{\mathbf{s}} \leftarrow \text{NewState}(\mathbf{s})$

After time t :
 sell bundles $\tilde{\mathbf{r}}^1, \dots, \tilde{\mathbf{r}}^{\tilde{N}}$ priced using \tilde{C}
 for the total cost $\tilde{C}(\tilde{\mathbf{s}} + \tilde{\mathbf{r}}) - \tilde{C}(\tilde{\mathbf{s}})$ where $\tilde{\mathbf{r}} = \sum_{i=1}^{\tilde{N}} \tilde{\mathbf{r}}^i$
 let $\tilde{\mathbf{s}}^{\text{fin}} = \tilde{\mathbf{s}} + \tilde{\mathbf{r}}$

Observe ω
 Pay $(\mathbf{r} + \tilde{\mathbf{r}}) \cdot \rho(\omega)$ to traders

PROTOCOL 2: Gradual Decrease Market Makers

Input: time-sensitive cost function $\mathbf{C}(\mathbf{q}; t)$, initial state \mathbf{s}^0 , initial time t^0 , update function $\text{NewState}(\mathbf{q}; t, t')$

For $i = 1, \dots, N$ (where N is an unknown number of trades):
 at time $t^i \geq t^{i-1}$: receive a request for a bundle \mathbf{r}^i
 $\tilde{\mathbf{s}}^{i-1} \leftarrow \text{NewState}(\mathbf{s}^{i-1}; t^{i-1}, t^i)$
 sell the bundle \mathbf{r}^i
 for the cost $\mathbf{C}(\tilde{\mathbf{s}}^{i-1} + \mathbf{r}^i; t^i) - \mathbf{C}(\tilde{\mathbf{s}}^{i-1}; t^i)$
 $\mathbf{s}^i \leftarrow \tilde{\mathbf{s}}^{i-1} + \mathbf{r}^i$

Observe ω
 Pay $\sum_{i=1}^N \mathbf{r}^i \cdot \rho(\omega)$ to traders

Example 3. *Piecewise linear cost.* Here we describe a non-differentiable cost function for a single binary security ($K = 1$). Let $\Omega = \{0, 1\}$ and $\rho(\omega) = \omega$, so $\mathcal{M} = [0, 1]$. The cost function is $C(q) = \max\{0, q\}$. It gives rise to the price map such that $p(q) = 0$ if $q < 0$, and $p(q) = 1$ if $q > 0$, but at $q = 0$, we have $p(q) = [0, 1]$, i.e., because of non-differentiability we have a bid-ask spread at $q = 0$. Here, $R(\mu) = \mathbb{I}[\mu \in [0, 1]]$ where $\mathbb{I}[\cdot]$ is a 0/ ∞ indicator, equal to 0 if true and ∞ if false. This market is uninteresting on its own, but will be useful to us in Sec. 3.3.

2.2 OBSERVATIONS AND ADAPTIVE COSTS

We study two settings. In the *sudden revelation setting*, it is known to both the market maker and the traders that at a particular point in time (the observation time) some information about the outcome (an observation) will be publicly revealed to the traders, but not to the market maker. More precisely, let any function on Ω be called a *random variable* and its value called the *realization* of this random variable. Given a random variable $X : \Omega \rightarrow \mathcal{X}$, we assume that its realization is revealed to the traders at the observation time. For a random variable X and a possible realization x , we define the *conditional outcome space* by $\Omega^x := \{\omega \in \Omega : X(\omega) = x\}$. After observing $X = x$ (where, using standard random variable shorthand, we write X for $X(\omega)$), the traders can conclude that

$\omega \in \Omega^x$. Note that the sets $\{\Omega^x\}_{x \in \mathcal{X}}$ form a partition of Ω .

We design *sudden revelation market makers* (Protocol 1) that replace the cost function C with a new cost function \tilde{C} , and the current market state s (i.e., the current value of \mathbf{q} in the definition above) with a new market state \tilde{s} in order to reflect the decrease in the utility for information about X . Such a switch would typically occur just before the observation time. Note that we allow the new cost function \tilde{C} as well as the new state \tilde{s} to be chosen adaptively according to the last state s of the original cost function C .

In the *gradual decrease* setting, the utility for information about a future observation X is decreasing continuously over time. We use a *gradual decrease market maker* (Protocol 2) with a time-sensitive cost function $\mathbf{C}(\mathbf{q}; t)$ which sells a bundle \mathbf{r} for the cost $\mathbf{C}(\mathbf{q} + \mathbf{r}; t) - \mathbf{C}(\mathbf{q}; t)$ at time t , when the market is in a state \mathbf{q} . We place no assumptions on \mathbf{C} other than that for each t , the function $\mathbf{C}(\cdot; t)$ should be an arbitrage-free bounded-loss cost function. The market maker may modify the state between the trades.

Protocol 2 alternates between trades and cost-function switches akin to those in Protocol 1. In each iteration i , the cost function $\mathbf{C}(\cdot; t^{i-1})$ is replaced by the cost function $\mathbf{C}(\cdot; t^i)$ while simultaneously replacing the state \mathbf{s}^{i-1} by the state $\tilde{\mathbf{s}}^{i-1}$. Crucially, unlike Protocol 1, the cost-function switch here is *state independent*, so any state-dependent adaptation happens through the state update.²

At a high level, within each of the protocols, our goal is to design switch strategies that satisfy the following criteria:

- Any information that has already been gathered from traders about the relative likelihood of the outcomes in the conditional outcome spaces is preserved.
- A trader who has information about the observation X but has no additional information about the relative likelihood of outcomes in the conditional outcome spaces is unable to profit from this information (for sudden revelation), or the profits of such a trader are decreasing over time (for gradual decrease).
- The market maker continues to reward traders for new information about the relative likelihood of outcomes in the conditional outcome spaces as it did before, with prices reflecting the market maker’s utility for information within these sets of outcomes.

To reason about these goals, it is necessary to define what we mean by the information that has been gathered in the market and the market maker’s utility.

2.3 MARKET MAKER’S UTILITY

By choosing a cost function, the market maker creates an incentive structure for the traders. Ideally, this incentive

²This simplifying restriction matches our solution concept in Sec. 4, but it could be dropped for greater generality.

structure should be aligned with the market maker’s subjective utility for information. That is, the amount the market maker is willing to pay out to traders should reflect the market maker’s utility for the information that the traders have provided. In this section, we study how the traders are rewarded for various kinds of information, and use the magnitude of their profits to define the market maker’s implicit “utility for information” formally.

We start by defining the market maker’s utility for a belief, where a *belief* $\boldsymbol{\mu} \in \mathcal{M}$ is a vector of expected security payoffs $\mathbb{E}[\boldsymbol{\rho}(\omega)]$ for some distribution over Ω .

Definition 1. *The market maker’s utility for a belief $\boldsymbol{\mu} \in \mathcal{M}$ relative to the state \mathbf{q} is the maximum expected payoff achievable by a trader with belief $\boldsymbol{\mu}$ when the current market state is \mathbf{q} :*

$$\text{Util}(\boldsymbol{\mu}; \mathbf{q}) := \sup_{\mathbf{r} \in \mathbb{R}^K} [\boldsymbol{\mu} \cdot \mathbf{r} - C(\mathbf{q} + \mathbf{r}) + C(\mathbf{q})] .$$

Any subset $\mathcal{E} \subseteq \Omega$ is referred to as an *event*. Observations $X = x$ correspond to events Ω^x . Suppose that a trader has observed an event, i.e., a trader knows that $\omega \in \mathcal{E}$, but is otherwise uninformed. The market maker’s utility for that event can then be naturally defined as follows.

Definition 2. *The utility for a (non-null) event $\mathcal{E} \subseteq \Omega$ relative to the market state \mathbf{q} is the largest guaranteed payoff that a trader who knows $\omega \in \mathcal{E}$ (and has only this information) can achieve when the current market state is \mathbf{q} :*

$$\text{Util}(\mathcal{E}; \mathbf{q}) := \sup_{\mathbf{r} \in \mathbb{R}^K} \min_{\omega \in \mathcal{E}} [\boldsymbol{\rho}(\omega) \cdot \mathbf{r} - C(\mathbf{q} + \mathbf{r}) + C(\mathbf{q})] .$$

Finally, consider the setting in which a trader has observed an event \mathcal{E} , and also holds a belief $\boldsymbol{\mu}$ consistent with \mathcal{E} . Specifically, let $\mathcal{M}(\mathcal{E})$ denote the convex hull of $\{\boldsymbol{\rho}(\omega)\}_{\omega \in \mathcal{E}}$, which is the set of beliefs consistent with the event \mathcal{E} , and assume $\boldsymbol{\mu} \in \mathcal{M}(\mathcal{E})$. Then we can define the “excess utility for the belief $\boldsymbol{\mu}$ ” as the excess utility provided by $\boldsymbol{\mu}$ over just the knowledge of \mathcal{E} .

Definition 3. *Given an event \mathcal{E} and a belief $\boldsymbol{\mu} \in \mathcal{M}(\mathcal{E})$, the excess utility of $\boldsymbol{\mu}$ over \mathcal{E} , relative to the state \mathbf{q} is:*

$$\text{Util}(\boldsymbol{\mu} \mid \mathcal{E}; \mathbf{q}) = \text{Util}(\boldsymbol{\mu}; \mathbf{q}) - \text{Util}(\mathcal{E}; \mathbf{q}) .$$

Note that in these definitions a trader can always choose not to trade ($\mathbf{r} = \mathbf{0}$), so the utility for a belief and an event is non-negative. Also it is not too difficult to see that $\text{Util}(\boldsymbol{\mu}; \mathbf{q}) \geq \text{Util}(\mathcal{E}; \mathbf{q})$ for any $\boldsymbol{\mu} \in \mathcal{M}(\mathcal{E})$, so the excess utility for a belief is also non-negative.

In Sec. 2.5, we show that given a state \mathbf{q} and a non-null event \mathcal{E} , there always exists a (possibly non-unique) belief $\boldsymbol{\mu} \in \mathcal{E}$ such that $\text{Util}(\boldsymbol{\mu} \mid \mathcal{E}; \mathbf{q}) = 0$. Thus, a trader with such a “worst-case” belief is able to achieve in expectation no reward beyond what any trader that just observed \mathcal{E} would receive. We show that these worst-case beliefs correspond to certain kinds of “projections” of the current price $\mathbf{p}(\mathbf{q})$ onto $\mathcal{M}(\mathcal{E})$. For LMSR, the projections are with respect to KL divergence and correspond to the usual conditional probability distributions. Moreover, for sufficiently

Table 1: Information Desiderata

PRICE	Preserve prices: $\tilde{\mathbf{p}}(\tilde{\mathbf{s}}) = \mathbf{p}(\mathbf{s})$.
CONDPRICE	Preserve conditional prices: $\tilde{\mathbf{p}}(X=x; \tilde{\mathbf{s}}) = \mathbf{p}(X=x; \mathbf{s}) \quad \forall x \in \mathcal{X}$.
DECUTIL	Decrease profits for uninformed traders: $\tilde{\text{Util}}(X=x; \tilde{\mathbf{s}}) \leq \text{Util}(X=x; \mathbf{s}) \quad \forall x \in \mathcal{X}$, with sharp inequality if $\text{Util}(X=x; \mathbf{s}) > 0$.
ZEROUTIL	No profits for uninformed traders: $\tilde{\text{Util}}(X=x; \tilde{\mathbf{s}}) = 0 \quad \forall x \in \mathcal{X}$.
EXUTIL	Preserve excess utility: $\tilde{\text{Util}}(\boldsymbol{\mu} X=x; \tilde{\mathbf{s}}) = \text{Util}(\boldsymbol{\mu} X=x; \mathbf{s})$ for all $x \in \mathcal{X}$ and $\boldsymbol{\mu} \in \mathcal{M}(X=x)$.

smooth cost functions (including LMSR) they correspond to market prices that result when a trader is optimizing his guaranteed profit from the information $\omega \in \mathcal{E}$ as in Definition 2 (see Appendix E). Because of this motivation, such beliefs are referred to as “conditional price vectors.”

Definition 4. A vector $\boldsymbol{\mu} \in \mathcal{M}(\mathcal{E})$ is called a conditional price vector, conditioned on \mathcal{E} , relative to the state \mathbf{q} if $\text{Util}(\boldsymbol{\mu}; \mathbf{q}) = \text{Util}(\mathcal{E}; \mathbf{q})$. The set of such conditional price vectors is denoted

$$\mathbf{p}(\mathcal{E}; \mathbf{q}) := \{\boldsymbol{\mu} \in \mathcal{M}(\mathcal{E}) : \text{Util}(\boldsymbol{\mu}; \mathbf{q}) = \text{Util}(\mathcal{E}; \mathbf{q})\}.$$

See Appendix F for additional motivation for our definitions of utility and conditioning. With these notions defined, we can now state our desiderata.

2.4 DESIDERATA

Recall that we aim to design mechanisms which replace a cost function C at a state \mathbf{s} , with a new cost function \tilde{C} at a state $\tilde{\mathbf{s}}$. Let Util denote the utility for information with respect to C and $\tilde{\text{Util}}$ with respect to \tilde{C} , and let \mathbf{p} and $\tilde{\mathbf{p}}$ be the respective price maps. In our mechanisms, we attempt to satisfy (a subset of) the conditions on information structures as listed in Table 1.

Conditions PRICE and CONDPRICE capture the requirement to preserve the information gathered in the market. The current price $\mathbf{p}(\mathbf{q})$ is the ultimate information content of the market at a state \mathbf{q} before the observation time, but it is not necessarily the right notion of information content after the observation time. When we do not know the realization x , we may wish to set up the market so that any trader who has observed $X = x$ and would like to maximize the guaranteed profit would move the market to the same conditional price vector as in the previous market. This is captured by CONDPRICE.

DECUTIL models a scenario in which the utility for information about X decreases over time, and ZEROUTIL represents the extreme case in which utility decreases to zero. These conditions are in friction with EXUTIL, which aims

to maintain the utility structure over the conditional outcome spaces. A key challenge is to satisfy EXUTIL and ZEROUTIL (or DECUTIL) simultaneously.

Apart from the information desiderata of Table 1, we would like to maintain an important feature of cost-function-based market makers: their ability to bound the worst-case loss to the market maker. Specifically, we would like to show that there is some *finite* bound (possibly depending on the initial state) such that no matter what trades are executed and which outcome ω occurs, the market maker will lose no more than the amount of the bound. It turns out that the solution concepts introduced in this paper maintain the same loss bound as guaranteed for using just the market’s original cost function C , but since the focus of the paper is on the information structures, worst-case loss analysis is relegated to Appendix H.

In Sec. 3, we study in detail the sudden revelation setting with the goal of instantiating Protocol 1 in a way that achieves ZEROUTIL while satisfying CONDPRICE and EXUTIL. Our key result is a characterization and a geometric sufficient condition for when this is possible.

In Sec. 4, we examine instantiations of Protocol 2 for the gradual decrease setting. Our construction focuses on linearly-constrained market makers (LCMM) [13], which naturally decompose into submarkets. We show how to achieve PRICE, CONDPRICE, DECUTIL and EXUTIL in LCMMs. We also show that it is possible to simultaneously decrease the utility for information in each submarket according to its own schedule, while maintaining PRICE.

Before we develop these mechanisms, we introduce the machinery of Bregman divergences, which helps us analyze notions of utility for information.

2.5 BREGMAN DIVERGENCE AND UTILITY

To analyze the market maker’s utility for information, we show how it corresponds to a specific notion of distance built into the cost function, the *mixed (or generalized) Bregman divergence* [13, 15]. Let R be the conjugate of C .³ The mixed Bregman divergence between a belief $\boldsymbol{\mu}$ and a state \mathbf{q} is defined as $D(\boldsymbol{\mu}||\mathbf{q}) := R(\boldsymbol{\mu}) + C(\mathbf{q}) - \mathbf{q} \cdot \boldsymbol{\mu}$. The conjugacy of R and C implies that $D(\boldsymbol{\mu}||\mathbf{q}) \geq 0$ with equality iff $\boldsymbol{\mu} \in \partial C(\mathbf{q}) = \mathbf{p}(\mathbf{q})$, i.e., if the price vector “matches” the state (see Appendix A). The geometric interpretation of mixed Bregman divergence is as a gap between a tangent and the graph of the function R (see Fig. 1).

To see how the divergence relates to traders’ beliefs, consider a trader who believes that $\mathbb{E}[\boldsymbol{\rho}(\omega)] = \boldsymbol{\mu}'$ and moves the market from state \mathbf{q} to state \mathbf{q}' . The expected payoff to this trader is $(\mathbf{q}' - \mathbf{q}) \cdot \boldsymbol{\mu}' - C(\mathbf{q}') + C(\mathbf{q}) = D(\boldsymbol{\mu}'||\mathbf{q}) - D(\boldsymbol{\mu}'||\mathbf{q}')$. This payoff increases as $D(\boldsymbol{\mu}'||\mathbf{q}')$

³The conjugate is also, less commonly, called the “dual”.

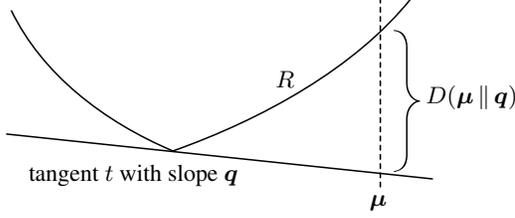

Figure 1: The mixed Bregman divergence $D(\boldsymbol{\mu} \parallel \mathbf{q})$ derived from the conjugate pair C and R measures the distance between the tangent with slope \mathbf{q} and the value of R evaluated at $\boldsymbol{\mu}$. By conjugacy, the tangent t is described by $t(\boldsymbol{\mu}) = \boldsymbol{\mu} \cdot \mathbf{q} - C(\mathbf{q})$. Note that the divergence is well defined even when R is not differentiable, because each slope vector determines a unique tangent.

decreases. Thus, subject to the trader’s budget constraints, the trader is incentivized to move to the state \mathbf{q}' which is as “close” to his/her belief $\boldsymbol{\mu}'$ as possible in the sense of a smaller value $D(\boldsymbol{\mu}' \parallel \mathbf{q}')$, with the largest expected payoff when $D(\boldsymbol{\mu}' \parallel \mathbf{q}') = 0$. This argument shows that $D(\cdot \parallel \cdot)$ is an implicit measure of distance used by traders.

The next theorem shows that the Bregman divergence also matches the concepts defined in Sec. 2.3. Specifically, we show that (1) the utility for a belief coincides with the Bregman divergence, (2) the utility for an event \mathcal{E} is the smallest divergence between the current market state and $\mathcal{M}(\mathcal{E})$, and (3) the conditional price vector is the (Bregman) projection of the current market state on $\mathcal{M}(\mathcal{E})$, i.e., it is a belief in $\mathcal{M}(\mathcal{E})$ that is “closest to” the current market state.

Theorem 1. *Let $\boldsymbol{\mu} \in \mathcal{M}$, $\mathbf{q} \in \mathbb{R}^K$ and $\emptyset \neq \mathcal{E} \subseteq \Omega$. Then*

$$\text{Util}(\boldsymbol{\mu}; \mathbf{q}) = D(\boldsymbol{\mu} \parallel \mathbf{q}) , \quad (1)$$

$$\text{Util}(\mathcal{E}; \mathbf{q}) = \min_{\boldsymbol{\mu}' \in \mathcal{M}(\mathcal{E})} D(\boldsymbol{\mu}' \parallel \mathbf{q}) , \quad (2)$$

$$\mathbf{p}(\mathcal{E}; \mathbf{q}) = \operatorname{argmin}_{\boldsymbol{\mu}' \in \mathcal{M}(\mathcal{E})} D(\boldsymbol{\mu}' \parallel \mathbf{q}) . \quad (3)$$

We finish this section by characterizing when EXUTIL is satisfied and showing that it implies CONDPRICE. Recall that $\Omega^x = \{\omega : X(\omega) = x\}$ and let $\mathcal{M}^x := \mathcal{M}(\Omega^x)$.

Proposition 1. *EXUTIL holds if and only if for all $x \in X$, there exists some c^x such that for all $\boldsymbol{\mu} \in \mathcal{M}^x$, $D(\boldsymbol{\mu} \parallel \mathbf{s}) - \bar{D}(\boldsymbol{\mu} \parallel \tilde{\mathbf{s}}) = c^x$. Moreover, EXUTIL implies CONDPRICE.*

3 SUDDEN REVELATION

In this section, we consider the design of sudden revelation market makers (Protocol 1). In this setting, partial information in the form of the realization of X is revealed to market participants (but not to the market maker) at a predetermined time, as might be the case if the medal winners of an Olympic event are announced but no human is available to input this information into the automated market maker on behalf of the market organizer. The random variable X and the observation time are assumed to be known, and the market maker wishes to “close” the submarket with respect to X just before the observation time, without knowing the realization x , while leaving the rest of the market unchanged.

Stated in terms of our formalism, we wish to find functions `NewState` and `NewCost` from Protocol 1 such that the desiderata CONDPRICE, EXUTIL, and ZEROUTIL from Table 1 are satisfied. This implies that traders who know only that $X = x$ are not rewarded after the observation time, but traders with new information about the outcome space conditioned on $X = x$ are rewarded exactly as before. As a result, trading immediately resumes in a “conditional market” on $\mathcal{M}(\Omega^x)$ for the correct realization x , without the market maker needing to know x and without any other human intervention. We refer to the goal of simultaneously achieving CONDPRICE, EXUTIL, and ZEROUTIL as achieving *implicit submarket closing*.

For convenience, throughout this section we write $\mathcal{M}^x := \mathcal{M}(\Omega^x)$ to denote the conditional price space, and $\mathcal{M}^* := \bigcup_{x \in \mathcal{X}} \mathcal{M}^x$ to denote prices possible after the observation.

3.1 SIMPLIFYING THE OBJECTIVE

We first show that achieving implicit submarket closing can be reduced to finding a function \tilde{R} satisfying a simple set of constraints, and defining `NewCost` to return the conjugate \tilde{C} of \tilde{R} . As a first step, we observe that it is without loss of generality to let `NewState` be an identity map, i.e., to assume that $\tilde{\mathbf{s}} = \mathbf{s}$; when this is not the case, we can obtain an equivalent market by setting $\tilde{\mathbf{s}} = \mathbf{s}$ and shifting \tilde{C} so that the Bregman divergence is unchanged.

Lemma 1. *Any desideratum of Table 1 holds for \tilde{C} and $\tilde{\mathbf{s}}$ if and only if it holds for $\tilde{C}'(\mathbf{q}) = \tilde{C}(\mathbf{q} + \tilde{\mathbf{s}} - \mathbf{s})$ and $\tilde{\mathbf{s}}' = \mathbf{s}$.*

To simplify exposition, we assume that $\tilde{\mathbf{s}} = \mathbf{s}$ throughout the rest of the section as we search for conditions on `NewCost` that achieve implicit submarket closing. Under this assumption, Proposition 1 can be used to characterize our goal in terms of \tilde{R} . Specifically, we show that EXUTIL and CONDPRICE hold if \tilde{R} differs from R by a (possibly different) constant on each conditional price space \mathcal{M}^x .

Lemma 2. *When $\tilde{\mathbf{s}} = \mathbf{s}$, EXUTIL and CONDPRICE hold together if and only if there exist constants b^x for $x \in \mathcal{X}$ such that $\tilde{R}(\boldsymbol{\mu}) = R(\boldsymbol{\mu}) - b^x$ for all $x \in \mathcal{X}$ and $\boldsymbol{\mu} \in \mathcal{M}^x$.*

This suggests parameterizing our search for \tilde{R} by vectors $\mathbf{b} = \{b^x\}_{x \in \mathcal{X}}$. For $\mathbf{b} \in \mathbb{R}^{\mathcal{X}}$, define a function

$$R^{\mathbf{b}}(\boldsymbol{\mu}) = \begin{cases} R(\boldsymbol{\mu}) - b^x & \text{if } \boldsymbol{\mu} \in \mathcal{M}^x, x \in \mathcal{X}, \\ \infty & \text{otherwise.} \end{cases}$$

If the sets \mathcal{M}^x overlap, $R^{\mathbf{b}}$ is not well defined for all $\boldsymbol{\mu}$. Whenever we write $R^{\mathbf{b}}$, we assume that \mathbf{b} is such that $R^{\mathbf{b}}$ is well defined. To satisfy Lemma 2 with a specific \mathbf{b} , it suffices to find a convex function \tilde{R} “consistent with” $R^{\mathbf{b}}$ in the following sense.

Definition 5. *We say that a function \tilde{R} is consistent with $R^{\mathbf{b}}$ if $\tilde{R}(\boldsymbol{\mu}) = R^{\mathbf{b}}(\boldsymbol{\mu})$ for all $\boldsymbol{\mu} \in \mathcal{M}^*$.*

We next simplify our objective further by proving that

whenever implicit submarket closing is achievable, it suffices to consider functions `NewCost` that set \tilde{C} to be the conjugate of the largest convex function consistent with R^b for some $b \in \mathbb{R}^{\mathcal{X}}$. To establish this, we examine properties of the *convex roof* of R^b , the largest convex function that lower-bounds (but is not necessarily consistent with) R^b .

Definition 6. Given a function $f : \mathbb{R}^K \rightarrow (-\infty, \infty]$, the convex roof of f , denoted $(\text{conv } f)$, is the largest convex function lower-bounding f , defined by

$$(\text{conv } f)(x) := \sup \{g(x) : g \in \mathcal{G}, g \leq f\}$$

where \mathcal{G} is the set of convex functions $g : \mathbb{R}^K \rightarrow (-\infty, \infty]$, and the condition $g \leq f$ holds pointwise.

The convex roof is analogous to a convex hull, and the epigraph of $(\text{conv } f)$ is the convex hull of the epigraph of f . See Urruty and Lemarchal [30, §B.2.5] for details.

Example 4. Recall the square market of Example 2. Let $X(\omega) = \omega_1$, so traders observe the payoff of the first security at observation time. Then $\mathcal{M}^x = \{x\} \times [0, 1]$ for $x \in \{0, 1\}$. For simplicity, let $b = \mathbf{0}$. We have $R^b(\mu) = \mu_2 \ln \mu_2 + (1 - \mu_2) \ln(1 - \mu_2)$ for $\mu \in \mathcal{M}^1 \cup \mathcal{M}^2$ and $R^b(\mu) = \infty$ for all other μ . Examining the convex hull of the epigraph of R^b gives us that for all $\mu \in [0, 1]^2$, we have $(\text{conv } R^b)(\mu) = \mu_2 \ln \mu_2 + (1 - \mu_2) \ln(1 - \mu_2)$.

As this example illustrates, the roof of R^b is the “flattest” convex function lower-bounding R^b . Given the geometric interpretation of Bregman divergence (Fig. 1), a “flatter” \tilde{R} yields a smaller utility for information. This flatness plays a key role in achieving `ZEROUTIL`. Assume that \tilde{R} is consistent with R^b , so `CONDPRICE` and `EXUTIL` hold by Lemma 2. Following the intuition in Fig. 1, to achieve `ZEROUTIL`, i.e., $\tilde{D}(\hat{\mu}^x \| s) = 0$ across all $x \in \mathcal{X}$ and $\hat{\mu}^x \in \mathcal{P}(\Omega^x; s)$, it must be the case that for all x and $\hat{\mu}^x$, the function values $\tilde{R}(\hat{\mu}^x)$ lie on the tangent of \tilde{R} with slope s . That is, the graph of \tilde{R} needs to be *flat* across the points $\hat{\mu}^x$. This suggests that the roof might be a good candidate for \tilde{R} . This intuition is formalized in the following lemma, which states that instead of considering arbitrary convex \tilde{R} consistent with R^b , we can consider \tilde{R} which take the form of a convex roof.

Lemma 3. If any convex function \tilde{R} is consistent with R^b then so is the convex roof $\tilde{R}' = (\text{conv } R^b)$. Furthermore, if \tilde{R} satisfies `ZEROUTIL` or `DECUTIL` then so does \tilde{R}' .

3.2 IMPLICIT SUBMARKET CLOSING

We now have the tools to answer the central question of this section: When can we achieve implicit submarket closing? Lemma 1 implies that we can assume that `NewState` is the identity function, and Lemmas 2 and 3 imply that it suffices to consider functions `NewCost` that set \tilde{C} to the conjugate of $\tilde{R} = (\text{conv } R^b)$ for some $b \in \mathbb{R}^{\mathcal{X}}$. What remains is to find the vector b that guarantees `ZEROUTIL`. As mentioned above, `ZEROUTIL` is satisfied if and only if $(\hat{\mu}^x, \tilde{R}(\hat{\mu}^x))$

lies on the tangent of \tilde{R} with the slope s for all $x \in \mathcal{X}$ and $\hat{\mu}^x \in \mathcal{P}(\Omega^x; s)$. This implies that $\tilde{R}(\hat{\mu}^x) = \hat{\mu}^x \cdot s - c$ for all x and $\hat{\mu}^x$ and some constant c . The specific choice of c does not matter since \tilde{D} is unchanged by vertical shifts of the graph of \tilde{R} . For convenience, we set $c = C(s)$, which makes the tangents of R and \tilde{R} with the slope s coincide. This and Lemma 2 then yield the choice of $b = \hat{b}$, with

$$\hat{b}^x := R(\hat{\mu}^x) + C(s) - \hat{\mu}^x \cdot s = D(\hat{\mu}^x \| s) \quad (4)$$

for all x and any choice of $\hat{\mu}^x \in \mathcal{P}(\Omega^x; s)$. The resulting construction of $\tilde{R} = (\text{conv } R^{\hat{b}})$ can be described using geometric intuition. First, consider the tangent of R with slope equal to the current market state s . For each $x \in \mathcal{X}$, take the subgraph of R over the set \mathcal{M}^x and let it “fall” vertically until it touches this tangent at the point $\hat{\mu}^x$. The set of fallen graphs for all x together describes $R^{\hat{b}}$ and the convex hull of the fallen epigraphs yields $\tilde{R} = (\text{conv } R^{\hat{b}})$.

Defining `NewCost` using this construction guarantees `ZEROUTIL`, but `CONDPRICE` and `EXUTIL` are achieved only when \tilde{R} is consistent with $R^{\hat{b}}$. Conversely, whenever the three properties are achievable, this construction produces a function \tilde{R} consistent with $R^{\hat{b}}$. This yields a full characterization of when implicit submarket closing is achievable.

Theorem 2. Let \hat{b} be defined as in Eq. (4). `CONDPRICE`, `EXUTIL`, and `ZEROUTIL` can be satisfied using Protocol 1 if and only if $(\text{conv } R^{\hat{b}})$ is consistent with $R^{\hat{b}}$. In this case, they can be achieved with `NewState` as the identity and `NewCost` outputting the conjugate of $\tilde{R} = (\text{conv } R^{\hat{b}})$.

3.3 CONSTRUCTING THE COST FUNCTION

Theorem 2 describes how to achieve implicit submarket closing by defining the cost function \tilde{C} output by `NewCost` implicitly via its conjugate \tilde{R} . In this section, we provide an explicit construction of the resulting cost function, and illustrate the construction through examples.

Fixing R , for each $x \in \mathcal{X}$ define a function $C^x(q) := \sup_{\mu \in \mathcal{M}^x} [q \cdot \mu - R(\mu)]$. Each function C^x can be viewed as a bounded-loss and arbitrage-free cost function for outcomes in Ω^x . The conjugate of each C^x coincides with R on \mathcal{M}^x (and is infinite outside \mathcal{M}^x). The explicit expression for \tilde{C} is described in the following proposition.

Proposition 2. For a given C with conjugate R , define \hat{b} as in Eq. (4) and let $\tilde{R} = (\text{conv } R^{\hat{b}})$. The conjugate \tilde{C} of \tilde{R} can be written $\tilde{C}(q) = \max_{x \in \mathcal{X}} [\hat{b}^x + C^x(q)]$. Furthermore, for each $x \in \mathcal{X}$, $\hat{b}^x = C(s) - C^x(s)$.

At any market state q with a unique $\hat{x} := \arg\max_{x \in \mathcal{X}} [\hat{b}^x + C^x(q)]$, the price according to \tilde{C} lies in the set $\mathcal{M}^{\hat{x}}$. When \hat{x} is not unique, the market has a bid-ask spread. The addition of \hat{b}^x ensures that the bid-ask spread at the market state s contains conditional prices $\hat{\mu}^x$ across all x . To illustrate this construction, we return to the example of a square.

Example 5. Consider again the square market from Examples 2 and 4 with $X(\omega) = \omega_1$. One can verify that $C^x(\mathbf{q}) = xq_1 + \ln(1 + e^{q_2})$ for $x \in \{0, 1\}$. Prop. 2 gives

$$\begin{aligned}\tilde{C}(\mathbf{q}) &= \max_{x \in \{0, 1\}} \left[x(q_1 - s_1) + \ln(1 + e^{q_2}) + \ln(1 + e^{s_1}) \right] \\ &= \max\{0, q_1 - s_1\} + \ln(1 + e^{s_1}) + \ln(1 + e^{q_2}).\end{aligned}$$

In switching from C to \tilde{C} we have effectively changed the first term of our cost from a basic LMSR cost for a single binary security to the piecewise linear cost of Example 3, introducing a bid-ask spread for security 1 when $q_1 = s_1$; states $\mathbf{q} = (s_1, q_2)$ have $\tilde{\mathbf{p}}(\mathbf{q}) = [0, 1] \times \{e^{q_2}/(1 + e^{q_2})\}$. The market for security 1 has thus implicitly closed; as the new market begins with $\mathbf{q} = \mathbf{s}$, any trader can switch the price of security 1 to 0 or 1 by simply purchasing an infinitesimal quantity of security 1 in the appropriate direction, at essentially no cost and with no ability to profit.

The example above illustrates our cost function construction, but does not show that \tilde{R} is consistent with R^b as required by Theorem 2. In fact, it is consistent. This follows from the sufficient condition proved in Appendix G.2. Briefly, the condition is that \mathcal{M}^* does not contain any price vectors $\boldsymbol{\mu}$ that can be expressed as nontrivial convex combinations of vectors from multiple \mathcal{M}^x .

In Appendix G.3, we show that this sufficient condition applies to many settings of interest such as arbitrary partitions of simplex and submarket observations in binary-payoff LCMMs (defined in Sec. 4), which were used to run a combinatorial market for the 2012 U.S. Elections [14].

A case in which the sufficient condition is violated is the square market with $X(\omega) = \omega_1 + \omega_2 \in \{0, 1, 2\}$, where $\mathcal{M}^0 = (0, 0)$ and $\mathcal{M}^2 = (1, 1)$ but $(\frac{1}{2}, \frac{1}{2}) = \frac{1}{2}(0, 0) + \frac{1}{2}(1, 1) \in \mathcal{M}^1$. This particular example also fails to satisfy Theorem 2 (see Appendix G.1), but in general the sufficient condition is not necessary (see Appendix G.4).

4 GRADUAL DECREASE

We now consider gradual decrease market makers (Protocol 2) for the gradual decrease setting in which the utility of information about a future observation X is decreasing continuously over time. We focus on *linearly constrained market makers* (LCMMs) [13], which naturally decompose into submarkets. Our proposed gradual decrease market maker employs a different LCMM at each time step, and satisfies various desiderata of Sec. 2.4 between steps.

As a warm-up for the concepts introduced in this section, we show how the “liquidity parameter” can be used to implement a decreasing utility for information.

Example 6. *Homogeneous decrease in utility for information.* We begin with a differentiable cost function C in a state \mathbf{s} . Let $\alpha \in (0, 1)$, and define $\tilde{C}(\mathbf{q}) = \alpha C(\mathbf{q}/\alpha)$, and $\tilde{\mathbf{s}} = \alpha \mathbf{s}$. \tilde{C} is parameterized by the “liquidity parameter” α .

The transformation $\tilde{\mathbf{s}}$ guarantees the preservation of prices, i.e., $\tilde{\mathbf{p}}(\tilde{\mathbf{s}}) = \nabla \tilde{C}(\tilde{\mathbf{s}}) = \alpha \nabla C(\tilde{\mathbf{s}}/\alpha)/\alpha = \nabla C(\mathbf{s}) = \mathbf{p}(\mathbf{s})$. We can derive that $\tilde{R}(\boldsymbol{\mu}) = \alpha R(\boldsymbol{\mu})$, and $\tilde{D}(\boldsymbol{\mu}||\mathbf{q}) = \alpha D(\boldsymbol{\mu}||\mathbf{q}/\alpha)$, so, for all $\boldsymbol{\mu}$, $\tilde{D}(\boldsymbol{\mu}||\tilde{\mathbf{s}}) = \alpha D(\boldsymbol{\mu}||\mathbf{s})$. In words, the utility for all beliefs $\boldsymbol{\mu}$ with respect to the current state is decreased according to the multiplier α .

This idea will be the basis of our construction. We next define the components of our setup and prove the desiderata.

4.1 LINEARLY CONSTRAINED MARKETS

Recall that $\boldsymbol{\rho} : \Omega \rightarrow \mathbb{R}^K$ is the payoff function. Let \mathcal{G} be a system of non-empty disjoint subsets $g \subseteq [K]$ forming a partition of coordinates of $\boldsymbol{\rho}$, so $[K] = \bigcup_{g \in \mathcal{G}} g$. We use the notation $\boldsymbol{\rho}_g(\omega) := (\rho_i(\omega))_{i \in g}$ for the block of coordinates in g , and similarly $\boldsymbol{\mu}_g$ and \mathbf{q}_g . Blocks g describe groups of securities that are treated as separate “submarkets,” but there can be logical dependencies among them.

Example 7. *Medal counts.* Consider a prediction market for the Olympics. Assume that Norway takes part in n Olympic events. In each, Norway can win a gold medal or not. Encode this outcome space as $\Omega = \{0, 1\}^n$. Define random variables $X_i(\omega) = \omega_i$ equal to 1 iff Norway wins gold in the i th Olympic event. Also define a random variable $Y = \sum_{i=1}^n X_i$ representing the number of gold medals that Norway wins in total. We create $K = 2n + 1$ securities, corresponding to 0/1 indicators of the form $\mathbf{1}[X_i = 1]$ for $i \in [n]$ and $\mathbf{1}[Y = y]$ for $y \in \{0, \dots, n\}$. That is, $\rho_i = X_i$ for $i \in [n]$ and $\rho_{n+1+y} = \mathbf{1}[Y = y]$ for $y \in \{0, \dots, n\}$. A natural block structure in this market is $\mathcal{G} = \{\{1\}, \{2\}, \dots, \{n\}, \{n+1, \dots, 2n+1\}\}$ with submarkets corresponding to the X_i and Y .

Given the block structure \mathcal{G} , the construction of a linearly constrained market begins with bounded-loss and arbitrage-free convex cost functions $C_g : \mathbb{R}^g \rightarrow \mathbb{R}$ with conjugates R_g and divergences D_g for each $g \in \mathcal{G}$. These cost functions are assumed to be easy to compute and give rise to a “direct-sum” cost $C_{\oplus}(\mathbf{q}) = \sum_{g \in \mathcal{G}} C_g(\mathbf{q}_g)$ with the conjugate $R_{\oplus}(\boldsymbol{\mu}) = \sum_{g \in \mathcal{G}} R_g(\boldsymbol{\mu}_g)$ and divergence $D_{\oplus}(\boldsymbol{\mu}||\mathbf{q}) = \sum_{g \in \mathcal{G}} D_g(\boldsymbol{\mu}_g||\mathbf{q}_g)$.

Since C_{\oplus} decomposes, it can be calculated quickly. However, the market maker C_{\oplus} might allow arbitrage due to the lack of consistency among submarkets since arbitrage opportunities arise when prices fall outside \mathcal{M} [1]. \mathcal{M} is always polyhedral, so it can be described as $\mathcal{M} = \{\boldsymbol{\mu} \in \mathbb{R}^K : \mathbf{A}^\top \boldsymbol{\mu} \geq \mathbf{b}\}$ for some matrix $\mathbf{A} \in \mathbb{R}^{K \times M}$ and vector $\mathbf{b} \in \mathbb{R}^M$. Letting \mathbf{a}_m denote the m th column of \mathbf{A} , arbitrage opportunities open up if the price of the bundle \mathbf{a}_m falls below b_m . For any $\boldsymbol{\eta} \in \mathbb{R}_+^M$, the bundle $\mathbf{A}\boldsymbol{\eta}$ presents an arbitrage opportunity if priced below $\mathbf{b} \cdot \boldsymbol{\eta}$.

A *linearly constrained market maker* (LCMM) is described by the cost function $C(\mathbf{q}) = \inf_{\boldsymbol{\eta} \in \mathbb{R}_+^M} [C_{\oplus}(\mathbf{q} + \mathbf{A}\boldsymbol{\eta}) - \mathbf{b} \cdot \boldsymbol{\eta}]$. While the definition of C is slightly involved, the conju-

gate R has a natural meaning as a restriction of the direct-sum market to the price space \mathcal{M} , i.e., $R(\boldsymbol{\mu}) = R_{\oplus}(\boldsymbol{\mu}) + \mathbb{I}[\boldsymbol{\mu} \in \mathcal{M}]$. Furthermore, the infimum in the definition of C is always attained (see Appendix D.1). Fixing \mathbf{q} and letting $\boldsymbol{\eta}^*$ be a minimizer in the definition, we can think of the market maker as automatically charging traders for the bundle $\mathbf{A}\boldsymbol{\eta}^*$, which would present an arbitrage opportunity, and returning to them the guaranteed payout $\mathbf{b} \cdot \boldsymbol{\eta}$. This benefits traders while maintaining the same worst-case loss guarantee for the market maker as C_{\oplus} [13].

Example 8. LCMM for medal counts. Continuing the previous example, for submarkets X_i , we can define LMSR costs $C_i(q_i) = \ln(1 + \exp(q_i))$. For the submarket for Y , let $g = \{n + 1, \dots, 2n + 1\}$ and use the LMSR cost $C_g(\mathbf{q}_g) = \ln(\sum_{y=0}^n \exp(q_{n+1+y}))$. The submarkets for X_i and Y are linked. One example of a linear constraint is based on the linearity of expectations: for any distribution, we must have $\mathbb{E}[Y] = \sum_{i=1}^n \mathbb{E}[X_i]$. This places an equality constraint $\sum_{y=0}^n y \cdot \mu_{n+1+y} = \sum_{i=1}^n \mu_i$ on the vector $\boldsymbol{\mu}$, which can be expressed as two inequality constraints (see Dudík et al. [13, 14] for more on constraint generation).

4.2 DECREASING LIQUIDITY

We now study the gradual decrease scenario in which the utility for information in each submarket g decreases over time. In the Olympics example, the market maker may want to continuously decrease the rewards for information about a particular event as the event takes place.

We generalize the strategy from Example 6 to LCMMs and extend them to time-sensitive cost functions by introducing the “information-utility schedule” in the form of a differentiable non-increasing function $\beta_g : \mathbb{R} \rightarrow (0, 1]$ with $\beta_g(t^0) = 1$. The speed of decrease of β_g controls the speed of decrease of the utility for information in each submarket. (We make this statement more precise in Theorem 3.)

We first define a gradual decrease direct-sum cost function $\mathbf{C}_{\oplus}(\mathbf{q}; t) = \sum_{g \in \mathcal{G}} \beta_g(t) C_g(\mathbf{q}_g / \beta_g(t))$ which is used to define a gradual decrease LCMM, and a matching `NewState` as follows:

$$\begin{aligned} \mathbf{C}(\mathbf{q}; t) &= \inf_{\boldsymbol{\eta} \in \mathbb{R}_+^M} [\mathbf{C}_{\oplus}(\mathbf{q} + \mathbf{A}\boldsymbol{\eta}; t) - \mathbf{b} \cdot \boldsymbol{\eta}] \\ \text{NewState}(\mathbf{q}; t, \tilde{t}) &= \tilde{\mathbf{q}} \\ &\text{such that } \tilde{\mathbf{q}}_g = \frac{\beta_g(\tilde{t})}{\beta_g(t)} (\mathbf{q}_g + \boldsymbol{\delta}_g^*) - \boldsymbol{\delta}_g^* \\ &\text{where } \boldsymbol{\eta}^* \text{ is a minimizer in } \mathbf{C}(\mathbf{q}; t) \text{ and } \boldsymbol{\delta}^* = \mathbf{A}\boldsymbol{\eta}^* . \end{aligned}$$

When considering the state update from time t to time \tilde{t} , the ratio $\beta_g(\tilde{t})/\beta_g(t)$ has the role of the liquidity parameter α in Example 6. The motivation behind the definition of `NewState` is to guarantee that $\tilde{\mathbf{q}}_g + \boldsymbol{\delta}_g^* = [\beta_g(\tilde{t})/\beta_g(t)](\mathbf{q}_g + \boldsymbol{\delta}_g^*)$, which turns out to ensure that $\boldsymbol{\eta}^*$ remains the minimizer and the prices are unchanged. The preservation of prices (PRICE) is achieved by a scaling sim-

ilar to Example 6, albeit applied to the market state in the direct-sum market underlying the LCMM.

This intuition is formalized in the next theorem, which shows that the above construction preserves prices and decreases the utility for information, as captured by the mixed Bregman divergence, according to the schedules β_g . We use the notation $C^t(\mathbf{q}) := \mathbf{C}(\mathbf{q}; t)$ and write D_g^t for the divergence derived from $C_g^t(\mathbf{q}_g) := \beta_g(t) C_g(\mathbf{q}_g / \beta_g(t))$.

Theorem 3. *Let \mathbf{C} be a gradual decrease LCMM, let $t, \tilde{t} \in \mathbb{R}$ and $\mathbf{s} \in \mathbb{R}^K$. The replacement of C^t by $\tilde{C} := C^{\tilde{t}}$ and \mathbf{s} by $\tilde{\mathbf{s}} := \text{NewState}(\mathbf{s}; t, \tilde{t})$ satisfies PRICE. Also,*

$$\tilde{D}(\boldsymbol{\mu} \parallel \tilde{\mathbf{s}}) = \sum_{g \in \mathcal{G}} \alpha_g D_g^{\tilde{t}}(\boldsymbol{\mu}_g \parallel \mathbf{s}_g + \boldsymbol{\delta}_g^*) + (\mathbf{A}^\top \boldsymbol{\mu} - \mathbf{b}) \cdot \boldsymbol{\eta}^* \quad (5)$$

for all $\boldsymbol{\mu} \in \mathcal{M}$, where $\boldsymbol{\eta}^*$ and $\boldsymbol{\delta}^*$ are defined by `NewState`($\mathbf{s}; t, \tilde{t}$), and $\alpha_g = \beta_g(\tilde{t})/\beta_g(t) > 0$.

The first term on the right-hand side of Eq. (5) is the sum of divergences in submarkets g , each weighted by a coefficient α_g which is equal to one at $\tilde{t} = t$ and weakly decreases as \tilde{t} grows. The divergences are between $\boldsymbol{\mu}_g$ and the state resulting from the arbitrager action in the direct-sum market. The second term is non-negative, since $\boldsymbol{\mu} \in \mathcal{M}$, and represents expected arbitrager gains beyond the guaranteed profit from the arbitrage in the direct-sum market. The only terms that depend on time \tilde{t} are the multipliers α_g . Since they are decreasing over time, we immediately obtain that the utility for information, $\text{Util}(\boldsymbol{\mu}; \tilde{\mathbf{s}}) = \tilde{D}(\boldsymbol{\mu} \parallel \tilde{\mathbf{s}})$, is also decreasing, with the contributions from individual submarkets decreasing according to their schedules β_g .

When only one of the schedules β_g is decreasing and the other schedules stay constant, we can show that the excess utility and conditional prices are preserved (conditioned on $\boldsymbol{\rho}_g$), and under certain conditions also DECUTIL holds.

For a submarket g , let $\mathcal{X}_g := \{\boldsymbol{\rho}_g(\omega) : \omega \in \Omega\}$ be the set of realizations of $\boldsymbol{\rho}_g$. Recall that $\mathcal{M}(\mathcal{E})$ is the convex hull of $\{\boldsymbol{\rho}(\omega)\}_{\omega \in \mathcal{E}}$. We show that DECUTIL holds if C_g is differentiable and the submarket g is “tight” as follows.

Definition 7. *We say that a submarket g is tight if for all $\mathbf{x} \in \mathcal{X}_g$ the set $\{\boldsymbol{\mu} \in \mathcal{M} : \boldsymbol{\mu}_g = \mathbf{x}\}$ coincides with $\mathcal{M}(\boldsymbol{\rho}_g = \mathbf{x})$, i.e., if all the beliefs $\boldsymbol{\mu}$ with $\boldsymbol{\mu}_g = \mathbf{x}$ can be realized by probability distributions over states ω with $\boldsymbol{\rho}_g(\omega) = \mathbf{x}$. (In general, the former is always a superset of the latter, hence the name “tight” when the equality holds.)*

While this condition is somewhat restrictive, it is easy to see that all submarkets with binary securities, i.e., with $\boldsymbol{\rho}_g(\omega) \in \{0, 1\}^g$, are tight (see Appendix D.4).

Theorem 4. *Assume the setup of Theorem 3. Let $g \in \mathcal{G}$ and assume that $\beta_g(\tilde{t}) < \beta_g(t)$ whereas $\beta_{g'}(\tilde{t}) = \beta_{g'}(t)$ for $g' \neq g$. Then the replacement of C^t by \tilde{C} and \mathbf{s} by $\tilde{\mathbf{s}}$ satisfies CONDPRICE and EXUTIL for the random variable $\boldsymbol{\rho}_g$. Furthermore, if C_g is differentiable and the submarket g is tight, we also obtain DECUTIL.*

Abstract

We develop a framework for convexifying a general class of optimization problems. We analyze the suboptimality of the solution to the convexified problem relative to the original nonconvex problem, and prove additive approximation guarantees under some assumptions. In simple settings, the convexification procedure can be applied directly and standard optimization methods can be used. In the general case we rely on stochastic gradient algorithms, whose convergence rate can be bounded using the convexity of the underlying optimization problem. We then extend the framework to a general class of discrete-time dynamical systems where our convexification approach falls under the paradigm of risk-sensitive Markov Decision Processes. We derive the first model-based and model-free policy gradient optimization algorithms with guaranteed convergence to the optimal solution. We also present numerical results in different machine learning applications.

1 INTRODUCTION

It has been said that the watershed in optimization is not between linearity and nonlinearity, but between convexity and nonconvexity. In this paper we develop a framework for convexifying a general class of optimization problems (section 3), turning them into problems that can be solved with efficient convergence guarantees. The convexification approach may change the problem drastically in some cases, which is not surprising since most nonconvex optimization problems are NP-hard and cannot be reduced to solving convex optimization problems. However, under additional assumptions, we obtain guarantees that bound the suboptimality of the solution relative to the original non-

convex problem (section 3.2). We adapt stochastic gradient methods to solve the resulting problems (section 4) and prove convergence guarantees that bound the distance to optimality as a function of the number of iterations. In section 5, we extend the framework to arbitrary dynamical systems and derive the first policy optimization approach with guaranteed convergence to the global optimum. The control problems we study fall under the framework of risk-sensitive control. The condition required for convexity is a natural one, relating the control cost, risk factor and noise covariance. It is very similar to the condition that reduces stochastic optimal control to a linear problem [Fleming and Mitter, 1982, Kappen, 2005, Todorov, 2009], which in turn has given rise to path-integral and other specialized methods for control [Theodorou et al., 2010a, Broek et al., 2010, Dvijotham and Todorov, 2011, Toussaint, 2009].

Smoothing with noise is a relatively common approach to simplify difficult optimization problems. It has been used in computer vision [Rangarajan, 1990] heuristically and formalized in recent work [Mobahi, 2012] where it is shown that under certain assumptions, adding sufficient noise eventually leads to a convex optimization problem. In contrast, we show that for any noise level one can choose the degree of risk-aversion so as to obtain a convex problem. This procedure may destroy minima that are not robust to perturbations – which is not necessarily undesirable, because in many applications it makes sense to seek a robust solution rather than the best one.

2 NOTATION

Gaussian random variables are denoted by $\omega \sim \mathcal{N}(\mu, \Sigma)$, where μ is the mean and Σ the covariance matrix. Given a random variable $\omega \in \Omega$ with distribution P and a function $h : \Omega \mapsto \mathbf{R}$, the expected value of the random variable $h(\omega)$ is written as $\mathbb{E}_{\omega \sim P}[h(\omega)]$. Whenever it is clear from the context, we will drop

the subscript on the expected value and simply write $\mathbb{E}[h(\omega)]$. We differ from convention here slightly by denoting random variables with lowercase letters and reserve uppercase letters for matrices. We will frequently work with Gaussian perturbations of a function, so we denote:

$$\bar{h}(\theta) = \mathbb{E}_{\omega \sim \mathcal{N}(0, \Sigma)} [h(\theta + \omega)], \tilde{h}_\omega(\theta) = h(\theta + \omega) - \bar{h}(\theta).$$

I_n denotes the $n \times n$ identity matrix. Unless stated otherwise, $\|\cdot\|$ refers to the Euclidean ℓ_2 norm. Given a convex set \mathcal{C} , we denote the projection onto \mathcal{C} of x by $\text{Proj}_{\mathcal{C}}(x)$: $\text{Proj}_{\mathcal{C}}(x) = \text{argmin}_{y \in \mathcal{C}} \|y - x\|$. The maximum eigenvalue of a symmetric matrix M is denoted by $\lambda_{\max}(M)$. Given symmetric matrices A, B , the notation $A \succeq B$ means that $A - B$ is a positive semidefinite matrix. Given a positive definite matrix $M \succ 0$, we denote the metric induced by M as $\|x\|_M = \sqrt{x^T M x}$.

3 GENERAL OPTIMIZATION PROBLEMS

We study optimization problems of the form:

$$\min_{\theta \in \mathcal{C}} g(\theta) \quad (1)$$

where g is an arbitrary function and $\mathcal{C} \subset \mathbf{R}^k$ is a convex set. We do not assume that g is convex so the above problem could be a nonconvex optimization problem. In this work, we convexify this problem by decomposing $g(\theta)$ as follows: $g(\theta) = f(\theta) + \frac{1}{2}\theta^T R \theta$ and perturbing f with Gaussian noise. Optimization problems of this form are very common in machine learning (where R corresponds to a regularizer) and control (where R corresponds to a control cost). The convexified optimization problem is:

$$\min_{\theta \in \mathcal{C}} f_\alpha(\theta) + \frac{1}{2}\theta^T R \theta \quad (2)$$

where $R \succeq 0$ and

$$f_\alpha(\theta) = \frac{1}{\alpha} \log \left(\mathbb{E}_{\omega \sim \mathcal{N}(0, \Sigma)} [\exp(\alpha f(\theta + \omega))] \right).$$

This kind of objective is common in risk-averse optimization. To a first order Taylor expansion in α , the above objective is equal to $\mathbb{E}[f(\theta + \omega)] + \alpha \text{Var}(f(\theta + \omega))$, indicating that increasing α will make the solution more robust to Gaussian perturbations. α is called the risk-factor and is a measure of the risk-aversion of the decision maker. Larger values of α will reject solutions that are not robust to Gaussian perturbations.

In order that the expectation exists, we require that f is bounded above:

$$\text{For all } \theta \in \mathbf{R}^k, f(\theta) \leq M < \infty. \quad (3)$$

We implicitly make this assumption throughout this paper in all the stated results. Note that this is not a very restrictive assumption, since, given any function g with a finite minimum, one can define a new objective $g' = \min(g, \bar{m})$, where \bar{m} is an upper bound on the minimum (say the value of the function at some point), without changing the minimum. Since the convex quadratic is non-negative, f is also bounded above by \bar{m} and hence $0 < \exp(\alpha f(\theta + \omega)) \leq \exp(\alpha \bar{m})$. This ensures that $f_\alpha(\theta)$ is finite. Some results will require differentiability, and we can preserve this by defining g' using a soft-min: For example, $g'(x) = \bar{m} \tanh\left(\frac{g(x)}{\bar{m}}\right)$.

Theorem 3.1 (Universal Convexification). *The optimization problem (2) is a convex optimization problem whenever \mathcal{C} is a convex set and $\alpha R \succeq \Sigma^{-1}$.*

Proof. Writing out the objective function in (2) and scaling by α , we get:

$$\log \left(\mathbb{E}_{\omega \sim \mathcal{N}(0, \Sigma)} [\exp(\alpha f(\theta + \omega))] \right) + \frac{\alpha}{2} \theta^T R \theta \quad (4)$$

Writing out the expectation, we have:

$$\begin{aligned} \mathbb{E}_{\omega \sim \mathcal{N}(0, \Sigma)} [\exp(\alpha f(\theta + \omega))] &= \mathbb{E}_{y \sim \mathcal{N}(\theta, \Sigma)} [\exp(\alpha f(y))] \\ &\propto \int \exp\left(-\frac{1}{2}(y - \theta)^T \Sigma^{-1} (y - \theta)\right) \exp(\alpha f(y)) \, dy \end{aligned}$$

where we omitted the normalizing constant $\left(\sqrt{(2\pi)^n \det(\Sigma)}\right)^{-1}$ in the last step. Thus, exponentiating (4), we get (omitting the normalizing constant):

$$\int \exp\left(\frac{\alpha}{2} \theta^T R \theta - \frac{1}{2}(y - \theta)^T \Sigma^{-1} (y - \theta) + \alpha f(y)\right) \, dy$$

The term inside the exponent can be rewritten as

$$\frac{1}{2} \theta^T (\alpha R - \Sigma^{-1}) \theta + \theta^T \Sigma^{-1} y + \alpha f(y) - \frac{1}{2} y^T \Sigma^{-1} y$$

Since $\alpha R \succeq \Sigma^{-1}$, this is a convex quadratic function of θ for each y . Thus, the overall objective is the composition of a convex and increasing function $\log \mathbb{E}[\exp(\cdot)]$ and a convex quadratic and is hence convex [Boyd and Vandenberghe, 2004]. Since \mathcal{C} is convex, the overall problem is a convex optimization problem. \square

3.1 INTERPRETATION

Theorem 3.1 is a surprising result, since the condition for convexity does not depend in any way on the

properties of f (except for the boundedness assumption (3)), but only on the relationship between the quadratic objective R , the risk factor α and the noise level Σ . In this section, we give some intuition behind the result and describe why it is plausible that this is true.

In general, arbitrary nonconvex optimization problems can be very challenging to solve. As a worst case example, consider a convex quadratic function $g(x) = x^2$ that is perturbed slightly: At some point where the function value is very large (say $x = 100$), we modify the function so that it suddenly drops to a large negative value (lower than the global minimum 0 of the convex quadratic). By doing this perturbation over a small finite interval, one can preserve differentiability while introducing a new global minimum far away from the original global minimum. In this way, one can create difficult optimization problems that cannot be solved using gradient descent methods, unless initialized very carefully.

The work we present here does not solve this problem: In fact, it will not find a global minimum of the form created above. The risk-aversion introduced destroys this minimum, since small perturbations cause the function to increase rapidly, ie, $g(\theta^* + \omega) \gg g(\theta^*)$, so that the objective (2) becomes large. Instead, it will find a “robust” minimum, in the sense that Gaussian perturbations around the minimum do not increase the value of the objective by much. This intuition is formalized by theorem 3.2, which bounds the suboptimality of the convexified solution relative to the optimal solution of the original problem in terms of the sensitivity of f to Gaussian perturbations around the optimum.

In figure 1, we illustrate the effect of the convexification for a 1-dimensional optimization problem. The blue curve represents the original function $g(\theta)$. It has 4-local minima in the interval $(-3, 3)$. Two of the shallow minima are eliminated by smoothing with Gaussian noise to get $\bar{g}(\theta)$. However, there is a deep but narrow local minimum that remains even after smoothing. Making the problem convex using risk-aversion and theorem 3.1 leads to the green curve that only preserves the robust minimum as the unique global optimum.

3.2 ANALYSIS OF SUB-OPTIMALITY

We have derived a convex surrogate for a very general class of optimization problems. However, it is possible that the solution to the convexified problem is drastically different from that of the original problem and the convex surrogate we propose is a poor approximation. Given the hardness of general non-convex opti-

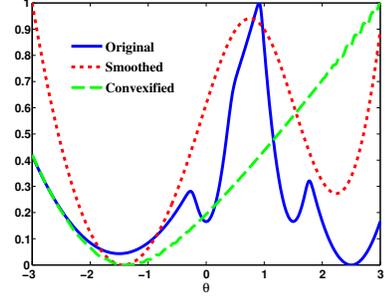

Figure 1: Illustration of Convexification for a 1-dimensional optimization problem

mization, we do not expect the two problems to have close solutions without additional assumptions. In this section, we analyze the gap between the original and convexified problem. In order to answer this, we first define the sensitivity function, which quantifies the gap between (1) and (2).

Definition 1 (Sensitivity Function). The sensitivity function of f at noise level Σ , risk α is defined as:

$$\begin{aligned} S_{\alpha, f}(\theta) &= \frac{1}{\alpha} \log \left(\mathbb{E} \left[\exp \left(\alpha \left(f(\theta + \omega) - \bar{f}(\theta) \right) \right) \right] \right) \\ &= \frac{1}{\alpha} \log \left(\mathbb{E} \left[\exp \left(\alpha \tilde{f}_{\omega}(\theta) \right) \right] \right). \end{aligned}$$

This is a measure of how sensitive f is to Gaussian perturbations at θ .

Theorem 3.2 (Suboptimality Analysis). Let $g(\theta) = f(\theta) + \frac{1}{2}\theta^T R \theta$ and define:

$$\theta_{\alpha}^* = \operatorname{argmin}_{\theta \in \mathcal{C}} f_{\alpha}(\theta) + \frac{1}{2}\theta^T R \theta, \quad \theta^* = \operatorname{argmin}_{\theta \in \mathcal{C}} \bar{g}(\theta).$$

Then,

$$\bar{g}(\theta_{\alpha}^*) - \bar{g}(\theta^*) \leq S_{\alpha, f}(\theta)$$

Proof. We have that $\forall \theta, \bar{g}(\theta) = \bar{f}(\theta) + \frac{1}{2}\theta^T R \theta + \frac{1}{2}\operatorname{tr}(\Sigma R)$. From the convexity of the function $y \rightarrow \exp(\alpha y)$ and Jensen’s inequality, we have

$$\begin{aligned} \bar{g}(\theta_{\alpha}^*) &= \bar{f}(\theta_{\alpha}^*) + \frac{1}{2}\theta_{\alpha}^{*T} R \theta_{\alpha}^* + \frac{1}{2}\operatorname{tr}(\Sigma R) \\ &\leq f_{\alpha}(\theta_{\alpha}^*) + \frac{1}{2}\theta_{\alpha}^{*T} R \theta_{\alpha}^* + \frac{1}{2}\operatorname{tr}(\Sigma R) \end{aligned}$$

Since $\theta_{\alpha}^* = \operatorname{argmin}_{\theta \in \mathcal{C}} f_{\alpha}(\theta) + \frac{1}{2}\theta^T R \theta$, for any $\theta \in \mathcal{C}$, we have

$$\begin{aligned} \bar{g}(\theta_{\alpha}^*) &\leq f_{\alpha}(\theta) + \frac{1}{2}\theta^T R \theta + \frac{1}{2}\operatorname{tr}(\Sigma R) \\ &= S_{\alpha, f}(\theta) + \bar{g}(\theta). \end{aligned}$$

The result follows by plugging in $\theta = \theta^*$ and subtracting $\bar{g}(\theta^*)$ from both sides. \square

Remark 1. Although we only prove suboptimality relative to the optimal solution of a smoothed version of g , we can extend the analysis to the optimal solution of g itself. Define $\theta^* = \operatorname{argmin}_{\theta \in \mathcal{C}} g(\theta)$. We can prove that

$$g(\theta_\alpha^*) - g(\theta^*) \leq (\bar{g}(\theta^*) - g(\theta^*)) + (g(\theta_\alpha^*) - \bar{g}(\theta_\alpha^*)) + S_{\alpha, f}(\theta)$$

Assuming that g changes slowly around θ^* and θ_α^* (indicative of the fact that θ^* is a ‘‘robust’’ minimum and θ_α^* is the minimum of a robustified problem), we can bound the first term. We leave a precise analysis for future work.

3.2.1 BOUNDING THE SENSITIVITY FUNCTION

The sensitivity function is exactly the moment generating function of the 0-mean random variable $f_\omega(\theta)$. Several techniques have been developed for bounding moment generation functions in the field of concentration inequalities [Boucheron et al., 2013]. Using these techniques, we can bound the moment generating function (i.e. the sensitivity function) under the assumption that f is Lipschitz-continuous. Before stating the lemma, we state a classical result:

Theorem 3.3 (Log-Sobolev Inequality, [Boucheron et al., 2013], theorem 5.4). *Let $\omega \sim \mathcal{N}(0, \sigma^2 I)$ and f be any continuously differentiable function of ω . Then,*

$$\mathbb{E} \left[f(\omega)^2 \log \left(\frac{f(\omega)^2}{\mathbb{E}[f(\omega)^2]} \right) \right] \leq 2\sigma^2 \mathbb{E} [\|\nabla f(\omega)\|^2].$$

Further, if f is Lipschitz with Lipschitz constant L , then

$$\mathbb{E} \left[\exp \left(\alpha \left(f(\omega) - \mathbb{E}[f(\omega)] \right) \right) \right] \leq \exp(\alpha^2 L^2 \sigma^2 / 2).$$

Finally, we can also prove that if f is differentiable and $\mathbb{E} \left[\exp \lambda \|\nabla f(\omega)\|^2 \right] < \infty$ for all $\lambda < \lambda_0$, then, given η such that $\lambda \sigma^2 < \eta \lambda_0$ and $\lambda \eta < 2$, we have

$$\begin{aligned} \log \left(\mathbb{E} \left[\exp \left(\lambda \left(f(\omega) - \mathbb{E}[f(\omega)] \right) \right) \right] \right) &\leq \\ \frac{\lambda \eta}{2 - \lambda \eta} \log \left(\mathbb{E} \left[\exp \left(\frac{\lambda \sigma^2}{\eta} \|\nabla f(\omega)\|^2 \right) \right] \right) & \end{aligned}$$

Theorem 3.4 (Lipschitz Continuous Functions). *Assume the same setup as theorem 3.2. Suppose further that f is Lipschitz continuous with Lipschitz constant L , that is,*

$$\forall \theta, \theta', |f(\theta) - f(\theta')| \leq L \|\theta - \theta'\|.$$

Then, $S_{\alpha, f}(\theta) \leq \frac{1}{2} \alpha L^2 \lambda_{\max}(\Sigma)$. Further,

$$\bar{g}(\theta) - \min_{\theta \in \mathcal{C}} \bar{g}(\theta) \leq \frac{\alpha L^2 \lambda_{\max}(\Sigma)}{2}.$$

Proof. We can write

$$\tilde{f}(\omega') = f(\theta + \Sigma^{1/2} \omega') - \bar{f}(\theta)$$

where $\omega' \sim \mathcal{N}(0, I_k)$.

$$\begin{aligned} |\tilde{f}(\omega'_1) - \tilde{f}(\omega'_2)| &= |f(\theta + \Sigma^{1/2} \omega'_1) - f(\theta + \Sigma^{1/2} \omega'_2)| \\ &\leq L \left\| \Sigma^{1/2} (\omega'_1 - \omega'_2) \right\| \leq L \lambda_{\max}(\Sigma^{1/2}) \|\omega'_1 - \omega'_2\| \end{aligned}$$

Since $\lambda_{\max}(\Sigma^{1/2}) = \sqrt{\lambda_{\max}(\Sigma)}$, this shows that \tilde{f} is Lipschitz with Lipschitz constant $\sqrt{\lambda_{\max}(\Sigma)}L$. The result now follows from theorem 3.3. From theorem 3.2, this implies that

$$\bar{g}(\theta) - \min_{\theta \in \mathcal{C}} \bar{g}(\theta) \leq \frac{\alpha L^2 \lambda_{\max}(\Sigma)}{2}.$$

□

4 ALGORITHMS AND CONVERGENCE GUARANTEES

In general, the expectations involved in (2) cannot be computed analytically. Thus, we need to resort to sampling based approaches in order to solve these problems. This has been studied extensively in recent years in the context of machine learning, where stochastic gradient methods and variants have been shown to be efficient, particularly in the context training machine learning algorithms with huge amounts of data. We now describe stochastic gradient methods for solving (2) and adapt the convergence guarantees of stochastic gradient methods to our setting.

4.1 Stochastic Gradient Methods with Convergence Guarantees

In this section, we will derive gradients of the convex objective function (2). We will assume that the function f is differentiable at all $\theta \in \mathbf{R}^k$. In order to get unbiased gradient estimates, we exponentiate the objective (2) to get:

$$\mathbf{G}(\theta) = \mathbb{E}_{\omega \sim \mathcal{N}(0, \Sigma)} \left[\exp \left(\alpha f(\theta + \omega) + \frac{\alpha}{2} \theta^T R \theta \right) \right].$$

Since $f(\theta)$ is differentiable for all θ , so is $\exp \left(\alpha f(\theta + \omega) + \frac{1}{2} \theta^T (\alpha R) \theta \right)$. Further, suppose that

$$\mathbb{E} \left[\exp \left(2\alpha f(\theta + \omega) \right) \|\nabla f(\theta + \omega) + R\theta\|^2 \right]$$

exists and is finite for each θ . Then, if we differentiate $\mathbf{G}(\theta)$ with respect to θ , we can interchange the expectation and differentiation to get

$$\mathbb{E} \left[\exp \left(\alpha f(\theta + \omega) + \frac{\alpha}{2} \theta^T R \theta \right) (\alpha \nabla f(\theta + \omega) + \alpha R \theta) \right]$$

Thus, we can sample $\omega \sim \mathcal{N}(0, \Sigma)$ and get an unbiased estimate of the gradient

$$\alpha \exp\left(\alpha f(\theta + \omega) + \frac{\alpha}{2} \theta^T R \theta\right) (\nabla f(\theta + \omega) + R\theta) \quad (5)$$

which we denote by $\hat{\nabla} \mathbf{G}(\theta, \omega)$. As in standard stochastic gradient methods, one saves on the complexity of a single iteration by using a single (or a small number of) samples to get a gradient estimate while still converging to the global optimum with high probability and in expectation, because over multiple iterations one moves along the negative gradient “on average”.

Algorithm 1 Stochastic Gradient Method for (2)

$\theta \leftarrow 0$
for $i = 1, \dots, T$ **do**
 $\omega \sim \mathcal{N}(0, \Sigma), \theta \leftarrow \text{Proj}_{\mathcal{C}}\left(\theta - \eta_i \hat{\nabla} \mathbf{G}(\theta, \omega)\right)$
end for

From standard convergence theory for stochastic gradient methods [Bubeck, 2013], we have:

Corollary 1. *Suppose that $\mathbb{E} \left[\left\| \hat{\nabla} \mathbf{G}(\theta, \omega) \right\|^2 \right] \leq \zeta^2$,*

\mathcal{C} is contained in a ball of radius $R(\mathcal{C})$ and $\alpha R \succeq \Sigma^{-1}$. Run algorithm 1 for T iterations with $\eta_i = \frac{R(\mathcal{C})}{\zeta} \sqrt{\frac{1}{2i}}$ and define $\hat{\theta} = \frac{1}{T} \sum_{i=1}^T \theta_i$, $\mathbf{G}^ = \text{argmin}_{\theta \in \mathcal{C}} \mathbf{G}(\theta)$. Then, we have*

$$\mathbb{E} \left[\mathbf{G}(\hat{\theta}) \right] - \mathbf{G}^* \leq R(\mathcal{C}) \zeta \sqrt{\frac{1}{2T}}$$

In the following theorem, we prove a convergence rate for algorithm 1.

Theorem 4.1. *Suppose that $R = \kappa I, \Sigma = \sigma^2 I, \alpha \kappa \succeq \frac{1}{\sigma^2}$, \mathcal{C} is contained in a sphere of radius $R(\mathcal{C})$ and that for all $\theta \in \mathcal{C}$ $\bar{g}(\theta) \leq \bar{m}$. Also, suppose that for some $\beta < (\alpha)^{-1}$:*

$$\frac{1}{2\alpha} \log \left(\mathbb{E}_{\omega \sim \mathcal{N}(0, \Sigma)} \left[\exp \left(2 \frac{\alpha \sigma^2}{\beta} \|\nabla f(\theta + \omega)\|^2 \right) \right] \right) \leq \gamma^2$$

Define $\delta = \sqrt{\frac{\beta \gamma^2}{\sigma^2(1-\alpha\beta)}} + \kappa R(\mathcal{C})$. Then, we can choose $\zeta \leq \alpha^2 \delta^2 \exp \left(2\alpha(\bar{m} + \gamma^2) + \frac{\alpha\beta}{1-\alpha\beta} - \sigma^2 \kappa \right)$.

Remark 2. The convergence guarantees are in terms of the exponentiated objective $\mathbf{G}(\theta)$. We can convert these into bounds on $\log(\mathbf{G}(\theta))$ as follows:

$$\mathbb{E} \left[\log \left(\mathbf{G}(\hat{\theta}) \right) \right] \leq \log \left(\mathbb{E} \left[\mathbf{G}(\hat{\theta}) \right] \right) \leq \log \left(\mathbf{G}^* + \frac{\zeta R(\mathcal{C})}{\sqrt{2T}} \right)$$

where the first inequality follows from concavity of the log function. Subtracting $\log(\mathbf{G}^*)$, we get

$$\mathbb{E} \left[\log \left(\mathbf{G}(\hat{\theta}) \right) \right] - \log(\mathbf{G}^*) \leq \log \left(1 + \frac{\zeta R(\mathcal{C})}{\sqrt{2T} \mathbf{G}^*} \right).$$

5 CONTROL PROBLEMS

In this section, we extend the above approach to the control of discrete-time dynamical systems. Stochastic optimal control of nonlinear systems in general is a hard problem and the only known general approach is based on dynamic programming, which scales exponentially with the dimension of the state space. Algorithms that approximate the solution of the dynamic program directly (approximate dynamic programming) have been successful in various domains, but scaling these approaches to high dimensional continuous state control problems has been challenging. In this section, we pursue the alternate approach of policy search or policy gradient methods [Baxter and Bartlett, 2001]. These algorithms have the advantage that they are directly optimizing the performance of a control policy as opposed to a surrogate measure like the error in the solution to the Bellman equation. They have been used successfully for various applications and are closely related to path integral control [Kappen, 2005, Theodorou et al., 2010b]. However, in all of these approaches, there were no guarantees made regarding the optimality of the policy that the algorithm converges to (even in the limit of infinite sampling) or the rate of convergence.

In this work, we develop the *first* policy gradient algorithms that achieve the *globally* optimal solutions to a class of *risk-averse* policy optimization problems.

5.1 Problem Setup

We deal with arbitrary discrete-time dynamical systems of the form

$$\begin{aligned} \boldsymbol{\epsilon} &= (\epsilon_1 \quad \dots \quad \epsilon_{N-1})^T \sim \mathbb{P}_{\boldsymbol{\epsilon}} \\ x_1 &= 0, \quad x_{t+1} = \mathcal{F}(x_t, y_t, \epsilon_t, t) \quad t = 1, \dots, N-1 \end{aligned} \quad (6)$$

$$y_t = u_t + \omega_t, \quad \omega_t \sim \mathcal{N}(0, \Sigma_t) \quad t = 1, \dots, N-1 \quad (7)$$

where $x_t \in \mathbf{R}^{n_s}$ denotes the state, $y_t \in \mathbf{R}^{n_u}$ the effective control input, $\epsilon_t \in \mathbf{R}^p$ external disturbances, $u_t \in \mathbf{R}^{n_u}$ the actual control input, $\omega_t \in \mathbf{R}^{n_u}$ the control noise, $\mathcal{F} : \mathbf{R}^{n_s} \times \mathbf{R}^{n_u} \times \mathbf{R}^p \times \{1, \dots, N-1\} \mapsto \mathbf{R}^{n_s}$ the discrete-time dynamics. In this section, we will use boldface to denote quantities stacked over time (like $\boldsymbol{\epsilon}$). Equation (6) can model any noisy discrete-time dynamical system, since \mathcal{F} can be any function of the current state, control input and external disturbance

(noise). However, we require that all the control dimensions are affected by Gaussian noise as in (7). This can be thought of either as real actuator noise or artificial exploration noise. The choice of zero initial state $x_1 = 0$ is arbitrary - our results even extend to an arbitrary distribution over the initial state.

We will work with costs that are a combination of arbitrary state costs and quadratic control costs:

$$\sum_{t=1}^N \ell_t(x_t) + \sum_{t=0}^{N-1} \frac{u_t^T R_t u_t}{2} \quad (8)$$

where $\ell_t(x_t)$ is the stage-wise state cost at time t . ℓ_t can be any bounded function of the state-vector x_t . Further, we will assume that the control-noise is non-degenerate, that is Σ_t is full rank for all $0 \leq t \leq N-1$. We denote $S_t = \Sigma_t^{-1}$. We seek to design feedback policies

$$u_t = K_t \phi(x_t, t), \phi: \mathbf{R}^{n_s} \times \{1, 2, \dots, N-1\} \mapsto \mathbf{R}^r \\ K_t \in \mathbf{R}^{n_u \times r} \quad (9)$$

to minimize the accumulated cost (8). We will assume that the features ϕ are fixed and we seek to optimize the policy parameters $\mathbf{K} = \{K_t : t = 1, 2, \dots, N-1\}$. The stochastic optimal control problem we consider is defined as follows:

$$\text{Minimize}_{\mathbf{K}} \mathbb{E}_{\epsilon, \omega_t} [\exp(\alpha \mathcal{L}(\mathbf{K}))]$$

$$\text{Subject to } x_1 = 0, x_{t+1} = \mathcal{F}(x_t, y_t, \epsilon_t, t)$$

$$y_t = u_t + \omega_t, u_t = K_t \phi(x_t, t)$$

$$\epsilon \sim \mathbb{P}_\epsilon, \omega_t \sim \mathcal{N}(0, \Sigma_t)$$

$$\mathcal{L}(\mathbf{K}) = \sum_{t=0}^N \ell_t(x_t) + \sum_{t=0}^{N-1} \frac{u_t^T R_t u_t}{2} \quad (10)$$

This is exactly the same as the formulation in Risk Sensitive Markov Decision Processes [Marcus et al., 1997], the only change being that we have explicitly separated the noise appearing in the controls from the noise in the dynamical system overall. In this formulation, the objective depends not only on the average behavior of the control policy but also on variance and higher moments (the tails of the distribution of costs). This has been studied for linear systems under the name of LEQG control [Speyer et al., 1974]. α is called the risk factor: Large positive values of α result in strongly risk-averse policies while large negative values result in risk-seeking policies. In our formulation, we will need a certain minimum degree of risk-aversion for the resulting policy optimization problem to be convex.

5.2 Convex Controller Synthesis

Theorem 5.1. *If $\alpha R_t \succeq (\Sigma_t)^{-1} = S_t$ for $t = 1, \dots, N-1$, then the optimization problem (10) is*

convex.

Proof. We first show that for a fixed ϵ , the quantity $\mathbb{E}_{\omega_t \sim \mathcal{N}(0, \Sigma_t)} [\exp(\alpha \mathcal{L}(\mathbf{K}))]$ is a convex function of \mathbf{K} . Then, by the linearity of expectation, so is the original objective. We can write down the above expectation (omitting the normalizing constant of the Gaussian) as:

$$\int \exp\left(-\sum_{t=1}^{N-1} \frac{1}{2} \|y_t - K_t \phi(x_t, t)\|_{S_t}^2 + \alpha \mathcal{L}(\mathbf{K})\right) dy$$

If we fix \mathbf{y}, ϵ , using (6), we can construct x_t for every $t = 1, \dots, N$. Thus, \mathbf{x} is a deterministic function of \mathbf{y}, ϵ and does not depend on \mathbf{K} . The term inside the exponential can be written as

$$-\frac{1}{2} \left(\sum_{t=1}^{N-1} \|y_t\|_{S_t}^2 \right) + \alpha \left(\sum_{t=1}^N \ell_t(x_t) \right) \\ + \sum_{t=1}^{N-1} \frac{1}{2} \text{tr} \left((K_t^T (\alpha R_t - S_t) K_t) \phi(x_t, t) \phi(x_t, t)^T \right) \\ - \sum_{t=1}^{N-1} y_t^T S_t \phi(x_t, t) K_t$$

The terms on the first line don't depend on \mathbf{K} . The function $(K_t^T (\alpha R_t - S_t) K_t)$ is convex in \mathbf{K} with respect to the semidefinite cone [Boyd and Vandenberghe, 2004] when $\alpha R_t - S_t \succeq 0$ and $\phi(x_t, t) \phi(x_t, t)^T$ is a positive semidefinite matrix. Hence the term on the second line is convex in \mathbf{K} . The term on the third line is linear in \mathbf{K} and hence convex. Since \exp is a convex and increasing function, the composed function (which is the integrand) is convex as well in \mathbf{K} . Thus, the integral is convex in \mathbf{K} . \square

We can add arbitrary convex constraints and penalties on \mathbf{K} without affecting convexity.

Corollary 2. *The problem*

$$\min_{\mathbf{K}} \mathbb{E}_{\epsilon \sim \mathbb{P}_\epsilon, \omega_t \sim \mathcal{N}(0, \Sigma_t)} [\exp(\alpha \mathcal{L}(\mathbf{K}))] \\ \text{Subject to} \quad (6), (7), \mathbf{K} \in \mathcal{C} \quad (11)$$

is a convex optimization problem for any arbitrary convex set $\mathcal{C} \subset \mathbf{R}^{n_u \times r \times (N-1)}$ if $\alpha R_t \succeq S_t \quad \forall t$.

6 NUMERICAL RESULTS

In this section, we present preliminary numerical results illustrating applications of the framework to various problems with comparisons to a simple baseline approach. These are not meant to be thorough numerical comparisons but simple illustrations of the power and applications of our framework.

6.1 BINARY CLASSIFICATION

We look at a problem of binary classification. Let y denote the actual label and \hat{y} denote the predicted label. We use the loss function

$$\ell(y, \hat{y}) = \begin{cases} -\infty & \text{if } y\hat{y} > 0 \\ 0 & \text{otherwise} \end{cases}.$$

This is a non-convex loss function (the logarithm of the standard 0-1 loss). We convexify this in the prediction \hat{y} using our approach:

$$\frac{1}{\alpha} \log \left(\mathbb{E} [\exp(\alpha \ell(y, \hat{y}))] \right) + \frac{(\hat{y})^2}{2\sigma^2}.$$

Plugging in $\hat{y} = \theta^T x$ where x is the feature vector, we get

$$\frac{1}{\alpha} \log \left(\mathbb{E}_{\omega \sim \mathcal{N}(0, \sigma^2)} [\exp(\alpha \ell(y, \theta^T x + \omega))] \right) + \frac{(\theta^T x)^2}{2\alpha\sigma^2}.$$

Plugging in the expression for ℓ gives

$$\frac{1}{\alpha} \log \left(\frac{1}{2} \operatorname{erfc} \left(\frac{y\theta^T x}{\sqrt{2}\sigma} \right) \right) + \frac{(\theta^T x)^2}{2\alpha\sigma^2}.$$

where erfc is the Gaussian error function. Given a dataset $\{(x_i, y_u)\}$, we can form the empirical risk-minimization problem with this convexified objective:

$$\sum_{i=1}^M \frac{1}{\alpha} \log \left(\frac{1}{2} \operatorname{erfc} \left(\frac{y^i \theta^T x^i}{\sqrt{2}\sigma} \right) \right) + \frac{(\theta^T x^i)^2}{2\alpha\sigma^2}$$

We can drop the α since it only scales the objective (this is a consequence of the fact that $\exp(\ell)$ is 0-1 valued and does not change on raising it to a positive power). Thus, we finally end up with

$$\frac{1}{M} \sum_{i=1}^M \left(\log \left(\frac{1}{2} \operatorname{erfc} \left(\frac{y^i \theta^T x^i}{\sqrt{2}\sigma} \right) \right) + \frac{(\theta^T x^i)^2}{2\sigma^2} \right).$$

The first term is a data-fit term (a smoothed version of the 0-1 loss) and the second term is a regularizer, although we penalize the prediction $\theta^T x$ rather than θ itself. If x are normalized and span all directions, by summing over the entire dataset we get something close to the standard Tikhonov regularization.

We compare the performance of our convexification-based approach with a standard implementation of a Support Vector Machine (SVM) [Chang and Lin, 2011]. We use the breast cancer dataset from [Bache and Lichman, 2013]. We compare the two algorithms on various train-test splits of the dataset (without using cross-validation or parameter tuning). For each split, we create a noisy version of the dataset by

adding Gaussian noise to the labels and truncating to $+1/-1$: $\hat{y}^i = \operatorname{sign}(y^i + \omega)$, $\omega \sim \mathcal{N}(0, \sigma^2)$. The accuracy of the learned classifiers on withheld test-data, averaged over 50 random train-test splits with label corruption as described above, are plotted as function of the noise level σ in figure 1. This is not a completely fair comparison since our approach explicitly optimizes for the worst case under Gaussian perturbations to the prediction (which can also be seen as a Gaussian perturbation to the label). However, as mentioned earlier, the purpose of these numerical experiments is to illustrate the applicability of our convexification approach to various problems so we do not do a careful comparison to robust variants of SVMs, which would be better suited to the setting described here.

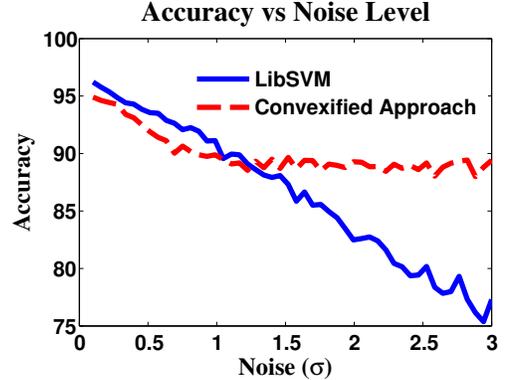

Figure 2: Binary Classification

6.2 CLASSIFICATION WITH NEURAL NETWORKS

We present an algorithm that does neural network training using the results of section 5. Each layer of the neural network is a time-step in a dynamical system, and the neural network weights correspond to the time-varying policy parameters. Let h denote a component-wise nonlinearity applied to its vector-input (a transfer function). The deterministic dynamics is

$$x_{t+1} = h(K_t x_t), x_0 = x$$

where x_t is the vector of activations at the t -th layer, K_t is the weight matrix and x is the input to the neural network. The output is x_N , where N is the number of layers in the network. The cost function is simply the loss function between the output of the neural network x_N and a desired output y : $\ell(y, x_N)$. To put this into our framework, we add noise to the input of the transfer function at each layer:

$$x_{t+1} = h(K_t x_t + \omega_t), x_1 = x, \omega_t \sim \mathcal{N}(0, \Sigma_t)$$

Additionally, we define the objective to be

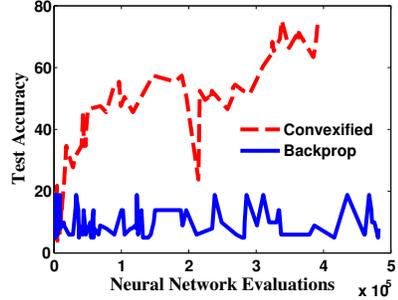

$$\mathbb{E} \left[\exp \left(\alpha \ell(y, x_N) + \sum_{t=1}^{N-1} \frac{\|K_t x_t\|_{\Sigma_{t-1}}^2}{2} \right) \right]$$

where the expectation is with respect to the Gaussian noise added at each layer in the network. Note that the above objective is a function of \mathbf{K}, x, y . The quadratic penalty on $K_t x_t$ can again be thought of as a particular type of regularization which encourages learning networks with small internal activations. We add this objective over the entire dataset $\{x^i, y^i\}$ to get our overall training objective.

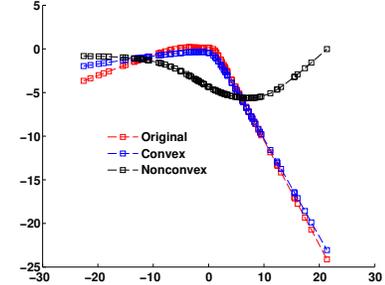

We evaluate this approach on a small randomly selected subset of the MNIST dataset [LeCun et al., 1998]. We use the version available at <http://nicolas.le-roux.name/> along with the MATLAB code provided for training neural networks. We use a 2-layer neural network with 20 units in the hidden layer and tanh-transfer functions in both layers. We use a randomly chosen collection of 900 data points for training and another 100 data points for validation. We compare training using our approach with simple backprop based training. Both of the approaches use a stochastic gradient - in our approach the stochasticity is both in selection of the data point i and the realization of the Gaussian noise ω while in standard backprop the stochasticity is only in the selection of i . We plot learning curves (in terms of generalization or test error) for both approaches, as a function of the number of neural network evaluations (forward+back prop) performed by the algorithm in figure 3a. The nonconvex approach based on standard backprop-gradient descent gets stuck in a local minimum and does not improve test accuracy much. On the other hand, the convexified approach is able to learn a classifier that generalizes better. We also compared backprop with training a neural network on a 1-dimensional regression problem where the red curve represents the original function with data-points indicated by squares, the blue curve the reconstruction learned by our convexified training approach and the black curve the reconstruction obtained by using backprop (figure 3b). Again, backprop gets stuck in a bad local minimum while our approach is able to find a fairly accurate reconstruction.

7 CONCLUSION AND FUTURE WORK

We have developed a general framework for convexifying a broad class of optimization problems, analysis that relates the solution of the convexified problem to the original one and given algorithms with convergence rate guarantees to solve the convexified problems. Ex-

(a) Classification

(b) Regression

Figure 3: Training Neural Networks

tending the framework to dynamical systems, we derive the first approach to policy optimization with optimality and convergence rate guarantees. We validated our approach numerically on problems of binary classification and training neural networks. In future work, we will refine the suboptimality analysis for our convexification approach. Algorithmically, stochastic gradient methods could be slow if the variance in the gradient estimates is high, which is the case when using the exponentiated objective (as in section 4). We will study the applicability of recent work on using better sampling algorithms with stochastic gradient [Atchade et al., 2014] to our convexified problems.

APPENDIX

Corollary 3. [Boucheron et al., 2013], corollary 4.15 Let P, Q are arbitrary distributions on some space Ω and $f : \Omega \rightarrow \mathbf{R}$ is such that $\mathbb{E}_{\omega \sim P} [\exp(f(\omega))] < \infty$. Then, the Kullback-Leibler divergence satisfies:

$$\text{KL}(Q \parallel P) = \sup_f \left[\mathbb{E}_{\omega \sim Q} [f(\omega)] - \log \left(\mathbb{E}_{\omega \sim P} [\exp(f(\omega))] \right) \right]$$

7.1 PROOF OF THEOREM 4.1

Throughout this section, Let $\tilde{\alpha} = 2\alpha$ and P denote the Gaussian density $\mathcal{N}(0, \Sigma)$. Define a new distribution Q with density $Q(\omega) \propto P(\omega) \exp(\tilde{\alpha} \tilde{f}_\omega(\theta))$. We denote $\hat{\nabla} \mathbf{G}(\theta, \omega)$ by $\hat{\nabla} \mathbf{G}$, $\nabla f(\theta + \omega)$ by $\hat{\nabla} f$ and

$\nabla f(\theta + \omega) + \kappa\theta$ by $\tilde{\nabla}f$ for brevity. Expectations are always with respect to $\omega \sim P$, unless denoted otherwise.

Proof. $(\alpha)^{-2} \mathbb{E} \left[\left\| \hat{\nabla} \mathbf{G} \right\|^2 \right]$ evaluates to

$$\begin{aligned} & \exp(\alpha\kappa\theta^T\theta) \mathbb{E} \left[\exp(\tilde{\alpha}f(\omega + \theta)) \left\| \tilde{\nabla}f \right\|^2 \right] = \\ & \exp\left(\tilde{\alpha} \left(\frac{\kappa}{2} \theta^T \theta + \bar{f}(\theta) \right)\right) \mathbb{E} \left[\exp(\tilde{\alpha}\tilde{f}_\omega(\theta)) \left\| \tilde{\nabla}f \right\|^2 \right] = \\ & \exp\left(\tilde{\alpha} \left(\bar{g}(\theta) - \frac{1}{2} \sigma^2 \kappa \right)\right) \mathbb{E} \left[\exp(\tilde{\alpha}\tilde{f}_\omega(\theta)) \left\| \tilde{\nabla}f \right\|^2 \right] \end{aligned} \quad (12)$$

By the theorem hypotheses, the term outside the expectation is bounded above by $\alpha^2 \exp(2\alpha\bar{m} - \sigma^2\kappa)$. We are left with

$$\mathbb{E} \left[\exp(\tilde{\alpha}\tilde{f}_\omega(\theta)) \left\| \tilde{\nabla}f \right\|^2 \right].$$

Dividing this by $\mathbb{E} \left[\exp(\tilde{\alpha}\tilde{f}_\omega(\theta)) \right]$, we get

$$\frac{\mathbb{E} \left[\exp(\tilde{\alpha}\tilde{f}_\omega(\theta)) \left\| \tilde{\nabla}f \right\|^2 \right]}{\mathbb{E} \left[\exp(\tilde{\alpha}\tilde{f}_\omega(\theta)) \right]} = \mathbb{E}_{\omega \sim Q} \left[\left\| \tilde{\nabla}f \right\|^2 \right]. \quad (13)$$

Expanding $\left\| \tilde{\nabla}f \right\|^2$, we get

$$\begin{aligned} & \left\| \hat{\nabla}f \right\|^2 + \kappa^2 \|\theta\|^2 + 2\hat{\nabla}f^T \theta \\ & \leq \left\| \hat{\nabla}f \right\|^2 + \kappa^2 \mathbf{R}(\mathcal{C})^2 + 2\kappa \left\| \hat{\nabla}f \right\| \mathbf{R}(\mathcal{C}) \end{aligned}$$

Finally from lemma 1, we have

$$\mathbb{E}_{\omega \sim Q} \left[\left\| \hat{\nabla}f \right\|^2 \right] \leq \frac{\beta\gamma^2}{\sigma^2(1-\alpha\beta)}$$

and by concavity of the square-root function,

$$\mathbb{E}_{\omega \sim Q} \left[\left\| \hat{\nabla}f \right\| \right] \leq \sqrt{\frac{\beta\gamma^2}{\sigma^2(1-\alpha\beta)}}.$$

Plugging this bounds into the square expansion and letting $\delta = \sqrt{\frac{\beta\gamma^2}{\sigma^2(1-\alpha\beta)}} + \kappa\mathbf{R}(\mathcal{C})$, we get

$$\mathbb{E}_{\omega \sim Q} \left[\left\| \nabla f(\theta + \omega) + \kappa\theta \right\|^2 \right] \leq \delta^2 \quad (14)$$

From (12),(13) and (14), $\mathbb{E} \left[\left\| \hat{\nabla} \mathbf{G} \right\|^2 \right]$ is smaller than

$$\alpha^2 \exp(2\alpha\bar{m} - \sigma^2\kappa) \delta^2 \mathbb{E} \left[\exp(\tilde{\alpha}\tilde{f}_\omega(\theta)) \right]$$

Finally, by the last part of theorem 3.3,

$$\mathbb{E} \left[\exp(\tilde{\alpha}\tilde{f}_\omega(\theta)) \right] \leq \exp\left(\frac{\alpha\beta}{1-\alpha\beta} + 2\alpha\gamma^2\right).$$

Combining the two above results gives the theorem. \square

lemma 1. *Under the assumptions of theorem 4.1,*

$$\mathbb{E}_{\omega \sim Q} \left[\sigma^2 \left\| \nabla f(\theta + \omega) \right\|^2 \right] \leq \frac{\beta\gamma^2}{1-\alpha\beta} \quad (15)$$

Proof. The KL-divergence between Q and P is given by

$$\int \frac{P(\omega) \exp(\tilde{\alpha}\tilde{f}_\omega(\theta))}{\mathbb{E} \left[\exp(\tilde{\alpha}\tilde{f}_\omega(\theta)) \right]} \log \left(\frac{\exp(\tilde{\alpha}\tilde{f}_\omega(\theta))}{\mathbb{E} \left[\exp(\tilde{\alpha}\tilde{f}_\omega(\theta)) \right]} \right) d\omega.$$

By theorem 3.3 applied to $\exp(\frac{\tilde{\alpha}}{2}f(\theta + \omega))$, the above quantity is bounded above by $\frac{1}{2}(\tilde{\alpha}\sigma)^2 \mathbb{E}_{\omega \sim Q} \left[\left\| \hat{\nabla}f \right\|^2 \right]$. Then, by corollary 3,

$$\begin{aligned} \text{KL}(Q \parallel P) & \geq \mathbb{E}_{\omega \sim Q} \left[\frac{\tilde{\alpha}\sigma^2}{\beta} \left\| \hat{\nabla}f \right\|^2 \right] \\ & \quad - \log \left(\mathbb{E} \left[\exp \left(\frac{\tilde{\alpha}\sigma^2}{\beta} \left\| \hat{\nabla}f \right\|^2 \right) \right] \right). \end{aligned}$$

Denote the second term in the RHS by Γ . Plugging in the upper bound on $\text{KL}(Q \parallel P)$, we get

$$\Gamma \geq \sigma^2 \left(\frac{\tilde{\alpha}}{\beta} - \frac{\tilde{\alpha}^2}{2} \right) \mathbb{E}_{\omega \sim Q} \left[\left\| \nabla f(\theta + \omega) \right\|^2 \right].$$

Since the LHS is upper bounded by $\tilde{\alpha}\gamma^2$ (hypothesis of theorem) which gives us the bound

$$\mathbb{E}_{\omega \sim Q} \left[\sigma^2 \left\| \nabla f(\theta + \omega) \right\|^2 \right] \leq \frac{2\beta\gamma^2}{2-\tilde{\alpha}\beta} = \frac{\beta\gamma^2}{1-\alpha\beta}.$$

\square

Abstract

Learning the association between observed variables and future trajectories of continuous-time stochastic processes is a fundamental task in dynamic modeling. Often the dynamics are non-homogeneous and involve a large number of interacting components. We introduce a conditional probabilistic model that captures such dynamics, while maintaining scalability and providing an explicit way to express the interrelation between the system components. The principal idea is a factorization of the model into two distinct elements: one depends only on time and the other depends on the system configuration. We developed a learning procedure, given either full or point observations, and tested it on simulated data. We applied the proposed modeling scheme to study large cohorts of diabetes and HIV patients, and demonstrate that the factorization helps shed light on the dynamics of these diseases.

1 INTRODUCTION

Studies of dynamic systems often attempt to investigate the dependency of these dynamics on a set of static explanatory variables. In many cases, the studied process is composed of interrelated components that evolve continuously in time; hence, inter-component interactions are of interest as well. Examples appear in diverse fields, ranging from medicine to computational biology and economics.

Inferring such conditional dynamics of a real life system involves several challenges. We illustrate these challenges by our motivating example of studying disease progression in patients infected with *Human Immunodeficiency Virus*

* Currently at: The Selim and Rachel Benin School of Computer Science and Engineering. The Hebrew University of Jerusalem.

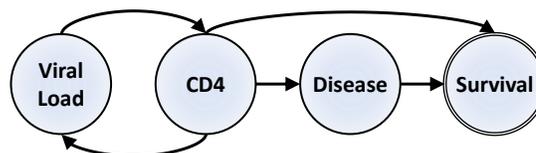

Figure 1: A graphical representation of a SCUP model for HIV. Directed arcs indicate directions of influence.

(HIV). The two common measures of the severity of HIV infection, viral load and the immune system CD4 protein count, are interrelated. A higher viral load weakens the immune system, while a weakened immune system potentially affects viral dynamics. A weakened immune system also increases the risk of death, either directly or by increasing the risk of contracting other diseases. These dynamics are depicted in Figure 1.

The typical properties of dynamic processes are a non-constant states transition rate (*non-homogeneity*), and the ability to observe the process states at only a finite set of time-points (*point observations*). Additionally, the processes may include highly diverse explanatory variables whose distribution is often difficult to learn. For example, this might include the type of drugs taken by each individual and their viral genome at that time. Due to these properties, a modeling framework for such processes should account for non-homogeneity, deal with point observations, be scalable in the number of components, and provide a robust way to account for observed explanatory variables without modeling their distribution.

The seminal work of (Cox, 1972) laid the foundations for rigorous analysis of the dynamics of non-homogeneous irreversible processes by introducing the *proportional hazard model*. A key point of this model is its focus on modeling the dynamics of a single binary-valued variable *conditioned* on some set of background variables. The proportional hazard framework proposed by Cox turned out to be extremely useful in modeling processes such

as survival after medical procedures, how specific drugs affect a disease, the failure of manufactured components, and many more.

In recent years, several extensions of this model have been proposed (e.g., (Du et al., 2013)). One notable extension of the Cox model is Multi-State models (MSTMs), which model single component processes that can occupy one of a finite number of states at each time point (Putter et al., 2007). MSTMs support non-homogeneity and learning from point observations, and allow us to condition the dynamics on explanatory variables, resolving the difficulties in explicitly modeling covariates.

MSTMs are increasingly being used in medical and epidemiological studies (e.g., (Looker et al., 2013; Walker et al., 2013; Taghipour et al., 2013)). Nevertheless, MSTMs are not naturally suited for analyzing multi-component processes, because they require defining a state space corresponding to the Cartesian product of the individual components, resulting in a representation that is exponential in the number of components.

In this paper we consider modeling the conditional distribution of a non-homogeneous multi-dimensional continuous-time Markov process $\mathbf{Y}(t) = Y_1(t), \dots, Y_n(t)$ given a set of covariates $\mathbf{x} \in R^p$, which we refer to as background covariates. Our goal is to construct a modeling language that is compact, interpretable, and scalable, meaning that it allows learning dependencies of specific components on specific covariates as well as on other components, while allowing efficient inference and learning.

A Continuous-Time Bayesian Network (CTBN) (Nodelman et al., 2002), the continuous-time extension of a dynamic Bayesian network, is a framework that enables the modeling of high-dimensional processes with complex dependencies; these dependencies are expressed via an interpretable network topology. CTBNs naturally deal with missing data, using exact inference for small topologies, and a variety of approximate methods for large topologies. Therefore, the principles that underlie CTBNs can serve as a basis to scale up MSTMs, by introducing structured representation and accompanying mathematical machinery from CTBNs.

In this work, we define StruCTured proportional jUmP Processes (SCUP), a new model combining ideas from the fields of proportional hazard models, MSTMs, and CTBNs. Our key modeling assumption decomposes the dynamics of the process into two elements. The first element is the *effect of time* on the dynamics of each individual component, independently of the others. The second element represent the dependence of the *evolution of each component* on the background covariates, as well as on the state of the other components. This decomposition allows a compact representation of

the combined effect of non-homogeneity, background variables, and interactions among components. We show how this model can be learned from point observations and demonstrate the properties of our approach on synthetic data, as well as on large cohorts of data from diabetes and HIV patients. Our analysis helps identify reliable markers that may predispose diabetes and HIV patients to medical complications. Namely, we find that routine blood tests can serve as a biomarker for an increase in glycated hemoglobin, which is a highly reliable marker for complications among diabetes patients.

2 BACKGROUND

A multi-component continuous-time stochastic process over a discrete state space is a collection of vector-valued random variables $\{\mathbf{Y}(t) = Y_1(t), \dots, Y_n(t) | t \geq 0\}$ where for each component i , $Y_i(t)$ takes on values from a finite set S_i . We say that such a process is *Markovian* if, for all sequences $t_1 \leq t_2 \leq \dots \leq t_k$, it satisfies

$$\begin{aligned} \Pr(\mathbf{Y}(t_k) = \mathbf{y}_k | \mathbf{Y}(t_{k-1}) = \mathbf{y}_{k-1}, \dots, \mathbf{Y}(t_1) = \mathbf{y}_1) \\ = \Pr(\mathbf{Y}(t_k) = \mathbf{y}_k | \mathbf{Y}(t_{k-1}) = \mathbf{y}_{k-1}) \end{aligned}$$

Continuous time Markov processes are completely characterized by the rate function $q(t; \mathbf{y}, \mathbf{y}')$, which determines the instantaneous transition probability between states:

$$\Pr(\mathbf{Y}(t+\Delta t) = \mathbf{y}' | \mathbf{Y}(t) = \mathbf{y}) = 1_{\mathbf{y}=\mathbf{y}'} + q(t; \mathbf{y}, \mathbf{y}')\Delta t + o(\Delta t) \quad (1)$$

where 1 is the indicator function and $o(\Delta t)$ is a function that converges to zero faster than its argument, i.e., $\lim_{\Delta t \downarrow 0} \frac{o(\Delta t)}{\Delta t} = 0$. The rate functions are non-negative for every $\mathbf{y} \neq \mathbf{y}'$. The diagonal elements $q(t; \mathbf{y}, \mathbf{y})$ are the exit rates from state \mathbf{y} at time t that satisfy $q(t; \mathbf{y}, \mathbf{y}) = -\sum_{\mathbf{y}' \neq \mathbf{y}} q(t; \mathbf{y}, \mathbf{y}')$. A Markov jump process is *homogeneous* if the rates do not depend on time, i.e., $q(t; \mathbf{y}, \mathbf{y}') = q_{\mathbf{y}, \mathbf{y}'}$, otherwise it is *non-homogeneous*.

Continuous time Bayesian networks (CTBNs) provide a compact representation for homogeneous Markov processes where only one component can change at a time, and where the instantaneous dynamics of each component i are influenced by a small set of parent components denoted by $pa(i)$. We refer to $pa(i)$ as the *context* of the component i . These assumptions are encoded by setting $q(t; \mathbf{y}, \mathbf{y}') = 0$ when \mathbf{y} and \mathbf{y}' differ by more than one component, and $q(t; \mathbf{y}, \mathbf{y}') = q_{y_i, y'_i | \mathbf{y}_{pa(i)}}$ when they differ in component i , where y_i and $\mathbf{y}_{pa(i)}$ are the states of component i and of the subset $pa(i)$, respectively. This dependency structure is represented by a directed graph \mathbf{G} over the nodes labeled $1 \dots n$, where the parents of node i are $pa(i)$. We note that the graph G need not be a DAG. In recent years, several approximate methods that exploit this structured representation have been developed (Saria et al.,

2007; Cohn et al., 2010; El-Hay et al., 2010; Celikkaya et al., 2011; Rao and Teh, 2011b; Opper and Sanguinetti, 2007).

3 STRUCTURED PROPORTIONAL JUMP PROCESSES

Consider a system of interacting components with two additional characteristics: (1) The dynamics of each component depends on a set of background variables $\mathbf{x} \in R^P$; and (2) Transition rates are non-homogeneous. This work deals with modeling and learning the interactions between the components as well as the relation between the background variable \mathbf{x} and the dynamics of the system represented by $\mathbf{Y}(t)$. As in regression and conditional models, the distribution of the background covariates \mathbf{x} will not be modeled.

Assuming Markovian dynamics, such systems are characterized by a conditional rate function $q(t; \mathbf{y}, \mathbf{y}' | \mathbf{x})$. To model this rate in a compact manner we first assume that, as in CTBNs, \mathbf{Y} has local dynamics, namely is governed by conditional rate functions for all $\mathbf{y} \neq \mathbf{y}'$:

$$q(t; \mathbf{y}, \mathbf{y}' | \mathbf{x}) \equiv q^i(t; y_i, y'_i | \mathbf{y}_{pa(i)}, \mathbf{x}) \cdot \mathbf{1}_{\{j: y_j \neq y'_j\} = \{i\}}.$$

Next, we need to capture the dependency of these dynamics on both time and covariates. To do this, we decompose the rate into two elements: the dependence on time and the joint dependence on context and background variables.

The effect of the time on the transition is captured by the notion of the *baseline rate*. For each component i and pair of states y_i to y'_i , we denote by $r_{y_i, y'_i}^i(t)$ the non-negative time dependent functions. The effect of the joint state of the covariates \mathbf{x} and the context $\mathbf{y}_{pa(i)}$ is mediated through a set of weight vectors $\mathbf{w}_{y_i, y'_i}^i \in R^N$. Combining these elements, we define the conditional transition of the SCUP model:

$$q^i(t; y_i, y'_i | \mathbf{y}_{pa(i)}, \mathbf{x}) \equiv r_{y_i, y'_i}^i(t) \cdot \exp\{\mathbf{w}_{y_i, y'_i}^i \cdot \phi^i(\mathbf{x}, \mathbf{y}_{pa(i)})\}, \quad (2)$$

where $\phi^i(\mathbf{x}, \mathbf{y}_{pa(i)})$ is a mapping of the covariates and parent states into an N -dimensional feature vector (where in general N could depend on i). This representation does not explicitly specify the dependency structure of the components on \mathbf{x} because it does not have a significant effect on the inference computational complexity, as shown in Section 4. Note that the time-dependent effect is common to the entire population, meaning that it does not depend on the covariates \mathbf{x} and $\mathbf{y}_{pa(i)}$. On the other hand, the covariates, as well as the parent components, modulate the transition rate between states y_i and y'_i through the second element, independently of time.

To gain some insight into the assumptions encoded in this model, we consider three examples. First, we note that

by setting the baseline rates to a constant value, removing the background variables, and setting ϕ^i to be a vector of indicators of the parents' joint state, we obtain a CTBN.

The second example is the *Cox proportional hazard model* (Cox, 1972). This model has a single binary outcome Y where $Y = 1$ represents a base state and $Y = 0$ represents a terminal *failure* state such as death. The rates in such a system are:

$$q(t; 1, 0 | \mathbf{x}) \equiv r_0(t) e^{\mathbf{w} \cdot \mathbf{x}} \quad \text{and} \quad q(t; 0, 1 | \mathbf{x}) \equiv 0, \quad (3)$$

where $r_0(t)$ is the baseline rate. In this model $q(t; 1, 0 | \mathbf{x})$ is called the *hazard function* and the probability of surviving for a time greater than t is

$$\Pr(Y(t) = 1 | \mathbf{x}, Y(0) = 1) = e^{-\int_0^t q(s; 1, 0 | \mathbf{x}) ds}.$$

In case the baseline is constant, the survival time distribution is exponential. A monomial baseline, $r_0(t) = \lambda k (\lambda t)^{k-1}$, gives a Weibull distribution. A common approach is to model the baseline in a non-parametric manner (see the seminal work of (Kaplan and Meier, 1958)).

The Cox model encapsulates an assumption that the failure rate proportion for two individuals with attributes \mathbf{x}_1 and \mathbf{x}_2 is time invariant as $q(t; 1, 0 | \mathbf{x}_1) / q(t; 1, 0 | \mathbf{x}_2) = e^{\mathbf{w} \cdot (\mathbf{x}_1 - \mathbf{x}_2)}$. This approach is generalized in *multi-state models* (Putter et al., 2007), which involve a single component and define $q(y, y' | \mathbf{x}; t) = r_{y, y'}(t) e^{\mathbf{w}_{y, y'} \cdot \mathbf{x}}$, resulting in a proportion of $e^{\mathbf{w}_{y, y'} \cdot (\mathbf{x}_1 - \mathbf{x}_2)}$.

The proportionality assumption in SCUP is conditional, that is, if we fix $\mathbf{Y}_{pa(i)}(t) = \mathbf{y}_{pa(i)}$ the proportion between conditional rates is

$\exp\{\mathbf{w}_{y_i, y'_i}^i \cdot (\phi^i(\mathbf{x}_1, \mathbf{y}_{pa(i)}) - \phi^i(\mathbf{x}_2, \mathbf{y}_{pa(i)}))\}$ for all t . However, the proportion of the actual marginal rate of moving from y_i to y'_i is time dependent because it is marginalized with time dependent weights, $\Pr(\mathbf{Y}_{pa(i)}(t) | \mathbf{x})$. A time invariance property also holds for proportions between transition rates that are conditioned on two different parent assignments for a fixed \mathbf{x} .

The third example deals with an HIV patient model, as shown in Figure 1. The proposed model contains components corresponding to the viral load (VL), CD4 concentration, the status of a certain disease of interest, and an absorbing survival component. The model topology encodes the assumption that the VL and CD4 components affect each other directly, whereas the effect of VL on survival is mediated through CD4 and the disease.

As a concrete example, the disease state space can be {"none", "mild", "severe"}, with the possible transitions "none" \leftrightarrow "mild", and "mild" \leftrightarrow "severe", and the CD4 state space can be {"high", "low"}. The CD4 \rightarrow disease arc encodes a parameter for each combination of the CD4 level and one of the four disease transitions. Notably, the

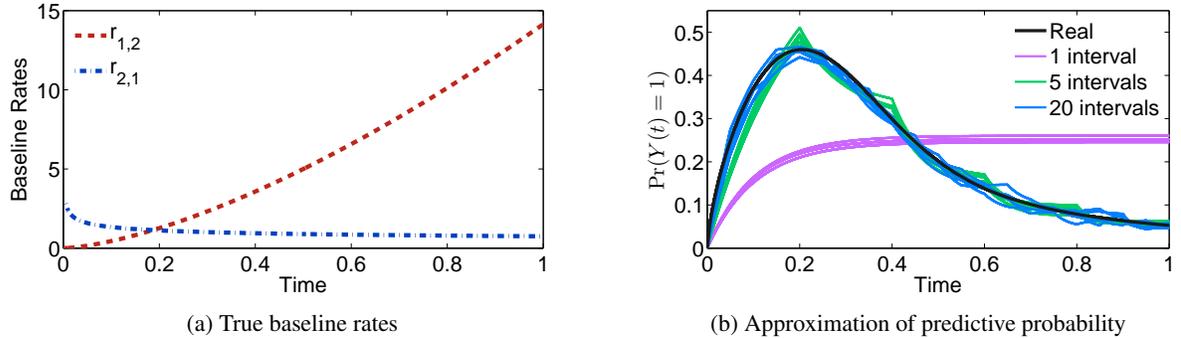

Figure 2: A Piecewise linear approximation for a non-homogeneous process.

ratio between the transition rates given CD4=“high” and given CD4=“low” is time independent, and determined solely according to the mapping $\phi^{disease}(CD4)$ and the parameters $w^{disease}$ for each transition.

3.1 REPRESENTATION OF BASELINE RATES

Time dependent baseline rates can either be represented non-parametrically as in the classical Cox model, or assume a parametric representation. Examples include Weibull hazard function $r(t) = \lambda k(\lambda t)^{k-1}$, log-logistic hazard, $r(t) = \frac{\lambda k t^{k-1}}{1 + \lambda t^k}$ and more. In this work we will adopt a piecewise constant representation, which can approximate well behaved processes with a high degree of accuracy.

To characterize such processes, we consider single-component models with a time-dependent state $Y(t)$ (every model can be represented as a single-component model whose state space is the Cartesian product of the components state spaces). Denote by $\mathbf{P}^{\mathbf{Q}}(s, t)$ the transition matrix whose y, y' entry is $\Pr(Y(t) = y | Y(s) = y')$, and by $\mu_y^{\mathbf{Q}}(t) \equiv \Pr^{\mathbf{Q}}(Y(t) = y)$ the time-dependent marginal probability. We say that a matrix \mathbf{P} is embeddable if there exists a matrix \mathbf{A} such that $\mathbf{P} = e^{\mathbf{A}}$. Let $\tau_0 < \tau_1 < \dots < \tau_K$ be an ordered set of time points, and suppose that $\mathbf{P}^{\mathbf{Q}}(\tau_{k-1}, \tau_k)$ is embeddable for every $k = 1, \dots, K$. From the Markov property, it follows that there exists a piecewise constant rate matrix function $\hat{\mathbf{Q}}(t) = \mathbf{Q}_k, \forall \tau_{k-1} \leq t < \tau_k$ that satisfies $\mu_y^{\mathbf{Q}}(\tau_k) = \mu_y^{\hat{\mathbf{Q}}}(\tau_k)$. Moreover, the following lemma bounds the error for rate matrices with bounded transition rates:

Lemma 3.1: *Let $Y(t)$ be a non-homogeneous process with bounded transition rates $\mathbf{Q}(t)$ and an embeddable rate matrix. Denote $\rho_k = \max_{y, \tau_{k-1} \leq t < \tau_k} |q_{y,y}(t)|$, $\hat{\rho}_k = \max_y |\hat{q}_{y,y}|$. Then, for all y and $\tau_{k-1} \leq t \leq \tau_k$, $|\mu_y^{\mathbf{Q}}(t) - \mu_y^{\hat{\mathbf{Q}}}(t)| < (\rho + \hat{\rho}) \cdot (\tau_k - \tau_{k-1})$.*

This lemma, proven in the appendix, suggests that the

number of intervals required to bound the bias by ϵ scales inversely linear with $1/\epsilon$. We note that tight approximations exist in the case of non-embeddable processes (Davies, 2010).

As an example, consider a two state model with time dependent baseline rates depicted in Figure 2a. This process induces a non-monotone marginal probability $\mu_1^{\mathbf{Q}}(t)$ given an initial condition $Y(0) = 2$, as shown by the smooth black line in Figure 2b. The initial rise follows from the relation $r_{2,1}(t) > r_{1,2}(t)$, and the subsequent decline from the opposite relation. The colored lines show estimated probabilities given by piecewise constant models with 1, 5 and 20 intervals of constant rates that were trained on 1000 simulated trajectories.

4 LEARNING

Generally, training data may include a mixture of point observations on some components and full (complete) trajectories of others. For example CD4 and viral load are point observations measured periodically, whereas time of death is usually exactly recorded resulting in a continuous observation on survival. To learn from such data, we will adapt the approach taken for CTBNs, which handles unseen state trajectories between observations as missing data and employs Expectation Maximization (EM). The first step is to derive the likelihood of the model given complete trajectories.

4.1 LIKELIHOOD FUNCTION

A fully observed trajectory is represented using the sequence t_0, \dots, t_M and states y_0, \dots, y_{M-1} such that $Y(t) = y_k$ for $t \in [t_k, t_{k+1})$. We denote such a trajectory by $y_{[0, t_M]}$. The likelihood of a non-homogeneous process

with a set of rates $\mathcal{M} = \{q(t; y, y')\}_{y, y'}$ is

$$l(\mathcal{M}|y_{[0, t_M]}) = \exp \left\{ \int_{t_{M-1}}^{t_M} q(t; y_{M-1}, y_{M-1}) dt \right\} \quad (4)$$

$$\cdot \prod_{k=0}^{M-2} \left[\exp \left\{ \int_{t_k}^{t_{k+1}} q(t; y_k, y_k) dt \right\} q(t_{k+1}; y_k, y_{k+1}) \right]$$

where $q(t; \mathbf{y}, \mathbf{y}) = -\sum_{y' \neq y} q(t; y, y')$.

Let \mathcal{D} be a data set that includes pairs of trajectories $y^{[c]}$ and covariates \mathbf{x}_c , where $c = 1, \dots, N_{\text{sequences}}$ and denote by $ll(\mathcal{M}|\mathcal{D})$ be the log-likelihood.

The log-likelihood is unbounded if there are no constraints on the baseline rate functions. Consider for example the survival model described in Equation 3, and suppose that no background variable is involved. In this case,

$$ll(r_0(t)|\mathcal{D}) = \sum_c \left[-\int_0^{t_c} r_0(t) dt + \log r_0(t_c) \right].$$

One can construct a series of baseline rates such that this term approaches infinity as $r_0(t) = \sum_c a_c \delta(t - t_c)$, implying that a naive maximum likelihood procedure tends to overfit $r_0(t)$ to a function that imposes transitions at the observed times if no constraints are put in place. An alternative approach for non-parametric estimation of a possibly arbitrary baseline is to use partial-likelihood (Cox, 1972, 1975). However, this direction does not generalize naturally to partially observed data. Two possible approaches for placing constraints use either a restricted parametric form or regularized baseline.

4.2 PARTIALLY OBSERVED DATA

To deal with partially observed data, we perform an EM procedure. On each iteration we compute the expected log-likelihood of a new model with respect to the posterior distribution of the current model \mathcal{M}_0 . The posterior distribution of a Markov process \mathcal{M}_0 given a sequence σ_c is characterized by a set of time-dependent functions (Cohn et al., 2010)

$$\mu_y(t|c) = \Pr(Y(t) = y|c, \mathcal{M}_0)$$

$$\gamma_{y, y'}(t|c) = \lim_{\Delta t \rightarrow 0} \frac{\Pr(Y(t) = y, Y(t + \Delta t) = y'|c, \mathcal{M}_0)}{\Delta t}$$

$\mu_y(t|c)$ is the singleton probability that the process is in state y at time t . $\gamma_{y, y'}(t|c)$ is the *intensity* of the pairwise probability of being in state y and then moving to y' at time t .

Using this characterization, taking the expectation on the log of the likelihood function in Equation 4 and plugging in the decomposition of the conditional intensities depicted

in Equation 2, gives the expected log-likelihood of a multi-component model:

$$E_{\mathcal{M}_0}[ll(\mathcal{M}, \mathcal{D})] = \sum_c \sum_{y_i, \mathbf{y}_{pa(i)}} \sum_{y'} \quad (5)$$

$$\left[-\exp\{\mathbf{w}_{y_i, y'_i}^i \cdot \phi^i(\mathbf{x}_c, \mathbf{y}_{pa(i)})\} \int_t \mu_{y_i, \mathbf{y}_{pa(i)}} r_{y_i, y'_i}^i dt \right.$$

$$\left. + \int_t \gamma_{y_i, y'_i | \mathbf{y}_{pa(i)}} \left(\log r_{y_i, y'_i}^i + \mathbf{w}_{y_i, y'_i}^i \cdot \phi^i(\mathbf{x}_c, \mathbf{y}_{pa(i)}) \right) dt \right]$$

where we omit t and c from μ , γ and r , $\mu_{y_i, \mathbf{y}_{pa(i)}}$ is the marginalization of the posterior distribution to the subset of components $i, pa(i)$, and similarly $\gamma_{y_i, y'_i | \mathbf{y}_{pa(i)}} = \sum_{\{\hat{\mathbf{y}} | \hat{y}_i = y_i, \hat{\mathbf{y}}_{pa(i)} = \mathbf{y}_{pa(i)}\}} \gamma_{\hat{\mathbf{y}}, \{\hat{\mathbf{y}} \setminus i, y'_i\}}$ is a marginalization of pairwise probability intensities. Additional details are given in the Appendix. An exact computation of these functions and their integrals is feasible for systems with a small number of components. Otherwise, a variety of approximate methods are available (Saria et al., 2007; Cohn et al., 2010; El-Hay et al., 2010; Celikkaya et al., 2011; Rao and Teh, 2011b; Opper and Sanguinetti, 2007).

4.3 OPTIMIZATION

The gradient of the log-likelihood with respect to \mathbf{w} is:

$$\frac{\partial E_{\mathcal{M}_0}[ll(\mathcal{M}, \mathcal{D})]}{\partial \mathbf{w}_{y_i, y'_i}^i} =$$

$$\sum_c \sum_{\mathbf{y}_{pa(i)}} \phi^i(\mathbf{x}_c, \mathbf{y}_{pa(i)}) (M_{\mathbf{y}_{pa(i)}}^c - MP_{\mathbf{y}_{pa(i)}}^c)$$

where the first term $M_{\mathbf{y}_{pa(i)}}^c = \int_t \gamma_{y_i, y'_i | \mathbf{y}_{pa(i)}} dt$ is the expected number of transitions from y_i to y'_i given the state of the parents $\mathbf{y}_{pa(i)}$, M_0 and the evidence in sequence c (see (Cohn et al., 2010)). The second term

$$MP_{\mathbf{y}_{pa(i)}}^c = \exp\{\mathbf{w}_{y_i, y'_i}^i \cdot \phi^i(\mathbf{x}_c, \mathbf{y}_{pa(i)})\} \int_t \mu_{y_i, \mathbf{y}_{pa(i)}}^i r_{y_i, y'_i}^i dt$$

is the integral of the probability of being in state $[y_i, \mathbf{y}_{pa(i)}]$, multiplied by the transition rate. Hence, this term can be interpreted as the expected number of *potential transitions*. The gradient weighs the feature vectors $\phi^i(\mathbf{x}_c, \mathbf{y}_{pa(i)})$ using the difference between the expected number of actual and potential transitions.

Optimization of the baseline that assumes a parametric form $r_{y_i, y'_i}^i(t) = r_{y_i, y'_i}^i(t; \theta)$ involves computation of its gradient with respect to the parameters θ

$$\frac{\partial E_{\mathcal{M}_0}[ll(\mathcal{M}, \mathcal{D})]}{\partial \theta} =$$

$$\sum_c \sum_{\mathbf{y}_{pa(i)}} \int_t \left[-\exp\{\mathbf{w}_{y_i, y'_i}^i \cdot \phi^i(\mathbf{x}_c, \mathbf{y}_{pa(i)})\} \mu_{y_i, \mathbf{y}_{pa(i)}} \right.$$

$$\left. + \frac{\gamma_{y_i, y'_i | \mathbf{y}_{pa(i)}}}{r_{y_i, y'_i}^i} \right] \frac{\partial r_{y_i, y'_i}^i}{\partial \theta} dt.$$

In the simplest case, if the baseline is constant or piecewise constant, the stationary point solution has a closed form.

A maximum likelihood estimator can be found using an EM procedure iterating between expectation and maximization steps. Expectation steps compute the functions that represent the posterior distribution, μ and γ . Maximization steps involve optimizing the covariate and cross component influence weights \mathbf{w}_{y_i, y'_i}^i using standard optimization methods and the gradient derived in Equation 6, as well as optimizing the baseline rates using the gradient in Equation 6. While the overall target function is not convex, the optimization of \mathbf{w}_{y_i, y'_i}^i is a convex problem given fixed baselines and posterior distributions, and so is the case for many choices of the baseline rates.

5 EXPERIMENTAL RESULTS

5.1 LEARNING EVALUATION

Our initial experiments test the validity of SCUP. To this end, we created synthetic SCUP data sets. We then trained SCUP using these data sets, and compared the similarity of the learned models with the actual ones.

The topology for all data generating models was similar to the HIV disease topology (Figure 1) with the exclusion of the survival state. All models included a single randomly drawn binary covariate. The baseline rates followed a Weibull rate, with a shape parameter $\kappa = 2$ and a scale parameter drawn from an inverse Gamma distribution (the Weibull distribution conjugate prior), with shape and scale parameters both equal to 2. For each component with parents y_1, y_2 , and a covariate x , we used the feature mapping $\phi(x, y_1, y_2) = (x, \mathbf{1}_{y_1=2}, \mathbf{1}_{y_2=2})$, with feature coefficients drawn from $\mathcal{N}(0, 1)$.

We evaluated learning performance as a function of dataset size and sampling rate. During the training, we divided the time interval $[0,1]$ into 5 equally sized intervals, and learned piecewise-constant baseline rates for each one. We considered both fully observed data and point observations, with observation times for each trajectory drawn uniformly from $[0,1]$. All trajectories were observed at times $t = 0$ and $t = 1$. Our evaluation compared the similarity of the learned models to the true generating models through the root mean square error (RMSE) of the learned coefficients. We also compared the integral of each baseline rate across the time interval $[0,1]$, to its true value. The baseline integral was used because it does not depend on parametric form, and because it is used in inference and learning tasks, rather than the baseline itself. Figure 3 shows that learning accuracy increases with sample size and sampling rate, as expected. As a further measure of validity, we verified that $\log(\text{RMSE})$ decreases linearly with \log dataset size, with slopes close to -0.5 , indicating consistency (data not shown).

5.2 THE EFFECT OF NON-HOMOGENEITY

To test the effect of non-homogeneity, we generated data from homogeneous and non-homogeneous SCUP models. We then trained the models with different levels of non-homogeneity on the generated datasets, and evaluated learning performance. The datasets were generated from two SCUP architectures similar to those described in the previous section, with the exception that the first architecture used a homogeneous constant baseline rate for all transitions, whereas the second one used baseline rates as previously described. The baseline rates for the first architecture were generated from a Gamma distribution, with scale and shape parameters equal to 1.0. We generated five models from each architecture, and generated a dataset of 500 trajectories using each model. Every trajectory was observed at times $t = 0$ and $t = 1$, and at three other uniformly drawn time-points. We trained SCUP models with increasing numbers of piecewise-constant baseline rate. Notably, models with one baseline rate are equivalent to CTBNs. We evaluated the learning performance via a five-fold cross validation of out of sample (OOS) likelihood.

The results, shown in Figure 4, demonstrate that homogeneous models cannot capture complex dynamics that change over time. Increasing the number of baseline rates leads to greater flexibility on the one hand, but to the risk of overfitting on the other.

5.3 COMPARISON WITH OTHER METHODS

To assess the relative performance of SCUP, we compared it to two competing methods, which can both be derived as special instances of SCUP: A factored model and a multi-state model. The factored model (FM) is a SCUP model with several independent components. There are no arcs between components, and thus transition probabilities are affected only by covariates and baseline rates. The multi-state model (MSTM) follows the implementation of a package called MSM (Jackson, 2011). It can be viewed as a SCUP model with a single component, whose state space is the Cartesian product of the SCUP components state spaces. We verified empirically that our implementation yields the same results as MSM on a wide variety of scenarios. SCUP can be seen as an intermediate method between these two extremes, balancing between compactness and expressiveness. Notably, all three methods fully support non-homogeneous dynamics.

We generated five models for each of the three architectures, each having a single binary covariate, with Weibull baseline rates and randomly drawn coefficients, as described in the previous section. The SCUP models were generated and used as described in the previous sections. The FM models contained three binary components, and the MSM models contained a single eight-state component,

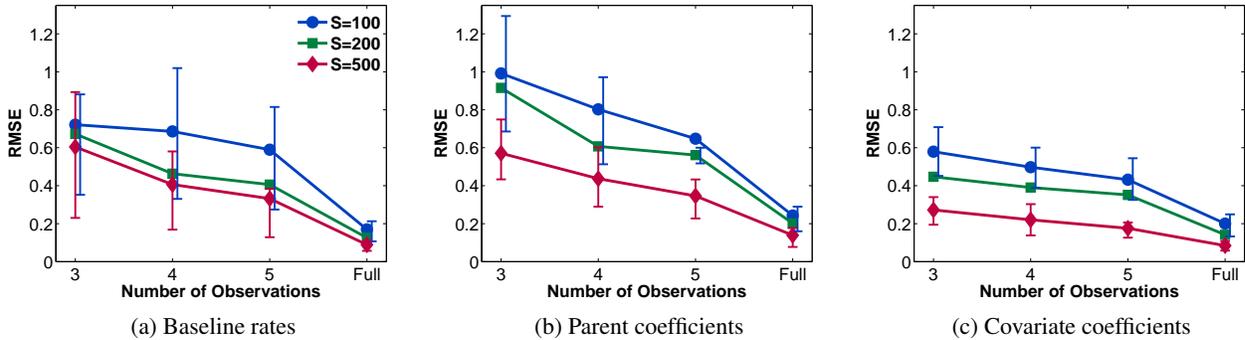

Figure 3: Root mean square error of estimated parameters for various sampling rates, and the 75% confidence intervals (confidence intervals for S=200 are omitted for clarity).

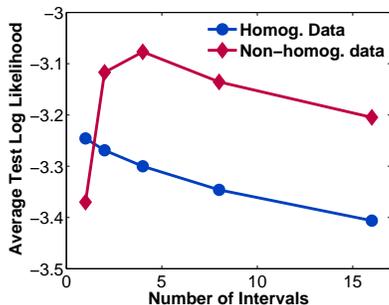

Figure 4: Out of sample likelihood for models trained with increasing number of piecewise-constant baseline rates.

Table 1: The number of parameters learned by FM, SCUP, and MSM. The number of piecewise-constant baseline rates is denoted by t .

	FM	SCUP	MSM
Cov. coefficients	6	6	56
Parents coefficients	0	12	0
Baseline rates	$6t$	$6t$	$56t$
Total number	$6+6t$	$18+6t$	$56+56t$

with one state corresponding to each assignment of the components' states in the SCUP model. Both the MSM and FM models used the feature mapping $\phi(x) = x$.

We generated datasets of 1,000 trajectories using each of the 15 models. We then examined how well a model from each architecture can be trained on each dataset, via a three-fold cross validation of OOS likelihood. The trajectories were observed as described in the previous section. All trained models used five piecewise constant baseline rates. The number of parameters for the three models is shown in Table 1, demonstrating that SCUP bridges between the two extremes.

Figure 5 demonstrates that SCUP is more flexible than the other two methods, allowing it to represent data generated

by different architectures, while retaining compactness. MSM exhibits poor learning capabilities for smaller datasets; this holds true even for data created by a model with the same architecture, demonstrating overfitting due to model complexity. The factored model does not suffer from overfitting, but has limited expressiveness, and thus cannot capture mutual influences between components.

5.4 ANALYSIS HIV DATA

We evaluated the performance of SCUP by analyzing real data from a data set containing lab measurements of HIV patients who took medication on a regular basis, previously described in (Rosen-Zvi et al., 2008). We defined models with two components corresponding to the two main measures of HIV severity, viral load (VL) and CD4 lymphocytes concentration, as well as a continuously observed binary absorbing component, representing survival. The resulting model is similar to the one described in Figure 1, with the omission of the disease component, and the addition of a VL→survival arc, which was added to obtain a fully connected topology. Following previous works, the CD4 level was dichotomized to have 2 states, using a threshold of 200 (D'Amico et al., 2011). The VL level was also dichotomized to have 2 states, using a threshold of 500, as previously done in analyses of this data (Rosen-Zvi et al., 2008).

For the analysis, we randomly selected 2000 patients whose VL and CD4 levels were both observed at each observation point. The resulting dataset contained 5.14 observations per patient on average (standard deviation 3.37). For every patient, we included covariates corresponding to age, sex, and whether the patient had undertaken a different therapy in the past. Feature mappings consisted of a concatenation of the covariates, with a binary 0/1 feature for each parent component. The initial time $t=0$ was set as the therapy start time. For patients who underwent several successive therapies, only observations taken during the period of the first one were included in the analysis. All patients had

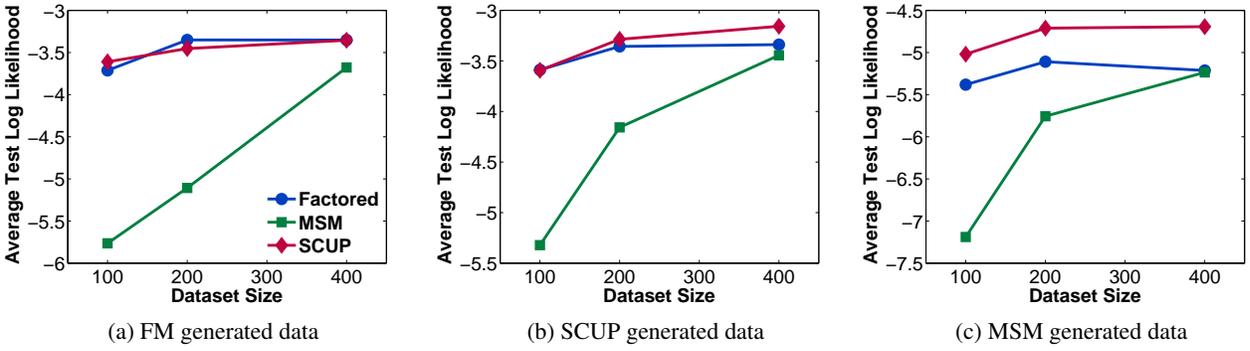

Figure 5: Test likelihoods of data learned by different models.

an observation at time $t=0$, using the closest measurement within a month from the therapy start date.

We computed the average OOS log likelihood obtained via a five-fold cross validation, with increasing numbers of piecewise constant baseline rates. The results, shown in Figure 6, clearly demonstrate the powerful effect of non-homogeneity, and the importance of modeling it correctly. MSM has an advantage when using a small number of baseline rates, owing to its richer model, which can capture richer interaction patterns between the system components. However, SCUP steadily improves as the number of baseline rates increases, until it eventually surpasses MSM. This increase indicates the presence of strong non-homogeneous dynamics. MSM can also capture non-homogeneous dynamics, but is hindered by its large number of parameters. The FM model exhibits weaker performance than the other methods for every number of baseline rates tested. This is due to the fact that it cannot capture the dynamics stemming from mutual influences between the system components. The decrease in OOS likelihood for FM when using 16 baseline rates may stem from overfitting, which occurs because it is trying to incorrectly capture mutual influences between the system components via baseline rates.

5.5 ANALYSIS OF DATA FROM DIABETES PATIENTS

We evaluated SCUP on a large cohort of diabetes patients, previously described by (Neuvirth et al., 2011). Following (Neuvirth et al., 2011), we define the main outcome of interest as the glycated hemoglobin (HbA1c) blood test, which is a reliable indicator of diabetes severity status. A higher HbA1c indicates increased risk of developing complications.

Our goal was to learn the interaction patterns between the HbA1c level and other potential diabetes biomarkers commonly measured in routine blood tests. The ability to predict HbA1c levels from routine blood tests can improve early detection of the disease progression. To this end,

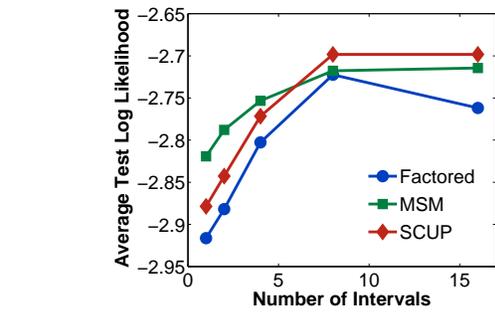

Figure 6: Performance of SCUP, FM, and MSM on the HIV dataset.

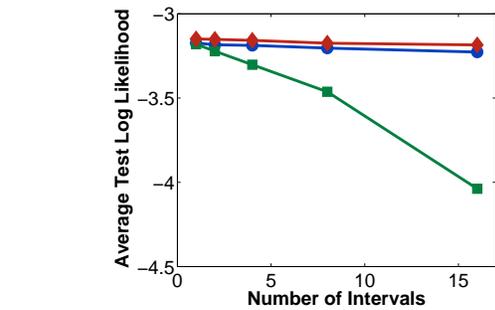

Figure 7: Performance of SCUP, FM, and MSM on the diabetes dataset.

we defined a SCUP model with binary components for HbA1c, low-density lipoprotein (LDL), and triglycerides levels. The two states of each component correspond to normal and abnormal clinical status, with the thresholds for HbA1c, LDL, and triglycerides set to 7, 130 and 200, respectively. We used a fully connected topology, and included the age and sex of each patient as covariates.

For the analysis, we randomly chose 1,000 patients with non-missing values for the components of interest at every observation point. Every patient had 3.25 observations on average (standard deviation 1.52). Feature mappings consisted of a concatenation of the covariates, with a

binary 0/1 feature for each parent component. The time $t = 0$ for each patient was determined according to the first observation time.

We computed the average OOS likelihood obtained via a five-fold cross validation, with increasing numbers of intervals. The results, shown in Figure 7, demonstrate that SCUP can scale to rich models without overfitting. The factored model, although scalable, does not capture the interactions between components, leading to weaker prediction power. The MSM model tends to suffer from overfitting due to its complexity. The lack of increase in OOS likelihood for increased numbers of intervals indicates that the components tend to follow homogeneous dynamics in this dataset. Nevertheless, SCUP does not overfit when trained with a large number of intervals, indicating its robustness to the type of underlying dynamics in the data.

To further investigate the different methods, we examined the coefficients describing mutual influence between the system components; these were learned across the different folds. We examined the models that assumed one piecewise-constant interval, as they had the best fit for this data. For every pair of components, we computed the coefficient describing the influence of one on a transition of the other. For MSM, we averaged the two corresponding coefficients over the two possible states of the third component. The results, shown in Table 2, demonstrate that SCUP models learned across the different folds are more consistent with each other, leading to substantially smaller variance.

The results demonstrate rich interaction patterns across the components. For example, increased triglycerides levels are associated with an increase in HbA1C, whereas increased HbA1C is associated with stabilization of the triglycerides levels via a reduction of their transition rate. Such observations cannot be performed directly in FM nor MSM, due to their lack of modular structure.

6 DISCUSSION

We proposed a proportional modeling scheme for non-homogeneous multi-component processes, by combining factorizations of CTBNs with a decomposition dating back to proportional hazard models. The key modeling assumption is a decomposition of the process into a time-dependent non-homogeneous component that does not depend on the model topology, and a time-independent component that depends on the model topology and additional features. This is a natural extension of classic hazard models, which can be considered as special SCUP instances with no underlying topology. This decomposition leads to compact models that can capture complex dynamics, as well as an efficient learning scheme, and easily interpretable results.

Table 2: The average coefficients of parent influence on increase (\uparrow) and decrease (\downarrow) learned in the diabetes dataset, and the minimum and maximum values obtained across the five folds.

	SCUP	MSM
LDL \rightarrow A1C \uparrow	.17 (.08, .25)	-.24 (-.73, .27)
Trig. \rightarrow A1C \uparrow	.31 (.09, .45)	.12 (-.65, .62)
LDL \rightarrow A1C \downarrow	.09 (.04, .16)	-.20 (-.50, .06)
Trig. \rightarrow A1C \downarrow	-.17 (-.23, .02)	-.22 (-.42, .22)
A1C \rightarrow LDL \uparrow	.34 (.20, .45)	1.15 (.86, 1.31)
Trig. \rightarrow LDL \uparrow	.57 (.33, .79)	.68 (.31, 1.14)
A1C \rightarrow LDL \downarrow	-.04 (-.23, .14)	-.18 (-.98, .33)
Trig. \rightarrow LDL \downarrow	-.38 (-.49, -.25)	.67 (.16, 1.46)
A1C \rightarrow Trig. \uparrow	-.28 (-.49, -.09)	-.51 (-.90, -.37)
LDL \rightarrow Trig. \uparrow	.82 (.67, .92)	-.54 (-1.13, .25)
A1C \rightarrow Trig. \downarrow	-.59 (-.71, -.50)	-1.24 (-1.82, -.89)
LDL \rightarrow Trig. \downarrow	.63 (.40, .82)	-.72 (-1.79, .09)

Our theoretical and empirical results demonstrate that non-homogeneous dynamics can be captured accurately using a piecewise homogeneous approximation. It would be interesting to compare this baseline rates representation to parametric forms. Learning such models is straightforward and can be performed by plugging in the partial derivative of a specific parametric form to the gradient in Equation 6.

Baseline rates can be regularized via spline approximations (Commenges, 2002; Joly et al., 2009; Farewell and Tom, 2012) or Gaussian process priors (Rao and Teh, 2011a). Splines can also be naturally adapted to regularize piecewise constant rates. This can be done by bounding the difference between rates in adjacent time intervals, or the rate of change of this difference, which is analogous to bounding the first and second derivative, respectively. Regularization of other model parameters, such as the covariate or parents coefficients, can potentially be handled using standard regularization methods such as elastic nets, as recently proposed for Cox regression (Simon et al., 2011).

In this work we studied moderately sized systems. Adapting approximate inference methods developed for CTBNs that support non-homogeneity, such as (Rao and Teh, 2011b) or (El-Hay et al., 2010), could scale up this framework to arbitrarily large systems.

Acknowledgments

We would like to thank our anonymous reviewers for useful comments, Hani Neuvirth-Telem for helping with processing of the diabetes data, the EuResist Network study group for providing the HIV data, Gal Elidan for insightful suggestions on earlier versions of the manuscript, and Amir Globerson for helpful discussions.

Abstract

Picking the best alternative in a given set is a well-studied problem at the core of social choice theory. In some applications, one can assume that there is an objectively correct way to compare the alternatives, which, however, cannot be observed directly, and individuals' preferences over the alternatives (votes) are noisy estimates of this ground truth. The goal of voting in this case is to estimate the ground truth from the votes. In this paradigm, it is usually assumed that the ground truth is a ranking of the alternatives by their true quality. However, sometimes alternatives are compared using not one but multiple quality parameters, which may result in cycles in the ground truth as well as in the preferences of the individuals. Motivated by this, we provide a formal model of voting with possibly intransitive ground truth and preferences, and investigate the maximum likelihood approach for picking the best alternative in this case. We show that the resulting framework leads to polynomial-time algorithms, and also approximates the corresponding \mathcal{NP} -hard problems in the classic framework.

1 INTRODUCTION

Typically, voting rules are viewed as vehicles for aggregating subjective preferences of individuals into a consensus or societal preference. However, another paradigm of voting theory, which dates back to Marquis de Condorcet [11], became increasingly popular in recent years, motivated in part by its relevance to the design of crowdsourcing platforms and human computation systems [14]. Condorcet suggested that votes cast by the individuals should be viewed as noisy estimates of an underlying objective ground truth—a ranking of the available alternatives by their true quality, and the aim of voting should be to aggregate the votes in order to uncover the ground truth

and thereby pick the best alternative. He proposed a simple approach for modeling the noise present in individuals' votes, which is known today as Mallows' model [18]. In this model, every voter compares each pair of alternatives independently, and orders them correctly (as in the ground truth) with a fixed probability $p > 1/2$, and incorrectly with probability $1-p$. If the generated vote contains cycles, it is discarded and the process restarts, continuing until the pairwise comparisons form a total order over the alternatives. While this model is somewhat unrealistic [19], it is widely used, in part because it provides control of the level of noise in the votes through a single parameter.

However, in many applications, alternatives are compared using not one, but multiple quality parameters [21, 28]. Under multi-criteria decision making, the preference relation that arises from the pairwise comparisons may contain cycles. Such preferences are known as tournaments. Also, when the number of alternatives is large (e.g., in many human computation systems), it is hard for voters to submit a total order over the alternatives. Hence, most systems employ vote elicitation techniques where the individuals iteratively submit parts of their preference, such as pairwise comparisons or partial orders. Bounded rationality of voters may again lead to cyclic preferences in this case. There are also settings where a voter may in fact be a meta-voter, representing a group of individuals (e.g., a country or region). Synthesizing preferences of the people in a group may also lead to cyclic preference for the meta-voter.

Motivated by this, we introduce a variant of Mallows' model where both the ground truth and the noisy preferences generated may be tournaments rather than rankings of the alternatives. In this model, the vote generation process described above simplifies: there is no need to restart the process if the generated vote has cycles. Consequently, the pairwise comparisons are independent of each other, resulting in a more tractable model: indeed, it appears that Young [29, p. 1238] in his analysis of Condorcet's approach to choosing the most likely winner uses the tournament-based model in his calculations, even though his intention was to study the ranking-based model.

Recently, Procaccia et al. [22] have formalized, corrected, and extended Young’s analysis of the optimal rule to pick the best alternative. They focused on the limiting case of Mallows’ model where the noise is very high ($p \rightarrow 1/2$), as they were motivated by crowdsourcing settings, in which this is often the case. As a side result, they have also analyzed the other extreme case of very low noise ($p \rightarrow 1$).

Our Contribution: We introduce the tournament variant of Mallows’ model and show that the most likely winners in our model can be identified in polynomial time for a given value of the noise parameter, as well as in the limiting cases of extremely high and low noise; this is in sharp contrast with the ranking-based model. We then focus on the limiting cases of the tournament-based model and show empirically that they provide a good approximation for the corresponding cases of the ranking-based model. As a side result, we prove that Tideman’s rule [24, pp. 199-201] (which is closely related to the high-noise setting in the tournament-based model) is a 2-approximation of Kemeny’s rule (which is closely related to the high-noise setting in the ranking-based model), a result that may be of independent interest to the social choice community. Finally, we propose an agnostic voting rule that circumvents the problem of not knowing the noise parameter and returns the set of alternatives that are MLE at some value of the parameter. Using simulations, we show that this rule is quite decisive, i.e., returns very few alternatives.

2 RELATED WORK

The maximum likelihood estimation (MLE) approach to voting was proposed by Condorcet [11]. Young [29] formalized Condorcet’s ideas, and showed that Condorcet’s approach to choosing the best ranking results in a voting rule that is known as Kemeny’s rule. Young has also considered the problem of selecting the most likely winner, focusing on the limit cases where the noise is extremely high or extremely low. However, his analysis of this setting is presented by means of an example and appears to be flawed. Procaccia et al. [22] formalized Young’s analysis and extended it to objectives other than picking the best alternative. Recently, Caragiannis et al. [5] have further generalized this approach by focusing on the design of voting rules that demonstrate robustness to noise originating from a wide family of noise models. Such robustness is also a feature of our agnostic rule, in that it returns a set of alternatives that is guaranteed to contain the most likely alternative irrespective of the value of the underlying parameter of Mallows’ model from which votes are generated.

Other variants of the maximum likelihood approach have been considered in the computational social choice literature [9, 8, 27]. Perhaps the closest to our work is that of Xia et al. [28], who studied the MLE approach in multi-issue domains, where alternatives represent combinations

of multiple issues. Xia et al. used CP-nets to represent the (possibly cyclic) preferences of the voters. However, they focused on dealing with the huge space of alternatives created by an exponential number of combinations.

Finally, we show that Tideman’s rule provides a very simple and elegant deterministic 2-approximation to Kemeny’s rule. Since Kemeny’s rule is \mathcal{NP} -hard to compute [2], its approximations have been studied extensively in the literature, varying from deterministic approximations [10, 26] through randomized approximations [1] to a polynomial time approximation scheme (PTAS) [13].

3 PRELIMINARIES

Let $[k] = \{1, \dots, k\}$. We consider a set of *alternatives* A with $|A| = m$. Let $\mathcal{L}(A)$ denote the set of *votes*, where a vote is a ranking (linear order) over the alternatives, denoted $\sigma : \{1, \dots, m\} \rightarrow A$. Thus, alternative $\sigma(i)$ is the i -th most preferred alternative in σ ; $\sigma(1)$ and $\sigma(m)$ are, respectively, the most and the least preferred alternatives in σ . Note that $|\mathcal{L}(A)| = m!$. A *profile* $\pi \in \mathcal{L}(A)^n$ is a collection of n votes. For alternatives $a, b \in A$, let n_{ab} denote the number of votes in π that rank a above b . Hence, $n_{ab} + n_{ba} = n$ for all $a, b \in A$. Let $\Delta_{ab} = n_{ab} - n_{ba}$; this quantity can be thought of as the advantage of a over b .

Voting rules. A *voting rule* is a function that maps every profile to a *winning alternative*, or a set of tied winning alternatives. Formally, a voting rule is a mapping $f : \mathcal{L}(A)^n \rightarrow \mathcal{P}(A)$, where $\mathcal{P}(\cdot)$ denotes the power set.¹ We review three prominent voting rules that play a crucial role in this paper.

- *The Borda count.* Under the Borda count, each voter awards $m - i$ points to the alternative she ranks in position i , i.e., each alternative receives a number of points equal to the number of alternatives it defeats. The scores of the alternatives are tallied across the votes. That is, the Borda score of an alternative $a \in A$ in profile π is

$$\text{SC}^{BD}(a) = \sum_{\sigma \in \pi} \sum_{b \in A \setminus \{a\}} \mathbb{I}[a \succ_{\sigma} b] = \sum_{b \in A \setminus \{a\}} n_{ab},$$

where the second equality follows by switching the order of summation. The winner(s) are the alternative(s) with the highest score.

- *Tideman’s rule.* More commonly known as *Tideman’s simplified Dodgson rule*,² this rule was put forward by Tideman [24, pp. 199-201] as a polynomial-time computable approximation to Dodgson’s rule [12], which is

¹Technically, such mappings are known as *social choice functions*. In contrast, *social welfare functions* map every profile to a ranking or a set of tied rankings over the alternatives.

²Tideman’s rule considered in this paper should not be confused with *the ranked pairs method*, also proposed by Tideman.

\mathcal{NP} -hard to compute. Under Tideman’s rule, the score of an alternative a is given by

$$\text{SC}^{TD}(a) = \sum_{b \in A \setminus \{a\}} \max(0, \Delta_{ba}).$$

That is, the Tideman score of a is the cumulative advantage of all alternatives that have a positive advantage over a . Importantly, the winners are the alternatives with the *minimum* score.

- *Kemeny’s rule.* The Kendall tau distance between two rankings is the number of pairs of alternatives on which they disagree, i.e., for $\sigma_1, \sigma_2 \in \mathcal{L}(A)$, $d(\sigma_1, \sigma_2) = |\{(a, b) \mid a \succ_{\sigma_1} b, b \succ_{\sigma_2} a\}|$. With slight abuse of notation, for a profile π and a ranking σ , let $d(\pi, \sigma) = \sum_{\sigma' \in \pi} d(\sigma, \sigma')$. Under Kemeny’s rule, the score of an alternative $a \in A$ is the minimum distance from the input profile to any ranking that puts a first. Formally,

$$\text{SC}^{KM}(a) = \min_{\sigma \in \mathcal{L}(A): \sigma(1)=a} d(\pi, \sigma).$$

The winners are the alternatives with the *minimum* score. Equivalently, the rankings with the smallest distance from the profile are selected, and the winners are the alternatives appearing first in these rankings.

Refinement of voting rules. We say that voting rule \hat{f} is a *refinement* of voting rule f if $\hat{f}(\pi) \subseteq f(\pi)$ for every profile π . That is, \hat{f} can be seen as a combination of f with a (partial) tie-breaking rule.

4 MODEL

We begin by presenting the well-known ranking version of Mallows’ model, and then we introduce a more general tournament version of this model.

4.1 THE RANKING MODEL

Assume there is a hidden true ranking $\sigma^* \in \mathcal{L}(A)$ over the alternatives, which reflects the order of their true strengths. We also make the standard assumption that σ^* is selected using a uniform prior over $\mathcal{L}(A)$. Thus, $\sigma^*(1)$ denotes the true best alternative. A *noise model* describes how votes are generated given the true ranking. Votes in a profile are then assumed to be iid samples from the noise model.

Specifically, in Mallows’ model [18] (also known as the *Condorcet noise model* [11]), which was described informally in the introduction, the probability of generating a vote σ when the true ranking is σ^* is given by

$$\Pr[\sigma \mid \sigma^*] = \frac{\varphi^{d(\sigma, \sigma^*)}}{Z_\varphi^m}. \quad (1)$$

Here, $\varphi = \frac{1-p}{p} \in (0, 1)$ is the noise parameter of the model and $p \in (1/2, 1)$ is the probability of making the correct

decision when comparing two alternatives. Thus, $\varphi \rightarrow 0$ represents a distribution concentrated around σ^* , whereas $\varphi \rightarrow 1$ converges to the uniform distribution, which has the greatest noise. Finally, d is the Kendall tau distance, and $Z_\varphi^m = \sum_{\sigma \in \mathcal{L}(A)} \Pr[\sigma \mid \sigma^*]$ is the normalization constant, which turns out to be independent of the true ranking σ^* (see, e.g., [16]).

Now, take a profile $\pi \in \mathcal{L}(A)^n$. Since individual votes are sampled iid, the probability of generating π is

$$\Pr[\pi \mid \sigma^*] = \prod_{\sigma \in \pi} \frac{\varphi^{d(\sigma, \sigma^*)}}{Z_\varphi^m} \propto \varphi^{d(\pi, \sigma^*)}.$$

Under the assumption of uniform prior over the true ranking σ^* , and for given φ , the probability of an alternative $a \in A$ being the true best alternative is proportional to

$$\sum_{\substack{\sigma^* \in \mathcal{L}(A): \\ \sigma^*(1)=a}} \Pr[\pi \mid \sigma^*] \propto \sum_{\substack{\sigma^* \in \mathcal{L}(A): \\ \sigma^*(1)=a}} \varphi^{d(\pi, \sigma^*)}. \quad (2)$$

Let $\Gamma_\varphi^R(a)$ be the “likelihood polynomial” of a , as given in the final expression of Equation (2). Then, the *maximum likelihood estimator* of the true best alternative, i.e., the set of alternatives having the highest probability of being the true best alternative, is given by $\text{MLE}_\varphi^R(\pi) = \arg \max_{a \in A} \Gamma_\varphi^R(a)$. Theorem 3.2 by Procaccia et al. [22] shows the following.

Theorem 1 (Procaccia et al. [22]). *Computing MLE_φ^R is \mathcal{NP} -hard.*

4.2 THE TOURNAMENT MODEL

We now introduce a variant of Mallows’ model where both the ground truth and the samples need not be total orders. Rather, they can be *tournaments*, i.e., sets of pairwise comparisons (one for each pair of alternatives). A tournament need not be transitive: it can be the case that a beats b , b beats c , and c beats a . As argued in the introduction, this is common when the alternatives are compared based on multiple quality parameters instead of a single parameter, and/or users are not required to submit total orders. Note that every ranking can be seen as a tournament.

Let $\mathcal{T}(A)$ denote the set of all tournaments over alternatives in A . We still use $a \succ_T b$ to denote that alternative a is preferred to alternative b in the tournament T . The Kendall tau distance extends to $\mathcal{T}(A)$ in a natural way: given two tournaments $T, T' \in \mathcal{T}(A)$, $d(T, T')$ is the number of pairs of alternatives on which T and T' disagree. Further, the quantities $(n_{ab})_{a, b \in A}$ remain well-defined for a profile of tournaments $\pi \in \mathcal{T}(A)^n$. As the three voting rules introduced in Section 3 (the Borda count, Tideman’s rule, and Kemeny’s rule) can be defined in terms of $(n_{ab})_{a, b \in A}$, these rules are well-defined over profiles of tournaments as well.

Let $T^* \in \mathcal{T}(A)$ denote the hidden true tournament over the alternatives. We assume that T^* is selected using a uniform prior over $\mathcal{T}(A)$. That is, for each pair of alternatives $a, b \in A$ we independently decide whether $a \succ_{T^*} b$ or $b \succ_{T^*} a$, with both possibilities being equally likely. When generating a vote, each pairwise comparison in T^* is retained with a fixed probability $1/2 < p < 1$ and flipped with probability $1 - p$. Unlike in the ranking model, the pairwise comparisons in the samples are independent of each other. Accordingly, the probability of generating a tournament T when the true tournament is T^* is given by

$$\Pr[T | T^*] = p^{\binom{m}{2} - d(T, T^*)} (1-p)^{d(T, T^*)} = p^{\binom{m}{2}} \varphi^{d(T, T^*)}.$$

We consider profiles consisting on n tournaments, which are sampled iid from the noise model. Let $d(\pi, T^*) = \sum_{T \in \pi} d(T, T^*)$. Then, the probability of generating a profile $\pi \in \mathcal{T}(A)^n$ is proportional to $\varphi^{d(\pi, T^*)}$, similarly to the ranking-based model.

Procaccia et al. [22] introduced the noisy choice model as the generalization of Mallows' model where the ground truth was a ranking but the samples could be tournaments. In that sense, our model is a further generalization where even the ground truth may be a tournament.

However, this causes a potentially serious problem: The best alternative in a ranking σ^* is $\sigma^*(1)$. But the definition of the best alternative in a tournament T^* is unclear. Following Condorcet's own definition of "Condorcet winners" for cyclic majority preferences, we say that an alternative is the winner in a tournament if it is preferred to every other alternative. Note that not every tournament has a winner. For a tournament T , define $\text{win}(T)$ to be the winner of T if it exists, and \emptyset otherwise.

Given a profile $\pi \in \mathcal{T}(A)^n$, we can now compute the likelihood of an alternative $a \in A$ being the best alternative in the unknown true tournament. Indeed, for every $T^* \in \mathcal{T}(A)$ with $\text{win}(T^*) = a$ we have

$$\begin{aligned} d(\pi, T^*) &= \sum_{b \in A \setminus \{a\}} n_{ba} \\ &+ \sum_{c, d \in A \setminus \{a\}} (n_{cd} \cdot \mathbb{I}[d \succ_{T^*} c] + n_{dc} \cdot \mathbb{I}[c \succ_{T^*} d]). \end{aligned}$$

Further, for each possible combination of pairwise comparisons of the alternatives in $A \setminus \{a\}$, the set $\{T^* \in \mathcal{T}(A) \mid \text{win}(T^*) = a\}$ contains exactly one tournament that realizes this combination. Hence, we have

$$\begin{aligned} \sum_{\substack{T^* \in \mathcal{T}(A): \\ \text{win}(T^*) = a}} \varphi^{d(\pi, T^*)} &= \varphi^{\sum_{b \in A \setminus \{a\}} n_{ba}} \cdot \prod_{c, d \in A \setminus \{a\}} (\varphi^{n_{cd}} + \varphi^{n_{dc}}) \\ &\propto \prod_{b \in A \setminus \{a\}} \frac{\varphi^{n_{ba}}}{\varphi^{n_{ba}} + \varphi^{n_{ab}}} = \prod_{b \in A \setminus \{a\}} \frac{1}{1 + \varphi^{n_{ab} - n_{ba}}}. \end{aligned}$$

Now, for an alternative $a \in A$, define its likelihood polynomial $\Gamma_\varphi^T(a) = \prod_{b \in A \setminus \{a\}} (1 + \varphi^{n_{ab} - n_{ba}})$. Technically,

$\Gamma_\varphi^T(a)$ is a Laurent polynomial, i.e., some of the powers of φ may be negative. Therefore, we will sometimes work with the function $\hat{\Gamma}_\varphi^T(a) = \varphi^{nm} \Gamma_\varphi^T(a)$, which is a polynomial of degree at most $2nm$. Note that the likelihood polynomial of a is proportional to the inverse of the likelihood, and is therefore to be minimized. Thus, the maximum likelihood estimator for the best alternative is given by $\text{MLE}_\varphi^T(\pi) = \arg \min_{a \in A} \Gamma_\varphi^T(a)$, or, equivalently, $\text{MLE}_\varphi^T(\pi) = \arg \min_{a \in A} \hat{\Gamma}_\varphi^T(a)$. Since $\Gamma_\varphi^T(a)$ can be computed for every alternative $a \in A$ and every $\varphi \in \mathbb{Q}$ in polynomial time, the following is trivial.

Theorem 2. *Computing MLE_φ^T is in \mathcal{P} .*

5 LIMITING VOTING RULES

We will now study the extreme cases with very low and very high noise in input votes, i.e., $\varphi \rightarrow 0$ and $\varphi \rightarrow 1$, respectively. First, we observe that both for rankings and for tournaments and in both limiting cases, the limiting rule is well-defined, i.e., there exist α and β with $0 < \alpha < \beta < 1$ such that for $P \in \{R, T\}$ $\text{MLE}_\varphi^P = \text{MLE}_\alpha^P$ for all $0 < \varphi \leq \alpha$ and $\text{MLE}_\varphi^P = \text{MLE}_\beta^P$ for all $\beta \leq \varphi < 1$. Indeed, fix a profile π . For each $a \in A$ the degree of the likelihood polynomials $\Gamma_\varphi^R(a)$ and $\hat{\Gamma}_\varphi^T(a)$ is finite, and therefore we can pick $\alpha^\pi, \beta^\pi \in (0, 1)$ so that no two of these polynomials for π intersect in $(0, \alpha^\pi)$ or in $(\beta^\pi, 1)$. Since the number of profiles with a *fixed number of votes* is finite, taking the minimum of α^π and the maximum of β^π over all such profiles gives the desired values of α and β . Note, however, that this argument breaks down if the number of votes may vary. For example, if $\Gamma_\varphi^R(a)$ and $\Gamma_\varphi^R(b)$ for a profile π intersect at φ , then $\Gamma_\varphi^R(a)$ and $\Gamma_\varphi^R(b)$ for the profile $k\pi$ intersect at $\sqrt[k]{\varphi}$ (where $k\pi$ is the profile where each entry of π is repeated k times). As k is unbounded, we obtain $\beta = \sup_\pi \beta^\pi = 1$.

Notation. For the ranking model, let $\text{MLE}_{\text{Acc}}^R$ and $\text{MLE}_{\text{Inacc}}^R$ denote the limiting rules in the accurate case ($\varphi \rightarrow 0$) and in the inaccurate case ($\varphi \rightarrow 1$), respectively. Similarly, for the tournament model, let $\text{MLE}_{\text{Acc}}^T$ and $\text{MLE}_{\text{Inacc}}^T$ denote the limiting rules in the accurate case and in the inaccurate case, respectively.

5.1 THE RANKING MODEL

The accurate case ($\varphi \rightarrow 0$): Procaccia et al. [22] showed that when $\varphi \rightarrow 0$, every MLE best alternative is first in some Kemeny ranking. Further, they also showed that finding even a single Kemeny winner is \mathcal{NP} -hard.³ These results can be restated as follows.

Theorem 3 (Procaccia et al. [22]). *$\text{MLE}_{\text{Acc}}^R$ is a refinement of Kemeny's rule, and is \mathcal{NP} -hard to compute.*

³Both results can be found in the proof of Theorem A.1 in the appendix of the full version available at <http://www.cs.cmu.edu/~arielpro/papers/mle.full.pdf>.

In fact, our tools enable us to describe $\text{MLE}_{\text{Acc}}^R$ in more detail; see Appendix A of the full version of the paper.⁴

The inaccurate case ($\varphi \rightarrow 1$): Procaccia et al. [22, Theorem 4.1] proved that every MLE best alternative in this case is also a Borda winner. However, they left open the question of computational complexity. Despite significant effort, we were unable to settle the computational complexity either. We conjecture that $\text{MLE}_{\text{Inacc}}^R$ is \mathcal{NP} -hard to compute.

Theorem 4 (Procaccia et al. [22]). $\text{MLE}_{\text{Inacc}}^R$ is a refinement of the Borda count.

Once again, the exact refinement is given in Appendix A of the full version. While the computational complexity of $\text{MLE}_{\text{Inacc}}^R$ is unknown, we remark that computing its output is easy whenever Borda's rule produces a unique winner, which is often the case.

See Section 5.3 for an example showing the computation of $\text{MLE}_{\text{Acc}}^R$ and $\text{MLE}_{\text{Inacc}}^R$ for a given profile.

5.2 THE TOURNAMENT MODEL

The accurate case ($\varphi \rightarrow 0$): In this case we show the following.

Theorem 5. $\text{MLE}_{\text{Acc}}^T$ is a refinement of Tideman's rule, and can be computed in polynomial time.

Proof. To determine the winner(s) under $\text{MLE}_{\text{Acc}}^T$ we need to compare the likelihood polynomials $\Gamma_\varphi^T(a) = \prod_{b \in A \setminus \{a\}} (1 + \varphi^{n_{ab} - n_{ba}})$ when $\varphi \rightarrow 0$. Pick $\alpha \in (0, 1)$ so that no two likelihood polynomials intersect in $(0, \alpha)$. As $\varphi \rightarrow 0$, the dominating term in $\Gamma_\varphi^T(a)$ is the smallest power of φ , i.e.,

$$t_\varphi(a) = \prod_{\substack{b \in A \setminus \{a\}, \\ n_{ab} \leq n_{ba}}} \varphi^{n_{ab} - n_{ba}} = \varphi^{-\sum_{b \in A \setminus \{a\}} \max\{0, \Delta_{ba}\}}$$

(where we take the product over the empty set to be 1). Hence, for $\varphi \in (0, \alpha)$ we have $\Gamma_\varphi^T(a) < \Gamma_\varphi^T(b)$ whenever $t_\varphi(a) < t_\varphi(b)$, or, equivalently, whenever $\text{SC}^{TD}(a) > \text{SC}^{TD}(b)$. Recall that we are interested in alternatives with the smallest value of the likelihood polynomial on $(0, \alpha)$; our calculation shows that every such alternative is a Tideman winner.

To show that $\text{MLE}_{\text{Acc}}^T$ is polynomial-time computable, it is *not* sufficient to observe that the functions $\Gamma_\varphi^T(a)$, $a \in A$, can be evaluated in polynomial time, as we also need to find a small enough value of φ at which they should be compared. Nevertheless, comparing likelihood polynomials at $\varphi \rightarrow 0$ is not difficult. We first multiply the terms of $\hat{\Gamma}_\varphi^T(a)$ one-by-one, followed by expansion at each stage,

⁴The full version can be found at <http://www.cs.cmu.edu/~nkshah/papers.html>

to obtain the coefficients of this polynomial. Note that the degree of $\hat{\Gamma}_\varphi^T(a)$ is at most $2mn$, so this step can be implemented efficiently. To compare two polynomials at $\varphi \rightarrow 0$, it suffices to consider their coefficients lexicographically, starting with the lowest-order terms. The details are given in Appendix A of the full version of the paper. \square

The inaccurate case ($\varphi \rightarrow 1$): This case has striking similarity with the inaccurate case of the ranking model.

Theorem 6. $\text{MLE}_{\text{Inacc}}^T$ is a refinement of the Borda count, and can be computed in polynomial time.

Proof. Note that $\hat{\Gamma}_1^T(a) = \Gamma_1^T(a) = 1$ for all $a \in A$. Therefore, to compare the likelihood polynomials as $\varphi \rightarrow 1$, we will first compare their derivatives at $\varphi = 1$. We have

$$\begin{aligned} \left. \frac{d}{d\varphi} \Gamma_\varphi^T(a) \right|_{\varphi=1} &= 2^{m-2} \sum_{b \in A \setminus \{a\}} \left. \frac{d}{d\varphi} (1 + \varphi^{n_{ab} - n_{ba}}) \right|_{\varphi=1} \\ &= 2^{m-2} \sum_{b \in A \setminus \{a\}} (n_{ab} - n_{ba}). \end{aligned}$$

As φ approaches 1 from the left, we have $\Gamma_\varphi^T(a) < \Gamma_\varphi^T(b)$ whenever $\left. \frac{d}{d\varphi} \Gamma_\varphi^T(a) \right|_{\varphi=1} > \left. \frac{d}{d\varphi} \Gamma_\varphi^T(b) \right|_{\varphi=1}$. Using $n_{ba} = n - n_{ab}$, we observe that the latter condition is equivalent to $\text{SC}^{BD}(a) > \text{SC}^{BD}(b)$. Thus, the winners under $\text{MLE}_{\text{Inacc}}^T$ must have the highest Borda score, i.e., $\text{MLE}_{\text{Inacc}}^T$ is a refinement of the Borda rule.

In contrast with the ranking-based model, the rule $\text{MLE}_{\text{Inacc}}^T$ can be computed in polynomial time. Similarly to the accurate case of the tournament model (see the proof of Theorem 5), we multiply the terms of each $\hat{\Gamma}_\varphi^T(a)$, $a \in A$, in order to obtain the coefficients of these polynomials. Then, for each polynomial we compute its first $2nm$ derivatives at $\varphi = 1$. As the degree of each of these polynomials does not exceed $2nm$, comparing two such polynomials at $\varphi \rightarrow 1$ amounts to lexicographically comparing these two lists of values. \square

Alternatively, we can show that $\text{MLE}_{\text{Acc}}^T$ and $\text{MLE}_{\text{Inacc}}^T$ are polynomial-time computable by using results on *root separation* of polynomials. A classic paper by Mahler [17] proved the following.

Fact: Any two distinct roots of a polynomial are separated by at least H^{-k+1} , where H is the maximum absolute value of any coefficient, and k is the degree.

See [3] for further explanation and improved results for polynomials with integer coefficients. In our case, we can consider the polynomial $P = \prod_{a, b \in A} (\hat{\Gamma}_\varphi^T(a) - \hat{\Gamma}_\varphi^T(b))$; its degree does not exceed $2nm^3$ and its coefficients are at most exponential in $\text{poly}(n, m)$. Thus, $\Delta = H^{-k+1}$ has *polynomially many bits*. An exponential upper bound on H (and hence the respective lower bound on Δ) can be

computed without expanding P . Since no two likelihood polynomials intersect on $(0, \Delta)$ or on $(1 - \Delta, 1)$, the outputs of $\text{MLE}_{\text{Acc}}^T$ and $\text{MLE}_{\text{Inacc}}^T$ can be computed by evaluating and comparing $\Gamma_\varphi^T(a)$, $a \in A$, in their product form at $\varphi = \Delta/2$ and $\varphi = 1 - \Delta/2$, respectively. We prefer the approach presented in the proofs above because it seems to work faster in practice, possibly due to the fact that it relies only on integer arithmetic.

5.3 THE TOURNAMENT MODEL VERSUS THE RANKING MODEL

The goal of this section is to compare the ranking-based model and the tournament-based model. We begin by presenting a profile on which the limiting voting rules for the two models differ.

Example 1. Consider a profile π consisting of the following 3 rankings over 4 alternatives.

$$a \succ b \succ c \succ d, \quad d \succ a \succ b \succ c, \quad c \succ d \succ b \succ a.$$

Recall that the likelihood polynomials $\Gamma_\varphi^R(a)$ (in the ranking model) and $\Gamma_\varphi^T(a)$ (in the tournament model) of an alternative $a \in A$ are given by

$$\begin{aligned} \Gamma_\varphi^R(a) &= \sum_{\substack{\sigma^* \in \mathcal{L}(A): \\ \sigma^*(1)=a}} \varphi^{d(\pi, \sigma^*)}, \\ \Gamma_\varphi^T(a) &= \prod_{b \in A \setminus \{a\}} (1 + \varphi^{n_{ab} - n_{ba}}). \end{aligned}$$

For profile π , the likelihood polynomials are given below.

$$\begin{aligned} \Gamma_\varphi^R(a) &= \varphi^8 + \varphi^8 + \varphi^8 + \varphi^9 + \varphi^9 + \varphi^9, \\ \Gamma_\varphi^R(b) &= \varphi^9 + \varphi^9 + \varphi^9 + \varphi^{10} + \varphi^{10} + \varphi^{10}, \\ \Gamma_\varphi^R(c) &= \varphi^8 + \varphi^9 + \varphi^9 + \varphi^{10} + \varphi^{10} + \varphi^{11}, \\ \Gamma_\varphi^R(d) &= \varphi^7 + \varphi^8 + \varphi^8 + \varphi^9 + \varphi^9 + \varphi^{10}, \\ \Gamma_\varphi^T(a) &= (1 + \varphi^1) (1 + \varphi^1) (1 + \varphi^{-1}), \\ \Gamma_\varphi^T(b) &= (1 + \varphi^{-1}) (1 + \varphi^1) (1 + \varphi^{-1}), \\ \Gamma_\varphi^T(c) &= (1 + \varphi^{-1}) (1 + \varphi^{-1}) (1 + \varphi^1), \\ \Gamma_\varphi^T(d) &= (1 + \varphi^1) (1 + \varphi^1) (1 + \varphi^{-1}). \end{aligned}$$

Now, we can compute the limiting voting rules using the likelihood polynomials as explained in Sections 5.1 and 5.2. The results of these rules along with those of the Borda count, Kemeny’s rule, and Tideman’s rule are given in Table 1.

While Example 1 shows that the accurate and the inaccurate cases of the tournament model differ from the respective cases of the ranking model, we show that the tournament model serves as a satisfactory polynomial-time approximation of the ranking model, where computing the limiting rules is non-trivial (and provably \mathcal{NP} -hard in the

Ranking, Accurate	$\text{MLE}_{\text{Acc}}^R(\pi) = \{d\}$
Ranking, Inaccurate	$\text{MLE}_{\text{Inacc}}^R(\pi) = \{d\}$
Tournament, Accurate	$\text{MLE}_{\text{Acc}}^T(\pi) = \{a, d\}$
Tournament, Inaccurate	$\text{MLE}_{\text{Inacc}}^T(\pi) = \{a, d\}$
Borda count	$\text{Borda}(\pi) = \{a, d\}$
Kemeny’s rule	$\text{Kemeny}(\pi) = \{d\}$
Tideman’s rule	$\text{Tideman}(\pi) = \{a, d\}$

Table 1: Various voting rules applied on π .

accurate case). While the tournament model—where both the ground truth and the estimates may be cyclic—has its intrinsic motivation (see Section 1), this offers an additional strong motivation for the model. The similarity of both models in the inaccurate case is evident: Both $\text{MLE}_{\text{Inacc}}^R$ and $\text{MLE}_{\text{Inacc}}^T$ are refinements of Borda’s rule. However, as seen in Example 1, these two rules are not identical. Moreover, we can show that neither of these rules is a refinement of the other: Appendix C in the full version presents an example with 8 rankings over 4 alternatives where both $\text{MLE}_{\text{Inacc}}^R$ and $\text{MLE}_{\text{Inacc}}^T$ have unique winners that are different. We remark, however, that these two rules return the same output most of the time (see Section 7), and always when the Borda winner is unique.

Motivated by the similarity in the inaccurate case, we compared Tideman’s rule and Kemeny’s rule, because the limiting rules in the accurate case of the ranking and the tournament models are refinements of Kemeny’s rule and Tideman’s rule, respectively. While the two rules were not previously thought to be connected, we show that Tideman’s rule is a 2-approximation of Kemeny’s rule.

Theorem 7. *The Kemeny score of a Tideman winner is at most twice the Kemeny score of a Kemeny winner.*

Proof. First, we describe an alternative interpretation of Kemeny’s rule proposed by Conitzer et al. [7]. Given a profile π over A , define a *weighted pairwise majority (WPM) graph* for a set of alternatives $A' \subseteq A$ to be the directed graph $G_{A'}$ where the vertices are the alternatives in A' , and there is an edge between every pair of alternatives $a, b \in A'$ with weight $|\Delta_{ab}| = |n_{ab} - n_{ba}|$. The edge goes from a to b if $n_{ab} > n_{ba}$ and from b to a if $n_{ba} > n_{ab}$. When $n_{ab} = n_{ba}$, the edge with zero weight may be drawn in either direction.

The *feedback* of a ranking with respect to a WPM graph $G_{A'}$ is defined as the sum of the weights of edges of $G_{A'}$ going in direction opposite to the ranking. Conitzer et al. [7] showed that Kemeny’s rule is equivalent to first finding the rankings with the smallest feedback with respect to G_A , and then returning their top alternatives.

Equivalently, we can say that in G_A for every pair of alternatives $a, b \in A$ there is an edge from a to b with weight $\max(0, \Delta_{ab})$. Thus, the Tideman score of an alternative

$a \in A$ is the sum of weights of its incoming edges, and the Tideman winners are the vertices that minimize this sum. For a subset of alternatives $S \subseteq A$, let $F(S)$ be the smallest feedback with respect to G_S , over all rankings of A . To compute the Kemeny score of an alternative $a \in A$, we consider the set of all rankings \mathcal{L}_a that put a first, and find a ranking in \mathcal{L}_a that has the minimum feedback with respect to G_A . Note that the feedback of any ranking in \mathcal{L}_a contains all incoming edges of a . Thus, to minimize feedback over \mathcal{L}_a , we order the alternatives in $A \setminus \{a\}$ so as to minimize the feedback over $G_{A \setminus \{a\}}$. Hence,

$$\text{SC}^{KM}(a) = \text{SC}^{TD}(a) + F(A \setminus \{a\}). \quad (3)$$

Further, for every pair of alternatives $a, b \in A$, $a \neq b$, we have

$$F(A \setminus \{a\}) \leq \text{SC}^{TD}(b) + F(A \setminus \{a, b\}). \quad (4)$$

Indeed, the left-hand side of (4) is the feedback of the best ranking with respect to $G_{A \setminus \{a\}}$, whereas the right-hand side of (4) is the feedback of the best ranking with respect to $G_{A \setminus \{a\}}$ among those that put b first, plus $\max(0, \Delta_{ab})$.

Now, consider a profile π . Let $a \in A$ be a Tideman winner and let $b \in A$ be a Kemeny winner. We want to show that $\text{SC}^{KM}(a) \leq 2\text{SC}^{KM}(b)$. If $a = b$, this is trivial. Thus, assume $a \neq b$. Combining (3) and (4), we obtain

$$\begin{aligned} \text{SC}^{KM}(a) &= \text{SC}^{TD}(a) + F(A \setminus \{a\}) \\ &\leq \text{SC}^{TD}(a) + \text{SC}^{TD}(b) + F(A \setminus \{a, b\}) \\ &\leq \text{SC}^{TD}(b) + \text{SC}^{TD}(b) + F(A \setminus \{b\}) \\ &\leq 2(\text{SC}^{TD}(b) + F(A \setminus \{b\})) = 2 \cdot \text{SC}^{KM}(b). \end{aligned}$$

Hence, the Kemeny score of any Tideman winner is a 2-approximation of the optimal Kemeny score. \square

It is easy to give an example using 4 alternatives where the approximation factor is exactly 2. Hence, the result of Theorem 7 is tight. Caragiannis et al. [4] show that Tideman’s rule, which was originally proposed as an approximation to Dodgson’s rule, is actually an asymptotically optimal approximation of Dodgson’s rule. Theorem 7 shows that it is also a 2-approximation of Kemeny’s rule. Dodgson’s rule and Kemeny’s rule are deeply connected [23]: While Dodgson’s rule makes the smallest number of pairwise swaps to reach a profile with a Condorcet winner (an alternative preferred by a majority of voters to every other alternative), Kemeny’s rule makes the swaps until the majority opinion becomes acyclic and then returns the first alternative in the acyclic order. Tideman’s rule can now be seen as a hybrid that provides a good approximation to both Dodgson’s rule and Kemeny’s rule.

Kemeny’s rule admits a polynomial time approximation scheme (PTAS) [13], which is, however, rather impractical. Constant approximations of Kemeny’s rule are studied

because they are fast and simple [10, 1, 26]. Tideman’s rule, which admits an elegant closed-form expression (see Section 3), is the simplest deterministic 2-approximation of Kemeny’s rule that we are aware of. We believe that this result, which originated from the observation that the tournament model seems closely related to the ranking model, may be of independent interest to the social choice community.

6 THE AGNOSTIC RULE

While the limiting cases of $\varphi \rightarrow 0$ and $\varphi \rightarrow 1$ may be appropriate in some scenarios (and their analysis yields interesting connections, e.g., Theorem 7), in most practical settings the level of noise is unknown. We could include φ as one of the unknown parameters and infer the best possible values for the true ranking/tournament and φ (see, e.g., [16]). However, this approach gives one specific value (a “point estimate”) of φ . If the point estimate is wrong, the estimate for the best alternative is also sub-optimal.

Consider instead an agnostic approach that refrains from estimating the value of φ . Rather, given a profile, it returns the set of *all* alternatives that are the most likely winners for *some value of* φ . Let MLE_{Ag}^R and MLE_{Ag}^T denote the agnostic rules in the ranking model and in the tournament model, respectively. Then for a profile π ,

$$\begin{aligned} \text{MLE}_{\text{Ag}}^R(\pi) &= \bigcup_{\varphi \in (0,1)} \text{MLE}_{\varphi}^R(\pi), \\ \text{MLE}_{\text{Ag}}^T(\pi) &= \bigcup_{\varphi \in (0,1)} \text{MLE}_{\varphi}^T(\pi). \end{aligned}$$

There are three advantages of this approach over the inference approach: First, as we show below, MLE_{Ag}^T can be computed in polynomial time, and results presented in Section 7 demonstrate that MLE_{Ag}^T is a good approximation of MLE_{Ag}^R as well. Thus, it is easy to compute and use the agnostic rule. Most inference problems, on the other hand, are hard to solve [16]. Second, if the data is indeed generated from a Mallows’ (ranking or tournament) model, the MLE best alternative is guaranteed to be in the set returned by the agnostic rule, which is not the case for the inference approach. Third, while the set of winners under the agnostic rules contains the set of winners for any specific value of φ , our simulations in Section 7 show that on average only a few winning alternatives are returned.

Now, we show that the agnostic rule can be computed in polynomial time for the tournament model. Note that this is not obvious: While the limiting cases can be analyzed by looking at the coefficients of the likelihood polynomials or using a root separation approach, these methods do not work for values of φ away from 0 and 1. We use another result regarding polynomials, which is known as root isolation (see, e.g., [6, 25]).

Fact: Given a polynomial, one can compute, in time polynomial in the input size, a set of disjoint intervals that isolate the roots of the polynomial, i.e., disjoint intervals that collectively contain all roots of the polynomial but each interval only contains a single distinct root.

Theorem 8. Computing MLE_{Ag}^T is in \mathcal{P} .

Proof. Once again, consider the polynomial $P = \prod_{a,b \in A} (\hat{\Gamma}_\varphi^T(a) - \hat{\Gamma}_\varphi^T(b))$. We have argued that the degree of P is at most $2nm^3$, and its coefficients can be computed in polynomial time. Next, we use root isolation to isolate the roots of P in polynomial time. Note that any value of $\varphi \in (0, 1)$ where some alternatives $a, b, a \neq b$, have equal likelihood is a root of P . Hence, in any region between two consecutive roots of P , the order of likelihoods of different alternatives is fixed.

Therefore, computing MLE_{Ag}^T amounts to taking one value of φ between each consecutive pair of isolating intervals, evaluating MLE_φ^T at every such φ , and returning the set of all MLE alternatives found. Note that the number of roots of P and therefore the number of evaluations of MLE_φ^T is polynomial in the input size, and we have already established that evaluating MLE_φ^T itself can be done in polynomial time (Theorem 2). Hence, the overall running time is polynomial in the input size. \square

7 EXPERIMENTS

In this section, we complement our theoretical results by two sets of experiments. The results of Section 5.3 establish that the tournament model can be thought of as a polynomial-time approximation to the ranking model. The first set of experiments analyzes how close the limiting rules (and the agnostic rules) in the two models are to each other on average. The second set of experiments aims to check whether the agnostic rules return reasonably small sets of winning alternatives. To this end, we compute the average number of winning alternatives returned by the agnostic rules in the two models.

For both sets of experiments, we generate profiles using iid samples from Mallows' (ranking) model with the noise parameter φ taking 10 different values from 0.1 to 1.⁵ In each case, we average our results over 5000 sampled profiles. It is easy to check that the Borda winner, the Tideman winner, and the Kemeny winner always coincide in case of 3 alternatives. Hence, in our experiments we set the number of alternatives m to 5 or 7; the number of votes n is also either 5 or 7. Thus, each of the graphs presented has four lines; one for each of $(n, m) = (5, 5), (5, 7), (7, 5), (7, 7)$,

⁵We use the ranking model to generate profiles so that the generated profiles consist of rankings, which are also tournaments. This allows applying the rules for both models on the same profiles.

and (7, 7). In all the graphs, the x -axis shows the noise parameter φ used to generate profiles. Importantly, while the tournament model admits polynomial-time algorithms, and can therefore be used with a large number of alternatives, we use a small number of alternatives to be able to compare the associated voting rules with the exponential-time rules of the ranking model.

For the first set of experiments, we measure the dissimilarity between three pairs of rules in terms of the dissimilarity between the sets of winning alternatives they return. As the measure of dissimilarity between two sets A and B , we use the *Jaccard distance*, which is defined as follows.

$$d_J(A, B) = \frac{|A \cup B| - |A \cap B|}{|A \cup B|}.$$

Figures 1(a), 1(b), and 1(c) respectively show the dissimilarity between the limiting rules for the accurate case, the limiting rules for the inaccurate case, and the agnostic rules of the two models—the ranking model and the tournament model—as a function of their noise parameter φ (note that, while the limiting rules were derived for a specific range of the noise parameter φ , we compare them at *all* values of φ). An interesting observation is that while the dissimilarity is quite low in both the accurate and the agnostic cases, it is surprisingly low in the inaccurate case. This observation holds true for all combinations of (n, m) . This indicates that the MLE rules of the tournament model are in general good approximations of the MLE rules of the ranking model, and the approximation becomes very good for the rules derived under the assumption of very high noise.

Continuing our comparison of the two models, note that Theorem 7 establishes that Tideman's rule is a 2-approximation of Kemeny's rule in the worst case (in terms of the Kemeny score of the winner). This is a significant improvement over the Borda count, which is known to give a 4-approximation in the worst case [10]. Thus, Tideman's rule improves over Borda's rule by a factor of 2 in the worst case. It is interesting to check if this relationship holds even in the average case.

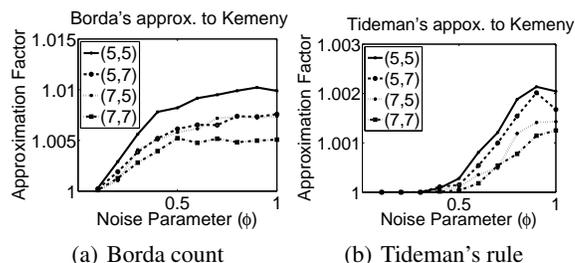

Figure 2: Approximations of Kemeny's rule.

Figures 2(a) and 2(b) show the average-case approximation factors of the Borda count and Tideman's rule, respectively, as a function of the noise parameter φ . It is evident

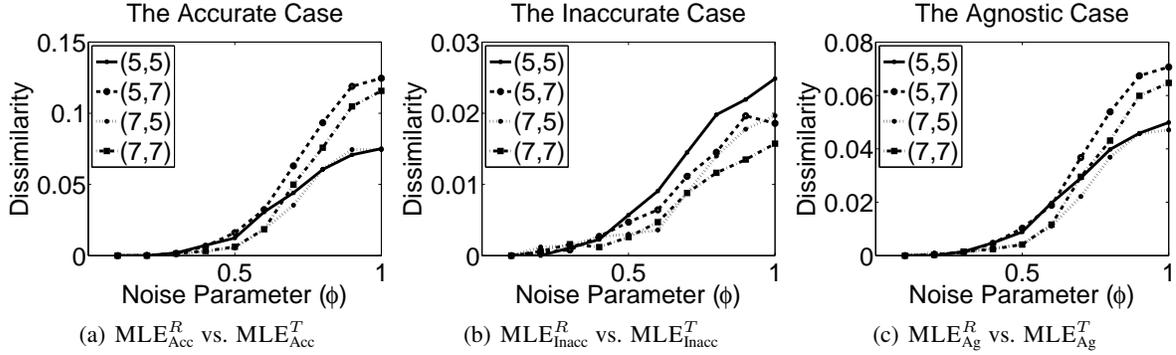

Figure 1: The dissimilarity between the ranking model and the tournament model.

that for both rules their average-case approximation factors are much better than their worst-case approximation factors. However, in the average case, the Borda count quickly reaches an approximation ratio of 1.01, while the approximation ratio of Tideman’s rule stays well below 1.003. That is, the improvement of Tideman’s rule over the Borda count is at least as good—in fact, slightly better—in the average case as in the worst case.

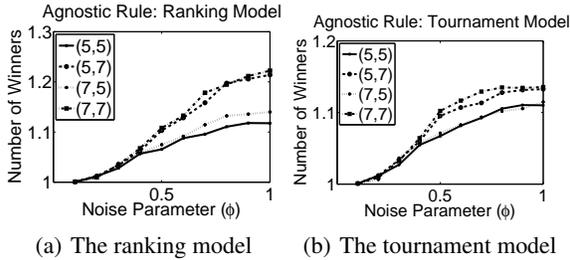

Figure 3: The average number of winning alternatives returned by the agnostic rules.

In our second set of experiments, we analyze the average number of winning alternatives returned by the agnostic rules in the ranking and the tournament models, again as a function of the noise parameter φ . Figures 3(a) and 3(b) show the results for the ranking and the tournament models, respectively. It can be seen that the agnostic rule—despite returning a set of alternatives that is guaranteed to contain the MLE best alternative for all values of $\varphi \in (0, 1)$ —outputs an average of less than 1.3 and 1.2 alternatives in the ranking model and the tournament model, respectively. In fact, in our simulations, the agnostic rules in both models return a single alternative, which is guaranteed to be the MLE best alternative for all values of φ , more than 80% of the time, for every $\varphi \in (0, 1)$.

8 DISCUSSION

We have studied methods for picking the best alternative given noisy estimates of an objective true comparison be-

tween the alternatives. Besides studying the standard Mallows’ model where both the ground truth and the estimates are acyclic total orders, we introduced and studied the setting where both may contain cycles. Procaccia et al. [22] studied the case where the ground truth is acyclic, but the estimates may or may not be cyclic. The only case not studied in the literature is that of possibly cyclic ground truth and acyclic estimates. However, this setting does not appear natural, and is also technically challenging: the denominator Z_φ^m in the probability expression of Mallows’ model (Equation 1) would not be independent of the ground truth, rendering the analysis extremely difficult.

Generalizations of Mallows’ model have been proposed in the literature [15, 20]. Some of these use critical information regarding positions of the alternatives in the ground truth ranking. Future work may also involve adapting such models to the case of tournaments; for example, one can use the number of alternatives defeated by a given alternative as a proxy for its rank, or one can develop distance metrics over tournaments to replace the Kendall tau distance in Equation (1). It would be interesting to see if such adaptations provide tractable approximations of the original ranking model.

The maximum likelihood approach to voting focuses solely on maximizing the likelihood of selecting the best alternative. This results in voting rules that can be difficult to understand, but have performance guarantees nonetheless. While simplicity is usually an important goal in the design of voting rules, it is less of an issue in human computation contexts, where the workers are paid for their input and do not need to know or understand how their estimates would be aggregated. Yet, in some practical applications, one may wish to use rules with additional desirable properties, either motivated by the application itself or as a safeguard in case the assumptions about the nature of the noise fail. A very exciting direction is to use Mallows’ model in order to inform the design of voting rules while trading off some of the likelihood for axiomatic properties such as Condorcet consistency or monotonicity.

Abstract

Binary matrices and tensors are popular data structures that need to be efficiently approximated by low-rank representations. A standard approach is to minimize the logistic loss, well suited for binary data. In many cases, the number m of non-zero elements in the tensor is much smaller than the total number n of possible entries in the tensor. This creates a problem for large tensors because the computation of the logistic loss has a linear time complexity with n . In this work, we show that an alternative approach is to minimize the quadratic loss (root mean square error) which leads to algorithms with a training time complexity that is reduced from $O(n)$ to $O(m)$, as proposed earlier in the restricted case of alternating least-square algorithms. In addition, we propose and study a greedy algorithm that partitions the tensor into smaller tensors, each approximated by a quadratic upper bound. This technique provides a time-accuracy trade-off between a fast but approximate algorithm and an accurate but slow algorithm. We show that this technique leads to a considerable speedup in learning of real world tensors.

1 INTRODUCTION

In multi-relational data factorization problems [20, 25], many negative examples are implicitly created for relations that are *not* true. For example, in a knowledge base of family relationships, the fact `isFather(x, y)` can be considered as a positive example and automatically induces $m - 1$ negative examples of the form `not(isFather(x, z))`, for all m individuals z different from y . In other words, for some relations, one positive example is always associated with several thousands of negative examples. The focus of our work is to consider algorithms that are independent of this number of negative

examples. In a different domain, state-of-the-art detection systems in computer vision are based on a binary classifier applied many times on a dense multi-resolution scan of an image [7]. Here, most of the examples do not contain the object to be detected and negative patches often overwhelm the number of positive examples. Finally, another classical example of such problems with unbalanced categories corresponds to recommender systems taking into account implicit feedback: in this domain, it corresponds to the signal that if a user did not do some action, such as buying an object in an online shopping web site or did not click on an online advertisement, then a *negative* training example is created to take into account the fact that the proposed item or advert might not be appropriate. While these negative examples are sometimes subject to controversy since one does not know whether the recommendation was correct or not, they are nevertheless considered as very useful by practitioners and are key components of most of online recommendation engines [9].

For a binary classification problem where the total number n^+ of positive examples is largely inferior to the total number n^- of negative examples, the complexity of most of the existing learning algorithms is *at least* linear in the number $n = n^+ + n^-$ of training samples, since it is a general belief that every training point needs to be loaded in memory at least once. In fact, the sparsity of the data can be used to drastically reduce the computation time of square-norm minimization problems, as proposed by [9] using an alternating least square algorithm, where each least square problem has a complexity linear in the number of positive data only. We will give an alternative derivation of this result and show that it is also valid for gradient-based algorithms.

However, the squared loss is not always satisfactory. For example, binary tensor decomposition with logistic loss gives much better predictive performance than minimizing the squared loss. The downside of it is that the computational cost increases significantly [14, 19], and one usually relies on heuristic rules to subsample the negative examples [11]. The time to minimize the logistic loss (or

other non-quadratic loss) scales linearly in the total number $n = n^+ + n^-$ of observations, which is a real issue in these heavily unbalanced datasets for which $n^+ \ll n^-$.

In this work, the key contributions are:

- For matrix and tensor factorization models learned by minimizing the squared loss, we show that all the algorithms can benefit from this speedup, i.e. it is not restricted to the alternating least square algorithm of [8],
- We propose a new algorithm to minimize non-quadratic losses. It is based on the partitioning of the tensor into blocks and the use of Jaakkola’s quadratic upper bound to the logistic loss [10]. While Jaakkola’s bound has already been used to factorize large matrices, the case of unbalanced datasets was not addressed [24]. Our work can be viewed as a novel application of these upper-bounding techniques, where the incremental refinement of the approximation provides a natural way to correct the optimality gap introduced by the bound.

2 PROBLEM FORMULATION

Let $\Omega := \{(i_1, \dots, i_D) ; i_d \in \{1, \dots, n_d\} \forall d = 1, \dots, D\}$ denotes the set of D -uplets for the dimensions n_1, n_2, \dots, n_D . For each of these D -uplets, we observe a noisy binary values $y_t \in \{0, 1\}$ indexed by $t \in \Omega$. These observations can also be represented as a noisy binary tensor $Y \in \{0, 1\}^{n_1 \times \dots \times n_D}$ where n_1, n_2, \dots, n_D correspond to the tensor dimensions. Typically, $D = 2$ will correspond to binary matrices, and $D = 3$ to third-order tensors as used in database factorization models such as RESCAL [20]. Our objective is to predict the value of some specific entries in the tensor, which can be understood as detecting which entries in the tensor are outliers y_t . To do this, we estimate a tensor $Z(\theta) \in \mathbb{R}^{n_1 \times \dots \times n_D}$ of log-odds parameterized by $\theta \in \Theta$.

We formulate the problem as an empirical loss minimization. In the training phase, the empirical loss \mathcal{L} is minimized with respect to the parameter vector θ :

$$\min_{\theta \in \Theta} \mathcal{L}(\theta) \quad \mathcal{L}(\theta) := \sum_{t \in \Omega} \ell(y_t, z_t(\theta)) \quad (1)$$

where $\ell(y, z) = -y \log(\sigma(z)) - (1 - y) \log(1 - \sigma(z))$ with σ representing the sigmoid function: $\sigma(z) := \frac{1}{1 + e^{-z}}$. The predicted tensor $Z(\theta) := \{z_t(\theta)\}_{t \in \Omega}$ is assumed to be a factored representation, i.e. it has a low rank structure. For clarity, we consider only multi-linear models based on the PARAFAC [6] tensor parametrization.¹ The predictions z_t are obtained by the multilinear product of rank- K factors

¹We can easily adapt this work to more general decompositions such as Tucker or RESCAL, or even to convex loss functions using trace-norm regularization.

represented in the rows of matrices $\Theta_d \in \mathbb{R}^{n_d \times K}$, $d \in \{1, \dots, D\}$:

$$\mathbf{z}_t(\theta) := \sum_{k=1}^K \prod_{d=1}^D \theta_{t_d k}^{(d)} := \langle \boldsymbol{\theta}_{t_1}^{(1)}, \dots, \boldsymbol{\theta}_{t_D}^{(D)} \rangle .$$

For matrices ($D = 2$), this model is a special case of exponential-family PCA [5] where the link function is logistic. For $D = 3$, this model has been studied in the context of multi-relational knowledge bases factorization [14, 18]. To solve Equation (1), several optimization methods have been proposed in the literature. Alternating optimization, gradient descent and stochastic gradient descent:

- The gradient descent algorithms are only based on the minimization of \mathcal{L} by doing small steps in the direction of the gradients. Since the loss is differentiable, we derive its gradient in closed form and use a generic software to choose the optimal descent direction. In the experiments below, we use Marc Schmidt’s `minFunc` Matlab function.²
- The alternating optimization procedure, also called block coordinate descent, consists in minimizing the loss \mathcal{L} with respect to the i -th component Θ_i , keeping all the other components Θ_j , $j \neq i$ fixed. This optimization makes use of existing optimized linear logistic regression algorithms. The optimization procedure is obtained through a round-robin schedule. This approach is simple to implement, but it involves an inner loop since linear logistic regression algorithms are also based on gradient minimization.
- For large scale optimization, there is a growing interest in stochastic gradient descent algorithms since every gradient computation can potentially be too expensive. It consists in computing the gradients for a subset of the observations.

For highly sparse matrices where the number of zeros is much larger than the number of ones, these approaches do not scale well with the dimension of the tensor. For each of these algorithms, the time to make one function evaluation is the key bottleneck. The gradient descent algorithm requires to sum $|\Omega|$ elements (one per possible prediction). One step of the alternating optimization procedure is computationally costly because it requires to solve a linear logistic regression with $|\Omega|$ observations. The stochastic gradient descent algorithm seems to be better as each iteration is very fast, but it still requires $|\Omega|$ iterations to do one pass through the data. For some problems, good predictive performances are obtained even before the first pass

²Can be found at <http://www.di.ens.fr/~mschmidt/Software/minFunc.html>.

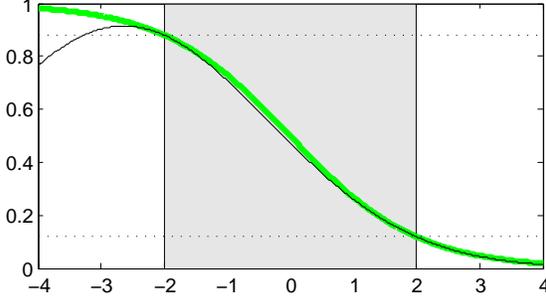

Figure 1: Comparison of the logistic function and the Gaussian distribution. The Gaussian distribution (the mean is -2.61 and the variance is 5.25) approximates well the logistic function in a range of values (gray area in the range [-2,2]) that corresponds to probabilities between 0.12 and 0.88 (dotted lines). In most of recommender systems applications, the probability of correctly predicting user choice is in this range, which explains that RMSE loss is reasonable.

through the data has been completed, but this case is relatively rare in practice. Our objective is to study methods that have a sub-linear complexity in the number of training sample, i.e. we can take into account *all* the $|\Omega|$ training samples while having a complexity that scales only in the number $n^+ = |\Omega^+|$ of non-zero elements. In the following we show that this complexity can be obtained by using a quadratic approximation to the logistic loss, leading to considerable speedup in our experiments.

3 QUADRATIC LOSS: FAST BUT OFTEN INACCURATE

As illustrated in Figure 1, the logistic loss can be reasonably approximated by a quadratic function, so the Root Mean Square Error (RMSE) should be a good surrogate function to minimize. A naive computation of the square loss $\mathcal{L}(\theta) = \sum_{t \in \Omega} (y_t - z_t(\theta))^2$ would require $O(KD \prod_d n_d)$ operations, since there are $\prod_d n_d$ possible predictions, but simple algebra shows that it is equal to:

$$\begin{aligned} \mathcal{L}(\theta) &= \sum_{t \in \Omega} (y_t - z_t)^2 \quad (2) \\ &= n^+ - 2 \sum_{t \in \Omega^+} z_t(\theta) + \sum_{k=1}^K \sum_{k'=1}^K \prod_{d=1}^D M_{kk'}^{(d)} \quad (3) \end{aligned}$$

where the $K \times K$ matrices $M^{(d)}$ are defined by $M_{kk'}^{(d)} := \sum_{j=1}^d \theta_{jk}^{(d)} \theta_{jk'}^{(d)}$. Hence, for tensors of high dimension, we get a significant speedup as Equation (3) can be computed in $O(Kn^+ + K^2 \sum_d n_d)$ operations. As an example, assume one wishes to compute the loss of a $1000 \times 1000 \times 1000$ tensor containing 10^5 entries and the low-rank approximation has rank $K = 100$. Then, we can see that there are $3 \cdot 10^{11}$ basic operations in the formula of Equation (2),

while the formula of Equation (3) contains $6 \cdot 10^7$ basic operations. This means that it will be 5000 times faster to compute exactly the same quantity!

If we minimize the loss $\mathcal{L}(\theta)$ with respect to θ using block-coordinate descent, the iterations end up being least squares problem with a per-iteration complexity that scales linearly with the number of positive examples only. This corresponds exactly to the iTALS algorithm [22], which is the tensor generalization of the alternating least squares algorithm of [9]. In our experiments, we used gradient descent to minimize the objective function, using Equation (3) to compute the gradient efficiently (the complexity is the same as the function evaluation).

4 SPEED-ACCURACY TRADE-OFF BY BOUNDING SPLITS

4.1 UPPER BOUNDING THE LOSS

To speed-up computation, we minimize a quadratic upper bound to the logistic loss. We use Jaakkola's bound to the logistic loss [10]:

$$\log(1 + e^z) \leq \lambda(\xi)(z^2 - \xi^2) + \frac{1}{2}(z - \xi) + \log(1 + e^\xi),$$

where $\lambda(\xi) := \frac{1}{2\xi}(\frac{1}{1+e^\xi} - \frac{1}{2})$ and ξ is a variational parameter. We keep the same value for ξ for all the elements of the tensor Z , so that the upper bound has exactly the form required to apply the computational speedup described in the previous section.

$$\bar{\mathcal{L}}(\theta, \xi) = \lambda(\xi) \sum_{t \in \Omega} \left(z_t - \frac{2y_t}{4\lambda(\xi)} \right)^2 + c(\xi)$$

where $c(\xi)$ is a constant function that does not depend on θ :

$$c(\xi) = |\Omega| \left(\log(1 + e^\xi) - \lambda(\xi)\xi^2 - \frac{1}{2}\xi - \frac{1}{16\lambda(\xi)} \right)$$

The optimization of this bound with respect to ξ gives exactly the Frobenius norm of the tensor:

$$\sum_{t \in \Omega} z_t(\theta)^2 = \arg \min_{\xi} \bar{\mathcal{L}}(\theta, \xi). \quad (4)$$

Note that $Z(\theta)$ is low rank in general. This means that it can also be efficiently computed using the third term of Equation (3). We have now an upper bound to the original loss \mathcal{L} that needs to be minimized:

$$\mathcal{L}(\theta) \leq \bar{\mathcal{L}}^\Omega(\theta, \xi). \quad (5)$$

As usual with bound optimization, we alternate between two steps: 1) minimizing the bound with respect to the variational parameter ξ using closed form updates (e.g. when using Jaakkola's bound) or dichotomic search where

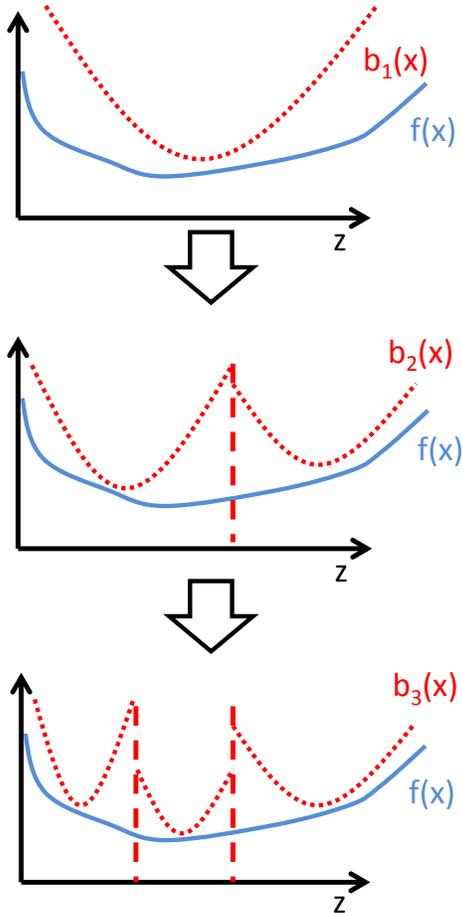

Figure 2: Illustration of the idea of bound refinement. The main idea is that computing the integral of the quadratic upper bound (such as b_1 in the top graph) is much faster than computing the integral of f directly. To improve the accuracy, we use piecewise bounds. To choose the domain of the pieces, we use a greedy algorithm that identifies the partition that leads to the diminished upper bound (leading to the upper bounds b_2 and b_3).

no closed form solution exists; and 2) minimizing the bound with respect to θ using a standard gradient descent algorithm. This algorithm is sometimes referred as Majorization-Minimization algorithm in the literature [16]. The algorithm minimizes the loss with a complexity per iteration equal to $O(Kn^+ + K^2 \sum_d n_d)$. In the experiments, this algorithm is called *Quad-App*. It is detailed in Algorithm 2.

4.2 SPLIT THE DATA TO IMPROVE ACCURACY

The drawback of the previous approach, even with one or two orders of magnitude speedups, the resulting quadratic approximation can be quite loose for some data, and the accuracy of the method can be too low. We give here a family of approximation that interpolates between this fast

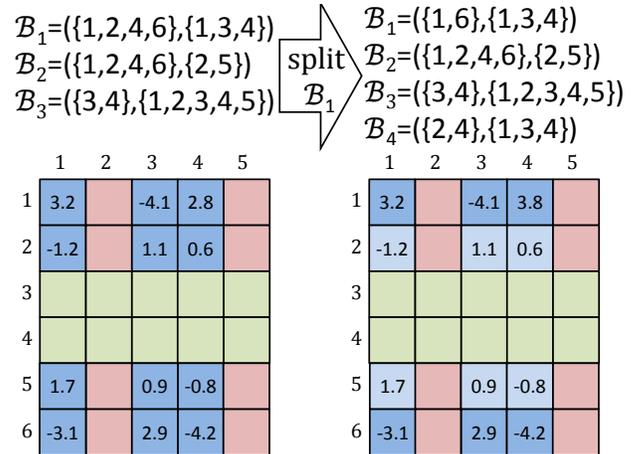

Figure 3: Example of matrix split to improve upper bound accuracy. Colors identify blocks. Numbers in the matrix represent predictions. The block 1 is decomposed into blocks 1 and 4, both having a small variance on the absolute value of the predictions.

but inaccurate quadratic approximation and the slow but exact minimization of the non-quadratic loss.

We propose to take advantage of the speedup due to the quadratic upper bound by applying it on a partition of the original tensor: we select a set $\mathcal{B} = \{B_1, \dots, B_{|\mathcal{B}|}\}$ of disjoint *blocks* that partitions the space of possible observation indices Ω . On each of these blocks, the bounding technique described in the previous section is applied, the main difference being that the minimization with respect to θ is done jointly on all the blocks. This process is illustrated in Figure 2. Formally, each block B_b , $b \in \{1, \dots, |\mathcal{B}|\}$ is identified by D sets of indices which represent the dimensions that are selected in the given block b . The split of these indices are illustrated in a toy matrix example in Figure 3. Blocks for tensors are computed the same way as matrices, but the depth indices are also splitted: At each refinement step, we choose to partition the rows indices, column indices or depth indices.

To select the blocks, we use a greedy construction of the blocks: starting with a single block containing all the indices, i.e. $\mathcal{B} = \{\Omega\}$, we iteratively refine the blocks using the following two-step procedure, called *RefineBlocks*:

1. select the block b to split that has the maximal variance in the absolute values of the predictions $|z_t|$;
2. split the block b into two block so that the variance of the absolute values of the predictions $|z_t|$ is minimized.

An example of such a split is shown in Figure 3. This method is fully described in Algorithm 1, which uses Al-

gorithm 2 as a sub-program to learn the parameters for a fixed set of blocks, following the approach described in the previous section. There is a tradeoff between optimizing the bound using Algorithm 2 and refining the partition \mathcal{B} in Algorithm 1. A simple strategy that worked well in practice was to refine the partition when the upper bound minimization did not improve more than a given tolerance level $\varepsilon/2$ in two successive iterations. This piecewise refinement strategy is called *PW Quad-App* in the experimental section.

We also introduced a slight variant of this basic algorithm, where we compute the exact logistic loss in blocks that are sufficiently dense, i.e. when computing Equation (3) requires more iterations than computing the loss in the classical way (Equation (3)). This condition is verified when $n^+(B) \geq \prod_{d=1}^D n_d^{(B)} - K \sum_{d=1}^D n_d^{(B)}$, where $n^+(B)$ and $n_d^{(B)}$ correspond to the number of non-zero elements and dimensions of the block tensor B . We call this variant *PW Quad-App + Logistic*.

5 EXPERIMENTS AND RESULTS

In this section, to evaluate the performances of our framework, we conducted experiments on both synthetic and real datasets.

Synthetic Data Experiments To explore the speed-accuracy tradeoff, we generated different binary matrices Y by randomly sampling noisy low-rank matrices $X =$

$UV + E$ where $U \in \mathbb{R}^{n_1 \times r}$ and $V \in \mathbb{R}^{r \times n_2}$ are generated using independent standard normal variables and $E \in \mathbb{R}^{n_1 \times n_2}$ is a normally distributed Gaussian noise with standard deviation σ . To create the binary matrix $Y \in \{0, 1\}^{n_1 \times n_2}$, we round the values of X using a high percentile of X as a threshold to produce a heavy tendency towards the negative class. We learn an estimation \hat{X} of the original matrix X on the data matrix Y assumed to be fully observed and compute the RMSE on the recovery of X , i.e. $\text{RMSE} = \|X - \hat{X}\|_F$. We measure the running time of each of the methods to understand their scalability to large datasets.

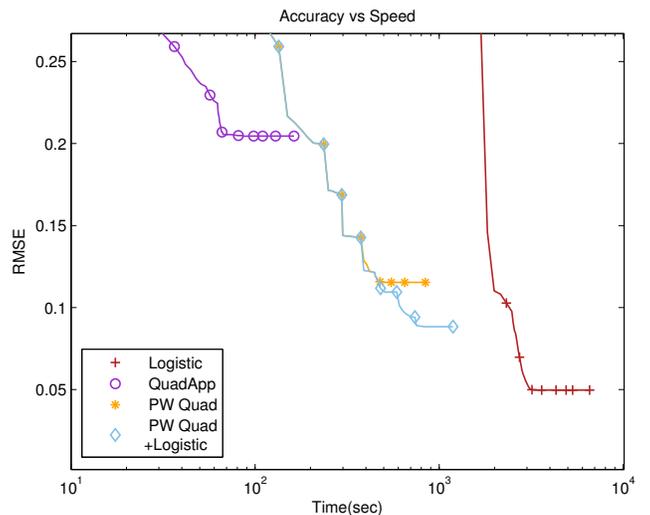

Figure 4: Matrix recovery results on simulation data with size 10000×5000 , sparsity %0.1 and noise $\sigma = 0.1$. Markers are plotted at iterations 10, 17, 28, 35, 52, 63 and 73 (these times correspond to the refinement of the piecewise bound).

The timing and accuracy performances of our methods on simulation data with various dimensions, noise levels and sparsity percentages are shown in Table 1. These results are averaged over 10 runs and we choose rank $r = 5$ for every simulation. Here, the baselines are logistic loss and quadratic loss. The logistic loss gives much smaller error rates than the quadratic loss (EUC-Full and EUC-Fast) and quadratic approximation, especially when the noise level is low. However, minimizing the logistic loss requires considerably more time than the alternative approaches as the problem size grows. These experiments highlight the fact that our unified framework for quadratic loss gives a significant improvement over logistic loss in terms of runtime performance. We also observe that the piecewise quadratic bounding technique has better predictive performance than the quadratic approximation, along with a huge speedup when we compare it to the time to train the model using the logistic loss. On Figure 4, we plotted the test RMSE with respect to the CPU time (each marker corresponds to

Table 1: Evaluation results of the synthetic experiments in terms of seconds for runtime and RMSE for matrix recovery.

an iteration). Because the error rate of quadratic loss is considerably bigger than the other methods, we show the results of logistic loss, quadratic approximation and piecewise methods in this figure. It is interesting to see that the piecewise quadratic bound reaches its goal of interpolating the performances between the fast but inaccurate quadratic approximation, and the slow but accurate logistic loss minimization: On a wide range of times (from 2 minutes to 1 hour), the piecewise quadratic bound gives the best performances. It is worth to note that the slight modification that was introduced to perform exact logistic on the smallest pieces improves performances when the methods have nearly converged (after 60 iterations). Note that this experiment was done on matrices, but the differences are even bigger for tensors of high order.

Real Data Experiments In order to evaluate the performances of our methods, we designed link-prediction experiments on standard multi-relational datasets: *Nations* that groups 14 countries (entities) with 56 binary relation types (like 'economic aid', 'treaties' or 'rel diplomacy') representing interactions among them; *Kinships* which is the complex relational structure of Australian tribes' kinship systems. In Kinships dataset, 104 tribe members were asked to provide the kinship terms they used for one another and this results in graph of 104 entities and 26 relation types, each of them depicting a different kinship term. And *UMLS* that contains data from the Unified Medical Language System semantic work used in [11]. This dataset consists in a graph with 135 entities (high-level concepts like 'Disease or Syndrome', 'Diagnostic Procedure') and 49 relation types (verbs depicting causal influence between concepts like 'affect' or 'cause'). In the end, these datasets results in tensors $Y \in \{0, 1\}^{14 \times 14 \times 56}$, $Y \in \{0, 1\}^{104 \times 104 \times 26}$ and $Y \in \{0, 1\}^{135 \times 135 \times 49}$ respec-

tively.

Then, we compared the Area Under the Receiver Operating Characteristic Curve (AUC) and runtime in seconds of piecewise methods to the results of quadratic approximation and logistic loss and also the results of RESCAL [20], SME [2] and LFM [11] that have the best published results on these benchmarks in terms of AUC.

In addition, we test the performances of these methods on three datasets in matrix form: MovieLens³, Last FM⁴ [4] and Sushi Preference [12]. MovieLens dataset contains movie ratings of approximately 1682 movies made by 943 MovieLens users and results in matrix $Y \in \{0, 1\}^{943 \times 1682}$. The Last FM dataset consists of music artist listening information from a set of 1892 users from *Last.fm* online music system. We construct a binary matrix $Y \in \{0, 1\}^{1892 \times 17632}$ from this dataset that contains the artists listened by each user. Lastly, the *Sushi Preference Data Set* includes 4950 users' responses of preference in 100 different kinds of *sushi*. In this dataset, the most disliked kind of sushi represented by 0 and the most preferred one is represented by 1. Eventually, sushi dataset results in matrix $Y \in \{0, 1\}^{100 \times 4950}$.

For the results given in Table 2, we performed 10-fold cross validation and averaged over 10 random splits of the datasets. In addition, we select the optimal regularization parameter λ^* by searching over the set $\{0.01, 0.05, 0.1, 0.5, 1\}$ that maximizes the AUC and we computed rank-20 decomposition of these datasets in order to get comparable results to RESCAL, SME and LFM. The time and accuracy comparisons are given in Table 2 in terms of seconds for time and AUC metric for predict-

ing missing values. These results demonstrate that logistic loss improves accuracy over RESCAL, SME and LFM in Nations, Kinships, MovieLens and Last FM datasets while it reaches almost the same score for UMLS and Sushi datasets. On the other side, piecewise methods provide very close approximation to logistic loss on all these datasets and they have a significant advantage in terms of runtime over the other methods. They take a small fraction of logistic loss’ running time, especially for large datasets.

6 RELATED WORK

In order to deal with learning on various forms of structured data such as large-scale knowledge bases, time-varying networks or recommendation data, tensor factorizations have become increasingly popular [3, 21, 23]. Recently, Nickel et al presented RESCAL [20], an upgrade over previous tensor factorization methods, which has been shown to achieve state-of-the-art results for various relational learning tasks such as link prediction and entity resolution. Independently, a similar logistic extension of the RESCAL factorization has been proposed in [14]. [21] is an extension to the RESCAL algorithm on the YAGO ontology and is based on alternating least-squares updates of the factor matrices, has been shown to scale up to large knowledge bases via exploiting the sparsity of relational data. Among the existing works, [18] is the most similar work with our, which is the logistic extension of RESCAL. It demonstrates that the logistic loss improves the prediction results significantly but their algorithm requires to compute the dense matrix and cannot scale to large data. In RESCAL, entities are modeled by real-valued vectors and relations by matri-

ces. Bordes *et al* has further improved this idea in the Structured Embeddings (SE) framework [3] by learning a model to represent elements of any knowledge base (KB) into a relatively low dimensional embedding vector space by tensor factorization method. Latent Factor Model (LFM) [11] is based on a bilinear structure, which captures various orders of interaction of the data, and also shares sparse latent factors across different relations. In [2], they present a new neural network designed to embed multi-relational graphs into a flexible continuous vector space via a custom energy function (SME) in which the original data is kept and enhanced. In all of these studies [3, 11, 2], the data is extremely skewed i.e., the number of negative examples \gg the number of positive examples. To overcome the sparsity, they first select a positive training triplet at random, then create a negative triplet by sampling an entity from the set of all entities. Unlike these approaches, we argue that it is in general more appropriate to consider *all* the negative examples.

Maaten et al [15] derive an upper bound to logistic loss which can be minimized as surrogate loss for linear predictors on binary labels. Khan et al [13] used Jaakkola’s bound for binary observations and Bohning’s bound for multinomial observations [1]. Our work can be easily extended to take into account Bohning’s bound. In addition, piecewise bounds have the important property: reducing the error as the number of pieces increase. Marlin et al. proposed an improvement on the logistic-loss with piecewise linear bounds, but this is a local approach and does not apply in our setting since we need a global quadratic bound to apply the squared norm trick [17].

7 CONCLUSION

There were several important techniques used in this paper: 1) the decomposition of the loss into a small positive part and a large but structured negative space; 2) the use of the squared norm trick that reduces the complexity of squared loss computation and 3) the use of the partitioning technique to gradually reduce the gap introduced by the usage of quadratic upper bounds for non-quadratic losses, particularly useful in the case of binary or count data. This combination of techniques can be applied in a broad range of other problems, such as probabilistic CCA, collective-matrix factorization, non-negative matrix factorization, as well as non-factorial models such as time series [7].

Abstract

Several recent algorithms for learning Bayesian network structures first calculate potentially optimal parent sets (POPS) for all variables and then use various optimization techniques to find a set of POPS, one for each variable, that constitutes an optimal network structure. This paper makes the observation that there is useful information implicit in the POPS. Specifically, the POPS of a variable constrain its parent candidates. Moreover, the parent candidates of all variables together give a directed cyclic graph, which often decomposes into a set of strongly connected components (SCCs). Each SCC corresponds to a smaller subproblem which can be solved independently of the others. Our results show that solving the constrained subproblems significantly improves the efficiency and scalability of heuristic search-based structure learning algorithms. Further, we show that by considering only the top p POPS of each variable, we quickly find provably very high quality networks for large datasets.

1 INTRODUCTION

Bayesian networks (BNs) are graphical models that represent uncertain relationships between random variables. While BNs have become one of the most popular and well-studied probabilistic model classes, a common bottleneck lies in deciding upon their structure. Often, experts are unable to completely specify the structure; in these cases, a good structure must be learned from expert knowledge and available data. In this work, we consider the problem of exact, score-based Bayesian network structure learning (BNSL), which is known to be NP-hard (Chickering 1996).

Despite the difficulty of BNSL, though, a variety of algorithms have been proposed which can solve modest-sized learning problems. The first exact algorithms were

based on dynamic programming (Koivisto and Sood 2004; Ott, Imoto, and Miyano 2004; Singh and Moore 2005; Silander and Myllymäki 2006). Later algorithms have used strategies such as integer linear programming (Jaakkola et al. 2010; Cussens 2011; Bartlett and Cussens 2013) and heuristic search (Yuan and Malone 2013; Malone et al. 2011; Malone and Yuan 2013). These algorithms generally take as input the potentially optimal parent sets (POPS) for each variable. They all improve upon dynamic programming by, either implicitly or explicitly, pruning the search space and considering only promising structures.

In this paper, we focus on the heuristic search approach first proposed by Yuan *et al.* (2011) in which BNSL is formulated as a shortest-path finding problem. A state space search strategy like A* or breadth-first branch and bound is then used to solve the transformed problem. Previous work in heuristic search for BNSL has focused on pruning unpromising structures based on bounds derived from admissible heuristic functions. In this work, we show that *POPS constraints*, which are implicit in the problem input, significantly improve the efficiency of the search by pruning large portions of the search space.

The remainder of this paper is structured as follows. Section 2 provides an overview of BNSL and the shortest-path finding formulation of the problem. Section 3 introduces POPS constraints and shows how they can be used to prune the search space. Additionally, we describe a pruning strategy which uses the constraints to trade guaranteed bounded optimality for more scalable performance in Section 4. The POPS constraints also reduce the space required by the heuristics used for pruning during search, as described in Section 5. In Section 6, we compare POPS constraints to related work. Section 7 gives empirical results on a set of benchmark datasets, and Section 8 concludes the paper.

2 BACKGROUND

This section reviews BNSL and the shortest-path finding formulation of the learning problem (Yuan and Malone 2013), which is the basis of our new algorithm.

2.1 BAYESIAN NETWORK STRUCTURE LEARNING

A Bayesian network (BN) consists of a directed acyclic graph (DAG) in which the vertices correspond to a set of random variables $\mathbf{V} = \{X_1, \dots, X_n\}$ and a set of conditional probability distributions $P(X_i|PA_i)$, where all parents of X_i are referred to as PA_i . The joint probability over all variables factorizes as the product of the conditional probability distributions.

We consider the problem of learning a network structure from a discrete dataset $\mathbf{D} = \{D_1, \dots, D_N\}$, where D_i is an instantiation of all the variables in \mathbf{V} . A scoring function s measures the goodness of fit of a network structure to \mathbf{D} (Heckerman 1998). The goal is to find a structure which optimizes the score. We only require that the scoring function is *decomposable* (Heckerman 1998); that is, the score of a network $s(N) = \sum_i s_i(PA_i)$. The $s_i(PA_i)$ values are often called *local scores*. Many commonly used scoring functions, such as MDL (Lam and Bacchus 1994) and BDe (Buntine 1991; Heckerman, Geiger, and Chickering 1995), are decomposable.

2.2 LOCAL SCORES

While the local scores are defined for all 2^{n-1} possible parent sets for each variable, this number is greatly reduced by pruning parent sets that are provably never optimal (de Campos and Ji 2011). We refer to this as *lossless score pruning* because it is guaranteed to not remove the optimal network from consideration. We refer to the scores remaining after pruning as *potentially optimal parent sets* (POPS).

Other pruning strategies, such as restricting the cardinality of parent sets, are also possible, but these techniques could eliminate parent sets which are in the globally optimal network; we refer to pruning strategies which might remove the optimal network from consideration as *lossy score pruning*. Of course, these, and any other, score pruning strategies can be combined.

Regardless of the score pruning strategies used, we still refer to the set of unpruned local scores as POPS and denote the set of POPS for X_i as \mathcal{P}_i . The POPS are given as input to the learning problem. We define the *Bayesian network structure learning* problem (BNSL) as follows.

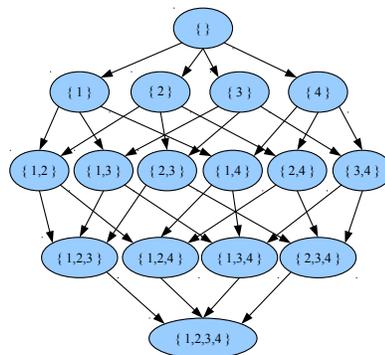

Figure 1: An order graph for four variables.

The BNSL Problem

INPUT: A set $\mathbf{V} = \{X_1, \dots, X_n\}$ of variables and a set of POPS \mathcal{P}_i for each X_i .

TASK: Find a DAG N^* such that

$$N^* \in \arg \min_N \sum_{i=1}^n s_i(PA_i),$$

where PA_i is the parent set of X_i in N and $PA_i \in \mathcal{P}_i$.

2.3 SHORTEST-PATH FINDING FORMULATION

Yuan and Malone (2013) formulated BNSL as a shortest-path finding problem. Figure 1 shows the *implicit* search graph for four variables. The top-most node with the empty variable set is the *start* node, and the bottom-most node with the complete set is the *goal* node. An arc from \mathbf{U} to $\mathbf{U} \cup \{X_i\}$ in the graph represents generating a successor node by adding a new variable X_i as a leaf to an existing subnetwork of variables \mathbf{U} ; the cost of the arc is equal to the score of the optimal parent set for X_i out of \mathbf{U} , which is computed by considering all subsets of the variables in $PA \subseteq \mathbf{U}, PA \in \mathcal{P}_i$, i.e.,

$$\begin{aligned} \text{cost}(\mathbf{U} \rightarrow \mathbf{U} \cup \{X_i\}) &= \text{BestScore}(X_i, \mathbf{U}) \\ &= \min_{PA_i \subseteq \mathbf{U}, PA_i \in \mathcal{P}_i} s_i(PA_i). \end{aligned} \quad (1) \quad (2)$$

In this search graph, each path from *start* to *goal* corresponds to an ordering of the variables in the order of their appearance, so the search graph is also called as *order graph*. Each variable selects optimal parents from the variables that precede it, so combining the optimal parent sets yields an optimal structure for that ordering. The shortest path gives the global optimal structure.

2.4 HEURISTIC SEARCH ALGORITHMS

This shortest path problem has been solved using several heuristic search algorithms, including A* (Yuan, Malone, and Wu 2011), anytime window A* (AWA*) (Malone and Yuan 2013) and breadth-first branch and bound (BF-BnB) (Malone et al. 2011).

In A* (Hart, Nilsson, and Raphael 1968), an admissible heuristic function is used to calculate a lower bound on the cost from a node \mathbf{U} in the order graph to *goal*. An f-cost is calculated for \mathbf{U} by summing the cost from *start* to \mathbf{U} (called $g(\mathbf{U})$) and the lower bound from \mathbf{U} to *goal* (called $h(\mathbf{U})$). For BNSL, $g(\mathbf{U})$ corresponds to the score of the subnetwork over the variables \mathbf{U} , and $h(\mathbf{U})$ estimates the score of the remaining variables. So $f(\mathbf{U}) = g(\mathbf{U}) + h(\mathbf{U})$. The f-cost provides an optimistic estimation on how good a path through \mathbf{U} can be. The search maintains a list of nodes to be expanded sorted by f-costs called *open* and a list of already-expanded nodes called *closed*. Initially, *open* contains just *start*, and *closed* is empty. Nodes are then expanded from *open* in best-first order according to f-costs. Expanded nodes are added to *closed*. As better paths to nodes are discovered, they are added to *open*. Upon expanding *goal*, the shortest path from *start* to *goal* has been found.

In AWA* (Aine, Chakrabarti, and Kumar 2007), a sliding window search strategy is used to explore the order graph over a number of iterations. During each iteration, the algorithm uses a fixed window size, w , and tracks the layer l of the deepest node expanded. For the order graph, the layer of a node corresponds to the number of variables in its subnetwork. Nodes are expanded in best-first order as usual by A*; however, nodes selected for expansion in a layer less than $l - w$ are instead *frozen*. A path to *goal* is found in each iteration, which gives an upper bound solution. After finding the path to *goal*, the window size is increased by 1 and the frozen nodes become *open*. The iterative process continues until no nodes are frozen during an iteration, which means the upper bound solution is optimal. Alternatively, the search can be stopped early if a resource bound, such as running time, is exceeded; the best solution found so far is output.

In BFBnB (Zhou and Hansen 2006), nodes are expanded one layer at a time. Before beginning the BFBnB search, a quick search strategy, such as AWA* for a few iterations or greedy hill climbing, is used to find a “good” network and its score. The score is used as an upper bound. During the BFBnB search, any node with an f-cost greater than the upper bound can safely be pruned.

Yuan *et al.* (2011) gave a simple heuristic function. Later, tighter heuristics based on pattern databases were developed (Yuan and Malone 2012). All of the heuristics were shown to be *admissible*, i.e., to always give a lower bound on the cost from \mathbf{U} to *goal*. Furthermore, the heuristics

have been shown to be *consistent*, which is a property similar to non-negativity required by Dijkstra’s algorithm. Consistent heuristics always underestimate the cost of the path between *any* two nodes (Edelkamp and SchrodL 2012). Primarily, in A*, consistency ensures that the first time a node is expanded, the shortest path to that node has been found, so no node ever needs to be re-expanded.

3 LEARNING UNDER POPS CONSTRAINTS

The main contribution of our current work focuses on taking advantage of the implicit information encoded in the POPS. We will first motivate our approach using a simple example and then describe the technical details.

3.1 A SIMPLE EXAMPLE

Table 1 shows the POPS for six variables. Based on these sets, we can see that not all variables can select all other variables as parents. For example, X_1 can only select X_2 as its parent (due to score pruning). We collect all of the potential parents for X_i by taking the union of all $PA \in \mathcal{P}_i$. Figure 2 shows the resulting *parent relation graph* for the POPS in Table 1. The parent relation graph includes an edge from X_j to X_i if X_j is a potential parent of X_i .

Naively, the complete order graph for six variables contains 2^6 nodes. However, from the parent relation graph, we see that none of $\{X_3, X_4, X_5, X_6\}$ can be a parent of X_1 or X_2 . Consequently, we can split the problem into two subproblems as shown in Figure 3: first, finding the shortest path from *start* to $\{X_1, X_2\}$, and then, finding the shortest path from $\{X_1, X_2\}$ to *goal*. Thus, the size of the search space is reduced to $2^2 + 2^4$.

3.2 ANCESTOR RELATIONS

This simple example shows that the parent relation graph can be used to prune the order graph without bounds. In general, we must consider *ancestor relations* to prune the order graph. In particular, if X_i can be an ancestor of X_j , and X_j cannot be an ancestor of X_i (due to local score pruning), then no node in the order graph which contains X_j but not X_i needs to be generated.

As a proof sketch, we can consider a node \mathbf{U} which includes neither X_i nor X_j . If we add X_i and then X_j , then the cost from \mathbf{U} to $\mathbf{U} \cup \{X_i, X_j\}$ is $BestScore(X_i, \mathbf{U}) + BestScore(X_j, \mathbf{U} \cup \{X_i\})$. On the other hand, if we add X_j first, then the cost from \mathbf{U} to $\mathbf{U} \cup \{X_i, X_j\}$ is $BestScore(X_j, \mathbf{U}) + BestScore(X_i, \mathbf{U} \cup \{X_j\})$. However, due to the ancestor relations, we know that $BestScore(X_i, \mathbf{U} \cup \{X_j\}) = BestScore(X_i, \mathbf{U})$. So, regardless of the order we add the two variables, X_i will have the same parent choices. If we add X_j first, though, then X_j

variable	POPS					
X_1	$\{X_2\}$	$\{\}$				
X_2	$\{X_1\}$	$\{\}$				
X_3	$\{X_1, X_2\}$	$\{X_2, X_6\}$	$\{X_1, X_6\}$	$\{X_2\}$	$\{X_6\}$	$\{\}$
X_4	$\{X_1, X_3\}$	$\{X_1\}$	$\{X_3\}$	$\{\}$		
X_5	$\{X_4\}$	$\{X_2\}$	$\{\}$			
X_6	$\{X_2, X_5\}$	$\{X_2\}$	$\{\}$

will have fewer choices. Therefore, adding X_j as a leaf first can never be better than adding X_i first (Yuan and Malone 2013).

3.3 POPS CONSTRAINTS PRUNING

We find the ancestor relations by constructing the parent relation graph and extracting its strongly connected components (SCCs). The SCCs of the parent relation graph form the *component graph*, which is a DAG (Cormen et al. 2001); each component graph node c_i corresponds to an SCC scc_i from the parent relation graph (which in turn corresponds to a set of variables in the Bayesian network). The component graph includes a directed edge from c_i to c_j if the parent relation graph includes an edge from a variable $X_i \in scc_i$ to $X_j \in scc_j$.

The component graph gives the ancestor constraints: if c_j is a descendent of c_i in the component graph, then variables in scc_j cannot be ancestors of variables in scc_i . Consequently, the component graph gives *POPS constraints* which allow the order graph to be pruned without considering bounds. In particular, the POPS constraints allow us to prune nodes in the order graph which do not respect the ancestor relations.

Tarjan’s algorithm (Tarjan 1972) extracts the SCCs from directed graphs, like the parent relation graph. We chose to use it because, in addition to its polynomial complexity, it

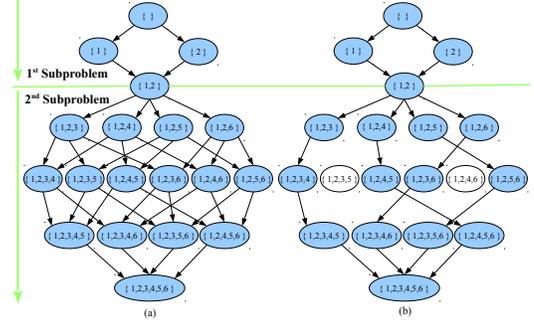

Figure 3: Order graphs after applying the POPS constraints. (a) The order graph after applying the POPS constraints once. (b) The order graph after recursively applying the POPS constraints on the second subproblem.

extracts the SCCs from the parent relation graph consistent with their topological order in the component graph. Consequently, all of the parent candidates of $X \in scc_i$ appear in $\mathbf{PC}_i = \cup_{k=1}^i scc_k$ ¹. After extracting the m SCCs, the search can be split into m independent subproblems: one for each SCC where $start_i$ is \mathbf{PC}_{i-1} and $goal_i$ is \mathbf{PC}_i . That is, during the i^{th} subproblem, we select the optimal parents for the variables in scc_i . Of course, $start_0 = \emptyset$ and $goal_m = \mathbf{V}$. The worst-case complexity of subproblem i is then $O(2^{|scc_i|})$. Figure 3(a) shows the pruned order graph resulting from the parent relation graph in Figure 2. In particular, it shows the first subproblem, from $\mathbf{PC}_0 = \emptyset$ to $\mathbf{PC}_1 = \{X_1, X_2\}$, and the second subproblem, from \mathbf{PC}_1 to $\mathbf{PC}_2 = \mathbf{V}$.

The (worst-case) size of the original order graph for n variables is as follows.

$$O(2^{|scc_1| + \dots + |scc_m|}) = O(2^n) \quad (3)$$

The worst-case size of the search space after splitting into subproblems using the SCCs is as follows.

$$O(2^{|scc_1|} + \dots + 2^{|scc_m|}) = O(m \cdot \max_{|i|} 2^{|scc_i|}) \quad (4)$$

That is, the complexity is at worst exponential in the size of the largest SCC. Consequently, our method can scale to

¹Depending on the structure of the component graph, this may be a superset of the parent candidates for X .

datasets with many variables if the largest SCC is of manageable size.

3.4 RECURSIVE POPS CONSTRAINTS PRUNING

As described in Section 3.3, the size of the search space for the i^{th} subproblem is $O(2^{|scc_i|})$, which can still be intractable for large SCCs. However, recursive application of the POPS constraints can further reduce the size of the search space. We refer to the constraints added by this strategy as *recursive POPS constraints*.

The intuition is the same as that behind the POPS constraints. As an example, consider the subproblem associated with scc_2 in Figure 3, which includes variables X_3 , X_4 , X_5 and X_6 . Naively, the order graph associated with this subproblem has $O(2^4)$ nodes. However, suppose we add variable X_3 as a leaf first. Then, the remaining variables split into three SCCs, and their order is completely determined. Similarly, selecting any of the other variables as the first to add as a leaf completely determines the order of the rest. Figure 3(b) shows the order graph after applying recursive POPS constraints.

In general, selecting the parents for one of the variables has the effect of removing that variable from the parent relation graph. After removing it, the remaining variables may split into smaller SCCs, and the resulting smaller subproblems can be solved recursively. These SCC checks can be implemented efficiently by again appealing to Tarjan’s algorithm. In particular, after adding variable X_i as a leaf from \mathbf{U} , we remove all of those variables from the parent relation graph. We then find the topologically first SCC and expand just the variables in that component. As we recursively explore the remaining variables, they will all eventually appear in the first SCC of the updated parent relation graph.

4 TOP- p POPS CONSTRAINT

As shown in Equation 4, the complexity of the search largely depends on the size of the largest strongly connected component. The recursive splitting described in Section 3.4 helps reduce this complexity, but for large, highly connected SCCs, the subproblems may still be too large to solve. For these cases, we can tradeoff between the complexity of the search and a bound on the optimality of the solution. In particular, rather than constructing the parent relation graph by aggregating *all* of the POPS, we can instead create the graph by considering only the best p POPS for each variable. We consider the minimization version of BNSL, so the best POPS are those with the lowest scores. This yields a set of parent candidates for each variable, and only POPS which are subsets of these parent candidates are retained. The empty set is always a subset of the parent candidates, so some DAG (e.g., the DAG with no edges) is always consistent with the resulting pruned set of POPS. We

call this score pruning strategy the *top- p POPS constraint*.

By removing some of the POPS in this manner, though, we can no longer guarantee to find the globally optimal Bayesian network. That is, this score pruning strategy is lossy. Despite losing the globally optimal guarantee, though, we can still offer a *bounded suboptimality* guarantee. In particular, suppose we apply the top- p POPS constraint and learn a BN N with score $s(N)$ in which X_i selects parents PA_i with score $s_i(PA_i)$. Additionally, suppose the best pruned parent set PA'_i for X_i has score $s_i(PA'_i)$. Then, the most improvement we could have in the score by including the pruned POPS for X_i is $\delta_i = \max(0, s_i(PA_i) - s_i(PA'_i))$. The max is necessary when the selected parent set is better than the best excluded parent set. Consequently, a suboptimality bound ϵ on the score of the unconstrained optimal network relative to $s(N)$ is as follows.

$$\epsilon = \frac{s(N)}{\sum_i (s_i(PA_i) - \delta_i)} \quad (5)$$

When ϵ is 1, N is the globally optimal network.

5 REDUCING THE SPACE REQUIREMENTS OF THE HEURISTIC

In this section we show that the POPS constraints can reduce the space requirements of the lower bound heuristic used during search.

A simple heuristic function was introduced for computing lower bounds for the order graph (Yuan and Malone 2013) which allows each remaining variable to choose optimal parents from all the other variables. This completely relaxes the acyclicity constraint on the BN structure. The heuristic was proven to be admissible, meaning it never overestimates the distance to *goal* (Yuan and Malone 2013). However, because of the complete relaxation of the acyclicity constraint, the simple heuristic may generate loose lower bounds.

5.1 THE k -CYCLE CONFLICT HEURISTIC

In (Yuan and Malone 2012), an improved heuristic function called *k-cycle conflict heuristic* was proposed which reduces the amount of relaxation. The idea is to divide the variables into multiple groups with a size up to k and enforce acyclicity within each group while still allowing cycles between the groups. Each group (subset of variables) is called a *pattern*. One approach to creating the patterns is to divide the variables \mathbf{V} into l approximately equal-sized static subsets \mathbf{V}_i (typically $l = 2$, so $k = n/2$). For each \mathbf{V}_i , a pattern database h_i is created by performing a breadth-first search in a “reverse” order graph in which *start* is \mathbf{V} and *goal* is \mathbf{V}_i . A node \mathbf{U}' in the graph is expanded by removing each of the variables $X \in \mathbf{V}_i$.

An arc from $\mathbf{U}' \cup \{X\}$ to \mathbf{U}' corresponds to selecting the best parents for X from among \mathbf{U}' and has a cost of $BestScore(X, \mathbf{U}')$. The optimal g cost for node \mathbf{U}' gives the cost of the pattern $\mathbf{V} \setminus \mathbf{U}'$. The patterns from different groups are guaranteed to be mutually exclusive, so the heuristic value of a node \mathbf{U} in the order graph is the sum of the pattern costs for the variables remaining in each partition. That is, $h(\mathbf{U}) = \sum_i^l h_i(\mathbf{V}_i \cap (\mathbf{V} \setminus \mathbf{U}))$. This approach is a *statically-partitioned additive pattern database heuristic* (Felner, Korf, and Hanan 2004) referred to as *static pattern databases*. Static pattern databases were shown to be consistent (Yuan and Malone 2013).

5.2 CREATING PATTERN DATABASES FOR SUBPROBLEMS

As described in Section 3, the search is split into an independent subproblem for each SCC. Furthermore, using Tarjan’s algorithm, the SCCs are ordered according to their topological order in the component graph. Consequently, we construct static pattern databases using a similar strategy as before. Namely, each SCC is partitioned into l groups $scc_i = scc_{i1} \dots scc_{il}$ (typically $l = 2$). For each partition, a pattern database h_{ik} is created. For h_{ik} , the pattern costs are calculated using a breadth-first search in a reverse order graph in which *start* is $\mathbf{PC}_{i-1} \cup scc_{ik}$ and *goal* is \mathbf{PC}_{i-1} . The arc costs in this graph are $BestScore(X, (\bigcup_{j \neq k} scc_{ij}) \cup \mathbf{U})$. Thus, the heuristic value from \mathbf{U} to \mathbf{PC}_i , referred to as h_1 , is as follows.

$$h_1(\mathbf{U}) = \sum_k^l h_{ik}(scc_{ik} \cap (\mathbf{V} \setminus \mathbf{U})) \quad (6)$$

The pattern databases are constructed at the beginning of the search based on the parent relation graph. That is, new pattern databases are not created for recursive subproblems.

The pattern databases based on the SCCs are typically smaller than those previously proposed for the entire space. The space complexity of pattern databases created based on l balanced partitions is $O(l \cdot 2^{n/l})$. On the other hand, the space complexity of pattern databases created based on l balanced partitions separately for m SCCs of size $O(\max_{|scc_i|} 2^{|scc_i|})$ is $O(m \cdot \max_{|scc_i|} 2^{|scc_i|/l})$. Thus, the space complexity of the pattern databases based on the SCCs is less than that based on the balanced partitions alone, unless there is only one SCC. In that case, the space complexity is the same.

5.3 CALCULATING THE HEURISTIC VALUE

The heuristic value for node \mathbf{U} in the subproblem for scc_i is calculated in two steps. We first calculate $h_1(\mathbf{U})$, the heuristic value from \mathbf{U} to \mathbf{PC}_i , using the the pattern databases described in Section 5.2. Second, we calculate

$h_2(\mathbf{U})$, the estimated distance from \mathbf{PC}_i to \mathbf{V} , as follows.

$$h_2(\mathbf{U}) = \sum_{j=i+1}^m h_1(scc_j) \quad (7)$$

That is, the h_2 value is the sum of h_1 values for the start nodes of the remaining subproblems. Due to the POPS constraints, none of these variables will have been added as leaves when considering the i^{th} subproblem. The total heuristic value is then $h'(\mathbf{U}) = h_1(\mathbf{U}) + h_2(\mathbf{U})$. The h_2 values are the same for all nodes in the i^{th} subproblem, so they can be precomputed.

Theorem 1. *The new heuristic h' is consistent.*

Proof. We prove the theorem by showing that both h_1 and h_2 are consistent. The consistency of h_1 follows from the consistency of the static pattern databases (Yuan and Malone 2013). The h_2 value is a sum of h_1 values for mutually exclusive patterns, so it is also consistent. Therefore, the entire heuristic is consistent. \square

6 RELATED WORK

The parent relation graph is, in effect, a *directed superstructure*. Consequently, the work presented in this paper is quite related to the work dealing with superstructures. To the best of our knowledge, Ordyniak and Szeider (2013) are the only other authors to consider *directed* superstructures. They prove that BNSL is solvable in polynomial time for acyclic directed superstructures; our algorithm agrees with this theoretical result because, if the parent relation graph is acyclic, then it will have n SCCs of size 1. Thus, the complexity of our algorithm would be $O(n)$.

The work on undirected superstructures, e.g., (Perrier, Imoto, and Miyano 2008), is also related to our work. Any undirected superstructure can be translated into a parent relation graph by replacing the undirected edges in the superstructure with directed edges in both directions. However, edges directed in only one direction give an order to the SCCs which further reduce the search space. So, our algorithm leverages all of the information available from the undirected superstructure, but further makes use of constraints those structures cannot express.

Recently, Parviainen and Koivisto (2013) explored precedence constraints, which are similar to our POPS constraints. In their work, ideals of partial orders on the variables are used to reduce the search space of dynamic programming for BNSL. This approach is similar in spirit to our use of the component graph to reduce the search space. In fact, the component graph could be used to reduce the search space of dynamic programming. However, after selecting the ideals, they are fixed. So the recursive decomposition described in Section 3.4 is not compatible with the ideals formulation. Experimentally, we show that the

recursive application of constraints is important for some datasets.

Integer linear programming (ILP) (Bartlett and Cussens 2013) is another successful strategy for BNSL. A recent study (Malone et al. 2014) found that the performances of ILP and heuristic search are largely orthogonal, particularly with respect to the number of POPS. Consequently, this work has focused on improvements to heuristic search. Nevertheless, the component graph is readily applicable to ILP by similarly creating subproblems and solving them with independent ILP instances. Indeed, an interesting avenue for future research is to dynamically select between ILP and heuristic search for each subproblem.

6.1 EXPERT KNOWLEDGE CONSTRAINTS

The formulation of BNSL as an optimization over POPS gives a natural method for including expert knowledge in the form of hard constraints on the structure to be learned, such as those proposed by, e.g., (de Campos and Ji 2011). In particular, given expert knowledge about required or forbidden parent relationships and maximum parent set cardinalities, we omit POPS which violate these constraints. The POPS constraints automatically prune the parts of the search space which violate the expert knowledge.

In general, hard expert knowledge constraints are lossy because they could disallow parent sets which would appear in an optimal structure based solely on the data and scoring function. Nevertheless, we still consider the network learned under expert knowledge constraints as optimal. For cases in which we use expert knowledge constraints and the top- p POPS constraint, parent sets disallowed by the expert knowledge constraints are not considered in the suboptimality bound calculation in Equation 5.

7 EMPIRICAL EVALUATION

In order to evaluate the efficacy of the POPS constraints and top- p POPS constraint, we ran a set of experiments on benchmark datasets from the UCI machine learning repository² and the Bayesian network repository³. We generated 1,000 records from the benchmark networks in the repository using logic sampling. The experiments were performed on an IBM System x3850 X5 with 16 2.67GHz Intel Xeon processors and 512G RAM; 1TB disk space was used. Our code is available online⁴.

Several heuristic search algorithms have been adapted for BNSL. We chose to evaluate A* (Yuan, Malone, and Wu 2011) because of its guarantee to expand a minimal number of nodes; AWA* (Malone and Yuan 2013) because it

has been shown to find high quality, often optimal, solutions very quickly; and breadth-first branch and bound (BF-BnB) (Malone et al. 2011) because it has been shown to scale to larger datasets by using external memory. We used MDL as the scoring function. In all cases, we used static pattern databases; the variable groups were determined by partitioning the parent relation graph after applying the top- $p = 1$ POPS constraint (Fan, Yuan, and Malone 2014). Pattern database construction occurs only once after constructing the parent relation graph.

7.1 POPS CONSTRAINTS

We first tested the effect of the POPS constraints, which always guarantee learning the globally optimal structure. Table 2 compares the original version of each algorithm to versions using the POPS constraints.

We first considered three variants of A*: a basic version not using POPS constraints; a version using the POPS constraints but not applying them recursively as described in Section 3.4; and a version which uses the recursive POPS constraints. As the table shows, the versions of A* augmented with the POPS constraints always outperform the basic version. The improvement in running time ranges from two times on several of the datasets to over an order of magnitude on three of the datasets. Additionally, the basic version is unable to solve Mildew, Soybean and Barley within the time limit (30 minutes); however, with the POPS constraints, all of the datasets are easily solved within the limit. The number of nodes expanded, and, hence, memory requirements, are similarly reduced.

The recursive POPS constraints always reduce the number of nodes expanded⁵. However, it sometimes increases the running time. The overhead of Tarjan’s algorithm to recursively look for SCCs is small; however, in some cases, such as when the parent relation graph is dense, the additional work yields minimal savings. In these cases, despite the reduction in nodes expanded, the running time may increase.

On the other hand, when the parent relation graph is sparse, the advantages of the recursive POPS constraints are sometimes more pronounced. For example, the running time of Mildew is reduced in half by recursively applying POPS constraints. Most networks constructed by domain experts, including those evaluated in this study, are sparse. Our analysis shows that these datasets also yield sparse parent relation graphs. Thus, our results suggest that the recursive constraints are sometimes effective when the generative process of the data is sparse. The overhead of looking for the recursive POPS constraints is minimal, and it sometimes offers substantial improvement for sparse generative processes. So we always use it in the remaining experiments.

⁵For some datasets, the precision shown in the table is too coarse to capture the change.

Table 2: The number of expanded nodes (in millions) and running time (in seconds) of A*, AWA* and BFBnB with/without the POPS constraints on a set of benchmark datasets. “n” gives the number of variables in the dataset, “N” gives the number of records in the dataset, “POPS” gives the number of POPS after lossless pruning, “Density” gives the density of the parent relation graph constructed from the POPS (defined as the number of edges divided by the number of possible edges), and “PD” gives the time (in seconds) to construct the pattern database. “A*,O” gives the statistics for A* using the POPS constraints, but not applying them recursively. “A*,R” gives the statistics for A* using the recursive POPS constraints. Similarly, “AWA*”, “AWA*, R”, “BFBnB” and “BFBnB, R” refer to the respective basic algorithms or the algorithm using recursive POPS constraints. “*” indicates the dataset was generated from a repository network using logic sampling; all other datasets are from UCI. OT means out of time (30 minutes).

The anytime window A* algorithm enjoyed improvements similar to those seen in A*. As the table shows, A* always expanded fewer nodes than AWA*; nevertheless, the runtimes of AWA* are often shorter than those of A*. This is because AWA* performs a series of iterations, and *open* is cleared after each of those iterations. Consequently, the associated priority queue operations are often faster for AWA* than A*.

A key factor in the performance for BFBnB is the upper bound it uses for pruning. Previous results (Malone and Yuan 2013) have shown that AWA* is effective at finding high quality solutions quickly, so we found the bound by running AWA* for 5 seconds on datasets with less than 35 variables and 10 seconds for larger datasets. AWA* used the POPS constraints when BFBnB used them. BFBnB exhibited improvements in line with those for A* and AWA*.

7.2 TOP- p POPS CONSTRAINT

We tested AWA* on the dataset Hailfinder, which has 56 variables. Even when using the recursive POPS constraints, though, AWA* was unable to prove optimality within the 30-minute time limit. Therefore, we used this dataset to test the effect of the top- p POPS constraint by varying p from 1 to 13. The upper bound on p was set to 13 because AWA* was unable to complete within the time limit for $p = 13$.

Primarily, we evaluated the running time and associated suboptimality bound as we increased p (which has the effect of pruning fewer POPS). As Figure 4 (top) shows, the recursive order constraints are quite effective under the top- p POPS constraint; the constrained problems are solved in under 15 seconds for p up to 12, and the provable suboptimality bound calculated using Equation 5 decreases very

rapidly. This provable suboptimality between the learned network and global optimum is less than 1% even when p is only 7.

The suboptimality bound usually decreases as p increases. From $p = 7$ to $p = 8$, though, it slightly increases; the scores of the learned networks were the same (not shown). This is a result of equivalence classes of Bayesian networks. The suboptimality bound calculation in Equation 5 focuses on parent sets of individual variables, so it is sensitive to which member of an equivalence class the algorithm learns. Future work could investigate tightening the bound by considering all members in the same equivalence class as the learned network.

As mentioned, AWA* was unable to find the provably optimal network under the $p = 13$ constraint. Equation 4 suggests that the size of the largest SCC in the parent relation graph is a key factor in determining the difficulty of an instance of BNSL. However, the recursive POPS constraints offer the potential to split large SCCs after considering a few of their variables. Figure 4 (middle) shows that the size of the largest SCC does substantially increase from $p = 12$ to $p = 13$, which empirically confirms our theoretical result. Somewhat unexpectedly, though, the figure also shows that the density of the parent relation graph does not significantly increase as more POPS are included. So, at least in this case, despite the sparsity of the parent relation graph, the recursive order constraints are unable to break the large SCC into manageable subproblems. This result agrees with those in Table 2 which show that sparsity does not necessarily indicate the efficacy of the recursive POPS constraints.

In addition to the characteristics of the parent relation graph, we also considered the number of POPS included as p in-

creases. Figure 4 (bottom) shows that the number of included POPS follows a similar trend to the density of the parent relation graph. That is, even as p increases, more POPS are not necessarily included for all variables. This is because we already include all subsets of parent candidates from the top p POPS at earlier iterations. Additionally, the number of POPS (479 when $p = 13$) is quite small for this dataset, although the number of variables is relatively large (56). Previous studies (Malone and Yuan 2013) have shown that basic heuristic search methods struggle with datasets like this; however, when augmented with the POPS constraints, heuristic search very quickly finds a network that is provably quite close to optimal. This result clearly shows that the POPS constraints significantly expand the applicability of heuristic search-based structure learning.

Despite the inability of AWA* to find the provably optimal network under the top- p POPS constraint when $p = 13$, we can nevertheless take advantage of its anytime behavior to calculate a suboptimality bound. At each iteration, AWA* produces an optimal network with respect to its current window size. We can then use Equation 5 to bound the suboptimality of the learned network. In principle, this even suggests that we may be able to prove global optimality before completing the AWA* search, although this likely would require a tighter bound under the top- p POPS constraint than the naive one proposed in this paper.

Even for very small values of p , though the top- p POPS constraint results in networks provably very close to the globally optimal solution. In order to more thoroughly understand why such constrained problems still give provably very high quality solutions, we plotted the scores of the top p POPS for variable X_{37} from Hailfinder in Figure 5. The figure shows that the first 4 scores are much better than the remaining ones; consequently, the globally optimal network is more likely to include one of these parent sets for X_{37} than the others, which are much worse. Most of the other variables behaved similarly; consequently, p does not need to be very large to still encompass most of the parent selections in the globally optimal network.

8 CONCLUSION

In this work, we have shown how POPS constraints, which are implicit in the input to a BNSL instance, can significantly improve the performance of heuristic search on the problem. Other algorithms, such as integer linear programming, can also benefit from the POPS constraints. We also introduced the top- p POPS constraint and showed how it can be used to further take advantage of the POPS constraints while still providing guaranteed error bounds. Empirically, we showed that the POPS constraints are practically effective and that the top- p POPS constraint can yield provably very high quality solutions very quickly. Future work includes more thorough empirical evaluation and comparison with other BNSL techniques as well as investigation into conditions when the POPS constraints are most effective.

Abstract

Bisimulation is a notion of behavioural equivalence on the states of a transition system. Its definition has been extended to Markov decision processes, where it can be used to aggregate states. A bisimulation metric is a quantitative analog of bisimulation that measures how similar states are from the perspective of long-term behavior. Bisimulation metrics have been used to establish approximation bounds for state aggregation and other forms of value function approximation. In this paper, we prove that a bisimulation metric defined on the state space of a Markov decision process is the optimal value function of an optimal coupling of two copies of the original model. We prove the result in the general case of continuous state spaces. This result has important implications in understanding the complexity of computing such metrics, and opens up the possibility of more efficient computational methods.

1 INTRODUCTION

Markov decision processes (MDPs) are a popular mathematical model for sequential decision-making under uncertainty (Puterman, 1994; Sutton & Barto, 2012). Many standard solution methods are based on computing or learning the optimal value function, which reflects the expected return one can achieve in each state by choosing actions according to the optimal policy. In finite MDPs, the optimal value function is guaranteed to be unique, and has at least one deterministic optimal policy associated with it.

A major challenge is how to deal with large, possibly continuous, state spaces, known more colourfully as *the curse of dimensionality* or *the state-space explosion problem*.

† Doina Precup's contribution was supported by NSERC.

Briefly, the number of parameters necessary to represent the value function scales exponentially with the number of state variables. In response to this issue, a number of researchers have advocated the use of metrics, which can be used to determine similarity between states, and cluster them accordingly. Ideally, one would like such a clustering to reflect similarity among states in terms of the value function, which reflects the long-term cumulative reward.

In the formal verification community, a similar problem arises in the analysis of transition systems, in which one wants to establish long-term properties (e.g., the probability that the system may enter a faulty state, or that a certain trajectory would terminate). Many researchers advocate tackling such problems by using approximation metrics based on strong probabilistic bisimulation. Bisimulation is a conservative behavioural equivalence between states: states that are bisimilar will have the same long-term behaviour (Larsen & Skou, 1991; Givan et al., 2003). Corresponding metrics are useful in order to measure state similarity, and are used both to directly aggregate system states and more generally to assess the quality of an approximation. Abate (2012) surveys historical and more recent developments in this area.

In the context of MDPs, such metrics - henceforth known as *bisimulation metrics* - were developed in (Ferns et al., 2004; Ferns et al., 2005; Ferns et al., 2011) based on the work of Desharnais et al. (2002; 2001a) for a related Markov transition system. In (Ferns et al., 2006), the authors experimentally compared several methods for estimating these metrics on small finite MDPs, with a Monte Carlo approach outperforming the others. However, the analyses therein were limited, lacking, for example, any sample complexity results.

The purpose of this work is to strengthen and unify theoretical and practical results for bisimulation metrics on a given MDP by showing that they are in fact the optimal value functions of an optimal coupling of that MDP with itself (Theorem 3.3). We establish this result in the general setting of continuous-state MDPs. To our knowledge, this is an original result, which both improves our under-

standing of bisimulation metrics in general, and opens up avenues of attack for more efficient computation.

The paper is organized as follows. In Section 2, we provide a brief summary of MDPs, optimal control theory, and bisimulation metrics on continuous spaces. In Section 3, we use a measurable selection theorem to prove the main result, and in Section 4 we relate the results we present to existing work within the artificial intelligence and formal verification communities. Finally, in Section 5, we discuss the implications of our result and directions for future research.

2 BACKGROUND

Since we deal primarily with uncountably infinite state spaces, we must take into account the tension between imposing the right amount of structure on a space for general theoretical usefulness and imposing the right amount of structure for useful practical applications. For that reason, much of the work on Markov processes has been cast in the setting of Polish spaces. The introductory chapter of (Doberkat, 2007) contains a self-contained exposition of probabilities on Polish spaces in the context of computer science. A more comprehensive mathematical description can be found in (Srivastava, 2008). By contrast, a gentler introduction to probabilities on continuous spaces can be found in the first four chapters of (Folland, 1999). We refer the reader to these three sources for the basic mathematical definitions that we present throughout.

2.1 PROBABILITIES ON METRIC SPACES

A *Polish metric space* is a complete, separable metric space. A *Polish space* is a topological space that is homeomorphic to a Polish metric space. A *standard Borel space* is a measurable space that is Borel isomorphic to a Polish space.

If (X, τ) is a topological space, then $\mathbb{C}^b(X)$ is the set of continuous bounded real-valued functions on X . If (X, \mathcal{B}_X) is a standard Borel space then we denote by $\mathbb{B}^b(X)$ the space of bounded measurable real-valued functions on X , and by $\mathbb{P}(X)$ the set of probability measures on X ; note that the latter is also a standard Borel space (Giry, 1982).

2.2 DISCOUNTED MARKOV DECISION PROBLEMS

Let (X, \mathcal{B}_X) and (Y, \mathcal{B}_Y) be standard Borel spaces. A *Markov kernel* is a Borel measurable map from (X, \mathcal{B}_X) to $(\mathbb{P}(Y), \mathcal{B}_{\mathbb{P}(Y)})$. Equivalently, K is a Markov kernel from X to Y iff $K(x)$ is a probability measure on (Y, \mathcal{B}_Y) for each $x \in X$, and $x \mapsto K(x)(B)$ is a measurable map for each $B \in \mathcal{B}_Y$.

Remark 1. *The use of the term kernel here should not be confused with the usual meaning, that being the set of points in the domain of a real-valued function that send the function to 0. We will refer to kernel in both senses throughout, with the meaning clear from the context.*

We will denote the set of all Markov kernels from X to Y by $\llbracket X \rightarrow \mathbb{P}(Y) \rrbracket$ and simply write “ K is a Markov kernel on X ” when it is implicitly assumed that $Y = X$. If I is an index set and $K = (K_i)_{i \in I}$ is an I -indexed collection of Markov kernels on X , we will say that “ K is a labelled Markov kernel on X ”. Such kernels play the role of transition relations in stochastic transition systems with continuous state spaces.

A *Markov decision process (MDP)* is a tuple $(S, \mathcal{B}_S, A, (P_a)_{a \in A}, r)$, where (S, \mathcal{B}_S) is a standard Borel space, A is a finite set of actions, $r : A \times S \rightarrow \mathbb{R}$ is a bounded measurable reward function, and for $a \in A$, P_a is a Markov kernel on S .

For each $a \in A$, we denote by $r_a : S \rightarrow \mathbb{R}$ the function defined by $r_a(s) = r(a, s)$, and for each $a \in A$ and $s \in S$. We use functional notation for integration with respect to $P_a(s)$, i.e. the integral of $f \in \mathbb{B}^b(S)$ with respect to $P_a(s)$ will be written as $P_a(s)(f)$.

A Markov decision process along with an optimality criterion is known as a *Markov decision problem*. In this work, we focus on Markov decision problems with the *expected total discounted reward optimality criterion*, which we now briefly describe based on (Hernández-Lerma & Lasserre, 1996) and especially Section 8.3 of (Hernández-Lerma & Lasserre, 1999). We rely on these sources instead of others who may be more familiar to the AI audience because they treat the infinitely uncountable state space setting. We direct the reader to these sources for full details.

Fix an MDP $\mathcal{M} = (S, \mathcal{B}_S, A, (P_a)_{a \in A}, r)$ and a discount factor $\gamma \in (0, 1)$. Let $t \in \mathbb{N}$. Then H_t , the family of *histories up to time t* , is defined by $H_0 = S$ and $H_{t+1} = H_t \times (A \times S)$ for $t \in \mathbb{N}$. An element $h_t = (s_0, a_0, \dots, s_{t-1}, a_{t-1}, s_t) \in H_t$ is called a *t -history*. A *randomized control policy* is a sequence of Markov kernels $\pi = (\pi_t)_{t \in \mathbb{N}}$ such that $\pi_t \in \llbracket H_t \rightarrow \mathbb{P}(A) \rrbracket$ for all $t \in \mathbb{N}$. The set of all policies is denoted by Π . A policy $\pi = (\pi_t)_{t \in \mathbb{N}}$ is said to be a *randomized stationary policy* if there exists a Markov kernel $\varphi \in \llbracket S \rightarrow \mathbb{P}(A) \rrbracket$ such that $\pi_t(h_t) = \varphi(s_t)$ for all $h_t \in H_t, t \in \mathbb{N}$, and a *deterministic stationary policy* if there exists a measurable selector f for $S \times A$ such that $\pi_t(h_t)$ is the Dirac measure at the point $f(s_t) \in A$ for all $h_t \in H_t, t \in \mathbb{N}$. We denote the sets of randomized stationary policies and deterministic stationary policies by Π_{RS} and Π_{DS} respectively and note that $\Pi_{DS} \subseteq \Pi_{RS} \subseteq \Pi$.

Let $\pi \in \Pi$ be a policy on \mathcal{M} . The *γ -discounted value function* for π , $V_\gamma(\pi)$, is defined by $V_\gamma(\pi)(s) =$

$\mathbb{E}_s^\pi[\sum_{t=0}^\infty \gamma^t r(a_t, x_t)]$ for all $s \in S$, where \mathbb{E}_s^π is the expectation taken with respect to the system dynamics when starting in state s and following policy π . The goal of this Markov decision problem is to find a policy whose value function dominates all others. Toward that end, one defines the γ -discounted optimal value function, V_γ^* , by $V_\gamma^*(s) = \sup_{\pi \in \Pi} V_\gamma(\pi)(s)$ for all $s \in S$, and the Bellman operator with respect to γ , $T_\gamma : \mathbb{B}^b(S) \rightarrow \mathbb{B}^b(S)$, by $T_\gamma(v)(s) = \max_{a \in A} [r_a(s) + \gamma \cdot P_a(s)(v)]$ for all $s \in S$. The following can be found within Theorem 8.3.6 and its preceding remarks in (Hernández-Lerma & Lasserre, 1999).

Theorem 2.1 (Value Iteration). *Define $(v_n)_{n \in \mathbb{N}} \subseteq \mathbb{B}^b(S)$ by $v_0(s) = 0$ for all $s \in S$ and $v_{n+1} = T_\gamma(v_n)$ for all $n \in \mathbb{N}$. Then the optimal value function V_γ^* is the unique solution in $\mathbb{B}^b(S)$ to the Bellman optimality equation $v = T_\gamma(v)$; $(v_n)_{n \in \mathbb{N}}$ converges uniformly to V_γ^* with $\|v_n - V_\gamma^*\| \leq \gamma^{-n}(1 - \gamma)$ for all $n \in \mathbb{N}$ and where $\|\cdot\|$ is the uniform norm; and there exists a deterministic stationary optimal policy $\pi^* \in \Pi_{DS}$ such that $V_\gamma^* = V_\gamma(\pi^*)$.*

We note that although Theorem 2.1 implies it is sufficient to search Π_{DS} for an optimal policy, in practice it is often useful to work with the larger class Π_{RS} . On the other hand, for more general theoretical considerations, e.g. other optimality criteria, we may need to consider all of Π .

2.3 BISIMULATION

We present bisimulation for MDPs as outlined in (Ferns et al., 2011).

Given an equivalence relation R on a measurable space (S, Σ) , a subset X of S is said to be R -closed if X is a union of R -equivalence classes. We write $\Sigma(R)$ for the set of those Σ -measurable sets that are also R -closed.

Let $(S, \mathcal{B}_S, A, (P_a)_{a \in A}, r)$ be an MDP. An equivalence relation R on S is a *bisimulation relation* if it satisfies $sRs' \iff$ for every $a \in A$, $r_a(s) = r_a(s')$ and for every $X \in \Sigma(R)$, $P_a(s)(X) = P_a(s')(X)$. *Bisimilarity* is the largest of the bisimulation relations.

2.4 THE KANTOROVICH METRIC

In order to define bisimulation metrics for MDPs, we first need to recall the definition and properties of the Kantorovich metric between distributions, which can be found in (Villani, 2003).

Definition 1 (Kantorovich Metric). *Let S be a Polish space, h a bounded pseudometric on S that is lower semi-continuous on $S \times S$ with respect to the product topology, and let $Lip(h)$ be the set of all $f \in \mathbb{B}^b(S)$ that satisfy the Lipschitz condition $f(x) - f(y) \leq h(x, y)$ for every $x, y \in S$. Let $P, Q \in \mathbb{P}(S)$. Then the Kantorovich metric $\mathcal{K}(h)$ is defined by $\mathcal{K}(h)(P, Q) = \sup_{f \in Lip(h)} (P(f) - Q(f))$.*

The Kantorovich metric is an infinite linear program and has a dual described in terms of couplings of probability measures.

Definition 2 (Coupling). *Let (X, \mathcal{B}_X) and (Y, \mathcal{B}_Y) be standard Borel spaces, and let $(X \times Y, \mathcal{B}_X \otimes \mathcal{B}_Y)$ be the product space. Let $\mu \in \mathbb{P}(X)$, $\nu \in \mathbb{P}(Y)$, and $\lambda \in \mathbb{P}(X \times Y)$. Then λ is a coupling of μ and ν if and only if its marginals on X and Y are μ and ν , respectively. We denote the set of all couplings of μ and ν by $\Lambda(\mu, \nu)$, i.e., $\lambda \in \Lambda(\mu, \nu) \iff \lambda(E \times Y) = \mu(E)$ and $\lambda(X \times F) = \nu(F)$ for all $E \in \mathcal{B}_X, F \in \mathcal{B}_Y$.*

The following is found within Section 1.1.1 of (Villani, 2003).

Lemma 2.2. *Let X and Y be Polish spaces and let μ and ν belong to $\mathbb{P}(X)$ and $\mathbb{P}(Y)$, respectively. Then $\lambda \in \Lambda(\mu, \nu)$ if and only if for every $(\varphi, \psi) \in \mathcal{C}^b(X) \times \mathcal{C}^b(Y)$*

$$\begin{aligned} \int_{X \times Y} [\varphi(x) + \psi(y)] \lambda(dx, dy) \\ = \int_X \varphi(x) \mu(dx) + \int_Y \psi(y) \nu(dy). \end{aligned}$$

In Section 3, we'll make use of the following simple lemma.

Lemma 2.3. *Let X and Y be Polish spaces and let μ and ν belong to $\mathbb{P}(X)$ and $\mathbb{P}(Y)$, respectively. Then $\Lambda(\mu, \nu)$ is a closed subset of $\mathbb{P}(X \times Y)$.*

Proof. Let $(\lambda_n)_{n \in \mathbb{N}} \subseteq \Lambda(\mu, \nu)$ be a sequence converging to some $\lambda \in \mathbb{P}(X \times Y)$ in the weak topology. Let $(\varphi, \psi) \in \mathcal{C}^b(X) \times \mathcal{C}^b(Y)$. Then

$$\begin{aligned} \int_{X \times Y} [\varphi(x) + \psi(y)] \lambda(dx, dy) \\ = \lim_{n \rightarrow \infty} \left(\int_{X \times Y} [\varphi(x) + \psi(y)] \lambda_n(dx, dy) \right) \\ = \lim_{n \rightarrow \infty} \left(\int_X \varphi(x) \mu(dx) + \int_Y \psi(y) \nu(dy) \right) \\ = \int_X \varphi(x) \mu(dx) + \int_Y \psi(y) \nu(dy). \end{aligned}$$

Here we have used the definition of weak convergence, as well as Lemma 2.2 for each λ_n . It follows from the same lemma that $\lambda \in \Lambda(\mu, \nu)$. \square

The following can be found in Theorem 1.3 and the proof of Theorem 1.14 in (Villani, 2003).

Theorem 2.4 (Kantorovich-Rubinstein Duality Theorem). *Assume the conditions of Definition 1. Then $\mathcal{K}(h)(P, Q)$ is equal to*

$$\sup_{f \in Lip(h, \mathcal{C}^b(S))} (P(f) - Q(f)) = \inf_{\lambda \in \Lambda(P, Q)} \lambda(h)$$

where $\text{Lip}(h, \mathbb{C}^b(S))$ denotes functions on S that are continuous and bounded, 1-Lipschitz with respect to h , and have range $[0, \|h\|]$. Moreover, the supremum and infimum are attained.

2.5 BISIMULATION METRICS

The following can be found in Theorem 3.12 of (Ferns et al., 2011) and Corollary 3 of (Ferns et al., 2014).

Theorem 2.5. *Let $\mathcal{M} = (S, \mathcal{B}_S, A, (P_a)_{a \in A}, r)$ be an MDP and let $c \in (0, 1)$ be a discount factor. Assume that the image of r is contained in $[0, 1]$. Then there exists a Polish topology τ generating \mathcal{B}_S such that for all $a \in A$, r_a is continuous with respect to τ and P_a is weakly continuous with respect to τ . Define $\theta^c : A \times (S \times S) \rightarrow [0, 1]$ by $\theta_a^c(x, y) = (1 - c)|r_a(x) - r_a(y)|$. Furthermore, let $\text{ls}\mathfrak{c}_m$ be the set of bounded pseudometrics on S that are lower semicontinuous on $S \times S$ endowed with the product topology induced by τ . Define $F_c : \text{ls}\mathfrak{c}_m \rightarrow \text{ls}\mathfrak{c}_m$ by setting $F_c(\rho)(s, s')$ equal to*

$$\max_{a \in A} \left[\theta_a^c(s, s') + c \cdot \mathcal{K}(\rho)(P_a(s), P_a(s')) \right]$$

Then F_c has a unique 1-bounded fixed-point pseudometric $\rho_c^* \in \mathbb{C}^b(S \times S)$ whose kernel is bisimilarity.

We call such a metric a *bisimilarity metric*, and more generally a *bisimulation metric* if its kernel is a bisimulation relation (but not necessarily the largest). The following result, Theorem 3.20 in (Ferns et al., 2011), relates the optimal values of states to their similarity as measured by the bisimulation metric.

Theorem 2.6. *Assume the setup and result of Theorem 2.5. Let $\gamma \in (0, c]$ be a reward discount factor and let V_γ^* be the optimal value function defined in Theorem 2.1. Then V_γ^* is Lipschitz continuous with respect to ρ_c^* with Lipschitz constant $(1 - c)^{-1}$, i.e., for all $s, s' \in S$,*

$$|V_\gamma^*(s) - V_\gamma^*(s')| \leq (1 - c)^{-1} \rho_c^*(s, s')$$

Since bisimulation is a behavioural equivalence, this result implies that the closer two states are in bisimilarity distance, the more likely they are to share the same optimal actions, and hence optimal policies, for achieving the same optimal values.

3 A BISIMULATION VALUE FUNCTION

Let $\mathcal{M} = (S, \mathcal{B}_S, A, (P_a)_{a \in A}, r)$ be an MDP with the image of r contained in $[0, 1]$ and let $c \in (0, 1)$ be a discount factor. The goal of this section is to show that the bisimilarity metric ρ_c^* given by Theorem 2.5 can be expressed as the optimal value function of some MDP. In order to do so, let us first extend the definition of a coupling of two probability measures to a coupling of two labelled Markov kernels in the obvious way.

Definition 3. *Let (X, \mathcal{B}_X) and (Y, \mathcal{B}_Y) be standard Borel spaces, and let $(X \times Y, \mathcal{B}_X \otimes \mathcal{B}_Y)$ be the product space. Let I be an index set, and let $K = (K_i)_{i \in I}$, $L = (L_i)_{i \in I}$, and $M = (M_i)_{i \in I}$ be labelled Markov kernels on X , Y , and $X \times Y$, respectively. Then M is a coupling of K and L if and only if for each $i \in I$, $x \in X$, and $y \in Y$, $M_i(x, y)$ is a coupling of $K_i(x)$ and $L_i(y)$ in the sense of Definition 2. We denote the set of all couplings of K and L by $\Lambda(K, L)$.*

Recall that ρ_c^* is the unique solution to the fixed-point equation

$$\rho_c^*(x, y) = \max_{a \in A} [\theta_a^c(s, s') + c \cdot \mathcal{K}(\rho_c^*)(P_a(x), P_a(y))].$$

Here is the crucial fact: Theorem 2.4 remarkably not only provides a statement of duality for each Kantorovich linear program $\mathcal{K}(\rho_c^*)(P_a(x), P_a(y))$, but guarantees the existence of minimizers in the minimization linear program as well. Therefore, for every $a \in A$ and $x, y \in S$ there exists $\lambda_{axy} \in \Lambda(P_a(x), P_a(y))$ such that $\mathcal{K}(\rho_c^*)(P_a(x), P_a(y)) = \lambda_{axy}(\rho_c^*)$. Suppose for every $a \in A$ the map from $S \times S$ to $\mathbb{P}(S \times S)$ that sends (x, y) to λ_{axy} is measurable. Then ρ_c^* would satisfy the Bellman optimality equation defined in Theorem 2.1 for the optimal value function with discount factor c for the MDP $(S \times S, \mathcal{B}_{S \times S}, A, (\lambda_a)_{a \in A}, \theta^c)$ where $\lambda_a(x, y) = \lambda_{axy}$. Remark that such a $\lambda = (\lambda_a)_{a \in A}$ is a coupling of P with P , where $P = (P_a)_{a \in A}$. Thus, if we can find a measurable way of selecting the minimizers amongst all the Kantorovich linear programs appearing in the definition of ρ_c^* , we will have shown that the bisimilarity metric is actually the optimal value function of an MDP whose labelled Markov kernel is a coupling of two copies of the labelled Markov kernel of the original model. This is our goal.

3.1 MEASURABLE SELECTORS AND SECTIONS

The following results can be found in Section 1.4 of (Doberkat, 2007) and Section 5 of (Srivastava, 2008).

Let X and Y be sets. A *multifunction* from X to Y is a set-valued map $\mathcal{R} : X \rightarrow 2^Y$ such that for all $x \in X$, $\mathcal{R}(x)$ is a nonempty subset of Y . A multifunction \mathcal{R} from X to Y can equivalently be viewed as a relation between X and Y .

Given a multifunction \mathcal{R} between measurable spaces X and Y , one usually seeks to measurably select a member of $\mathcal{R}(x)$ for each $x \in X$. Here, we recount one way of doing so.

Let \mathcal{R} be a multifunction from X to Y , and let $G \subseteq Y$. The *weak inverse* of G with respect to \mathcal{R} is the set $\exists \mathcal{R}(G) = \{x \in X \mid \exists y \in G \text{ such that } (x, y) \in \mathcal{R}\} = \{x \in X \mid \mathcal{R}(x) \cap G \neq \emptyset\}$. The importance of the weak inverse lies in trying to utilise the property of measurability for a multifunction \mathcal{R} . A measurable function requires the preimage of every measurable set to be measurable. Here, we need only consider the preimages of compact sets.

Suppose \mathcal{R} is a multifunction between a measurable space X and a Polish space Y . Let $G \subseteq Y$. If $\exists \mathcal{R}(G)$ is measurable whenever G is compact then \mathcal{R} is called a \mathcal{C} -measurable relation on $X \times Y$.

Assume X is a measurable space, Y is Polish, \mathcal{R} is a multifunction from X to Y and for each $x \in X$, $\mathcal{R}(x)$ is a non-empty closed subset of Y . Then a measurable map $f : X \rightarrow Y$ is called a *measurable selector* for \mathcal{R} if and only if $f(x) \in \mathcal{R}(x)$ for all $x \in X$.

The following measurable selection result can be found as Proposition 1.57 and Proposition 1.58 in (Doberkat, 2007).

Proposition 3.1. *Assume that X is a measurable space, Y is a Polish space, and R is a \mathcal{C} -measurable relation on $X \times Y$. Then there exists a measurable selector f for \mathcal{R} .*

Finally, the following appears in Proposition 2.34 of (Folland, 1999), and will be used in conjunction with the preceding measurable selection theorem to establish our main result.

Proposition 3.2. *Suppose that (X, \mathcal{B}_X) , (Y, \mathcal{B}_Y) , and (Z, \mathcal{B}_Z) are measurable spaces and that $f : X \times Y \rightarrow Z$ is a product-measurable function. Let $x \in X$. Define the X -section of f at x , $f_x : Y \rightarrow Z$, to be the function defined by $f_x(y) = f(x, y)$ for all $y \in Y$. Then f_x is measurable.*

3.2 BISIMILARITY AS A VALUE FUNCTION

Theorem 3.3. *Let us assume the setup and result of Theorem 2.5. Let $K = (K_a)_{a \in A} \in \Lambda(P, P)$, where $P = (P_a)_{a \in A}$. Define the coupling of \mathcal{M} with itself through K to be the MDP $\mathcal{M}(K) = (S \times S, \mathcal{B}_{S \times S}, A, (K_a)_{a \in A}, \theta^c)$. Let $V_c^*(K)$ denote its optimal value function with respect to c , as defined in Theorem 2.1. Then there exists a $K^* \in \Lambda(P, P)$ such that $\rho_c^* = V_c^*(K^*) = \min_{K \in \Lambda(P, P)} V_c^*(K)$.*

In order to prove Theorem 3.3, we will need to make use of the following result, which can be found within the proof of Lemma 3.14 in (Ferns et al., 2011).

Lemma 3.4. *Assume the setup and result of Theorem 2.5. Then for each $a \in A$, the map sending (s, s') to $\mathcal{K}(\rho_c^*)(P_a(s), P_a(s'))$ is continuous on $S \times S$.*

Proof of Theorem 3.3. In order to prove the existence of K^* , we follow the method of part 3 of the proof of Lemma 4.9 in (Doberkat, 2007). First, however, we appeal to Theorem 2.5 to assert the existence of a Polish topology τ on S making each r_a continuous and each P_a weakly continuous for all $a \in A$. Let $X = A \times S \times S$ and $Y = \mathbb{P}(S \times S)$. The set A is a Polish space since it is finite, and X is a Polish space since it is a finite product of Polish spaces. Additionally, Y is also a Polish space (Giry, 1982). Define $\mathcal{R} : X \rightarrow 2^Y$ by setting $\mathcal{R}(a, x, y)$ to be the set of all $\lambda \in \Lambda(P_a(x), P_a(y))$ such that $\mathcal{K}(\rho_c^*)(P_a(x), P_a(y)) = \lambda(\rho_c^*)$. Theorem 2.4 implies that each $\mathcal{R}(a, x, y)$ is non-empty. Suppose $(\lambda_n)_{n \in \mathbb{N}} \subseteq \mathcal{R}(a, x, y)$ converges to $\lambda \in$

Y . By Lemma 2.3, $\lambda \in \Lambda(P_a(x), P_a(y))$. Theorem 2.5 implies that $\rho_c^* \in \mathbb{C}^b(S \times S)$, so that by weak convergence $\lambda(\rho_c^*) = \lim_{n \rightarrow \infty} \lambda_n(\rho_c^*) = \mathcal{K}(\rho_c^*)(P_a(x), P_a(y))$. Therefore, $\lambda \in \mathcal{R}(a, x, y)$, i.e. $\mathcal{R}(a, x, y)$ is closed.

Next, let $G \subseteq Y$ be compact, hence, closed. We will show that $\exists \mathcal{R}(G)$ is closed, and hence measurable. Let $(a_n, x_n, y_n)_{n \in \mathbb{N}} \subseteq \exists \mathcal{R}(G)$ be a sequence converging to some $(a, x, y) \in X$. So there exists $(\lambda_n)_{n \in \mathbb{N}} \subseteq G$ such that $\lambda_n \in \mathcal{R}(a_n, x_n, y_n)$ for all $n \in \mathbb{N}$. Since G is compact, it is also sequentially compact and therefore there exists a subsequence $(\lambda_{k_n})_{n \in \mathbb{N}}$ converging to some $\lambda \in G$. Remark that since A is finite, the sequence $(a_n)_{n \in \mathbb{N}}$ is eventually constant, i.e. there exists $N \in \mathbb{N}$ such that $(a_n, x_n, y_n) = (a, x_n, y_n)$ for all $n \geq N$. Let $(\varphi, \psi) \in \mathbb{C}^b(S) \times \mathbb{C}^b(S)$. Then

$$\begin{aligned} & \int_{S \times S} [\varphi(s) + \psi(s')] \lambda(ds, ds') \\ &= \lim_{n \rightarrow \infty} \left(\int_{S \times S} [\varphi(s) + \psi(s')] \lambda_{k_n}(ds, ds') \right) \\ &= \lim_{n \rightarrow \infty} \left(\int_S \varphi(s) P_{a_{k_n}}(x_{k_n})(ds) \right. \\ & \quad \left. + \int_S \psi(s') P_{a_{k_n}}(y_{k_n})(ds') \right) \\ &= \lim_{n \rightarrow \infty} \left(\int_S \varphi(s) P_a(x_{k_n})(ds) \right. \\ & \quad \left. + \int_S \psi(s') P_a(y_{k_n})(ds') \right) \\ &= \int_S \varphi(s) P_a(x)(ds) + \int_S \psi(y) P_a(y)(ds') \end{aligned}$$

so that $\lambda \in \Lambda(P_a(x), P_a(y))$. Here we have used the weak convergence of $(\lambda_{k_n})_{n \in \mathbb{N}}$ to λ , $(P_a(x_{k_n}))_{n \in \mathbb{N}}$ to $P_a(x)$, and of $(P_a(y_{k_n}))_{n \in \mathbb{N}}$ to $P_a(y)$, and the repeated use of Lemma 2.2. Moreover, by weak convergence and Lemma 3.4

$$\begin{aligned} \lambda(\rho_c^*) &= \lim_{n \rightarrow \infty} \lambda_{k_n}(\rho_c^*) \\ &= \lim_{n \rightarrow \infty} \mathcal{K}(\rho_c^*)(P_a(x_{k_n}), P_a(y_{k_n})) \\ &= \mathcal{K}(\rho_c^*)(P_a(x), P_a(y)), \end{aligned}$$

whence it follows that $\lambda \in \mathcal{R}(a, x, y)$. Therefore, $\mathcal{R}(a, x, y) \cap G \neq \emptyset$, $(a, x, y) \in \exists \mathcal{R}(G)$, and $\exists \mathcal{R}(G)$ is closed and hence measurable. By definition, \mathcal{R} is a \mathcal{C} -measurable relation on $X \times Y$. Applying Proposition 3.1 there exists a measurable selector $f : X \rightarrow Y$ for \mathcal{R} . Finally, set $K^* = (K_a^*)_{a \in A}$ where $K_a^*(x, y) = f(a, x, y) \in \mathcal{R}(a, x, y)$ for all $a \in A$, $x, y \in S$. For each $a \in A$, K_a^* is simply the A -section of f at a , so that by Proposition 3.2, each $K_a^* \in \llbracket S \times S \rightarrow \mathbb{P}(S \times S) \rrbracket$. Therefore, $\rho_c^* = V_c^*(K^*)$, the optimal value function for $\mathcal{M}(K^*)$.

Clearly $\inf_{K \in \Lambda(P, P)} V_c^*(K) \leq V_c^*(K^*)$. To establish the reverse inequality, let $K = (K_a)_{a \in A} \in \Lambda(P, P)$. Then for

any $a \in A$ and $x, y \in S$,

$$\begin{aligned} & \theta_a^c(x, y) + c \cdot K_a^*(x, y)(\rho_c^*) \\ &= \theta_a^c(x, y) + c \cdot \mathcal{K}(\rho_c^*)(P_a(x), P_a(y)) \\ &= \theta_a^c(x, y) + c \cdot \inf_{\lambda \in \Lambda(P_a(x), P_a(y))} \lambda(\rho_c^*) \\ &\leq \theta_a^c(x, y) + c \cdot K_a(x, y)(\rho_c^*). \end{aligned}$$

By taking the maximum over all $a \in A$ and noting that the result holds for all $x, y \in S$, we then obtain $\rho_c^* \leq T_c(K)(\rho_c^*)$, where $T_c(K)$ is the Bellman optimality operator for the MDP $\mathcal{M}(K)$. Therefore, it follows that $V_c^*(K^*) \leq V_c^*(K)$ for any $K \in \Lambda(P, P)$, and finally that $V_c^*(K^*) \leq \inf_{K \in \Lambda(P, P)} V_c^*(K)$. \square

Thus, we can interpret every discounted bisimulation metric as the optimal value function of some MDP; moreover, that MDP is optimal in the sense that it is the best coupling of the transition structure of the original MDP with itself when one seeks to minimize the expected total discounted *absolute difference* in rewards coming from the original model.

An immediate consequence is that we can now interpret the topology of convergence with respect to a bisimulation metric in terms of MDP optimality criteria. Conversely, when examining behavioural equivalence for the state space of a given MDP it no longer suffices to consider the structural model alone; one *must* take into account the full Markov decision problem, i.e. its intended use by means of an optimality criterion. This is yet another advantage of the pseudometric approach over that of exact equivalences. We discuss this further in Section ??.

Practical implications are less immediate, but no less important, particularly in regard to determining what might be effective in attempting to calculate or estimate the distances. Consider a finite MDP. If we adjoin one new absorbing state with no immediate rewards then it is not hard to show that the bisimulation distance from that state to another state is the optimal value of the latter state. So computing a bisimulation metric is at least as hard as computing an optimal value function. On the other hand, we have just shown that computing a bisimulation metric amounts to computing an optimal value function - albeit, with the caveat that this amounts to a search over possibly infinitely many couplings. If one could restrict this search to polynomially many couplings, then it would follow that computing bisimulation metrics and computing optimal value functions belong to the same polynomial-time complexity class - and we conjecture that this is so. At first glance, this is a disappointing result; if one followed the naive approach, one would be attempting to solve for an optimal value function by solving for another optimal value function over a quadratically larger MDP. However, computing a bisimulation metric is of interest in its own right; the value function formulation allows for state-of-the-art

reinforcement learning techniques (Sutton & Barto, 2012; Pazis & Parr, 2013) to be applied in its computation while at the same time informing us of what methods are unlikely to work well in practice for truly large systems.

A better practical approach would be to find more easily computable similarity metrics that are related in some meaningful way to the bisimulation metric. In that case, one would have a practical similarity measure with the theoretical guarantees given by bisimulation, as in Theorem 2.6. Our value function formulation permits a very natural way to do this, through the use of couplings.

Definition 4. Let $f : X \times X \rightarrow [0, \infty)$ be a function on a set X . Define the function $\varrho(f) : X \times X \rightarrow [0, \infty)$ by $\varrho(f)(x, y) = \inf\{\sum_{j=1}^m \omega(f)(a_{j-1}, a_j)\}$, where $\omega(f)(u, v) = \min\{f(u, v), f(v, u)\}$ and the infimum is taken over all $m \in \mathbb{N}$ and $(a_j)_{j=0}^m \subseteq X$ such that $a_0 = x$ and $a_m = y$. Then $\varrho(f)$ is the largest pseudometric less than f .

Notice that if X is finite and f is computable then the problem of computing $\varrho(f)$ is the *All-Pairs Shortest Paths* problem.

Corollary 3.5. Assume the setup and result of Theorem 3.3. For $\pi \in \Pi$ defined over $S \times S$ we let $V_c(K)(\pi)$ denote the value function of $\mathcal{M}(K)$ with respect to π and c and we let $V_c^*(K)$ denote its optimal value function with respect to c , as defined in Theorem 2.1. Then

1. $\forall K \in \Lambda(P, P), \rho_c^* \leq \varrho(V_c^*(K)) \leq V_c^*(K)$.
2. $\forall \pi \in \Pi, \varrho(V_c(K^*)(\pi)) \leq V_c(K^*)(\pi) \leq \rho_c^*$.

Corollary 3.5 allows us to easily bound the bisimulation metric from above for any coupling $K \in \Lambda(P, P)$. For example, the product coupling $P \otimes P$ defined in the obvious way (and assuming measurability) by $(P \otimes P)_a(x, y) = P_a(x) \otimes P_a(y)$ should provide a trivial upper bound. Corollary 3.5 also provides a lower bound but only in the case where we know the optimal coupling K^* beforehand. Potentially more interesting is the case where we combine the two, i.e. for an arbitrary coupling $K \in \Lambda(P, P)$ and an arbitrary policy $\pi \in \Pi$ defined on $\mathcal{M}(K)$, does the equivalence induced by $\varrho(V_c(K)(\pi))$ lead to something that is more easily computable but that still provides good theoretical guarantees?

4 RELATED WORK

This work lies at the intersection of artificial intelligence and formal verification, and owes much to both. The concept of bisimulation has been in use within the uncertainty in artificial intelligence community for some time now. Indirectly in (Boutillier et al., 2000) and directly in (Givan et al., 2003), the notion of bisimulation had

been transferred from the theory of concurrent processes to MDP model minimization and the reinforcement learning paradigm. These papers work directly with factored or structured representations, which is an advantage over our approach for problems where such structure in the environment exists and is known explicitly. On the other hand, they deal only with discrete MDPs, exhibit the brittleness inherent in using exact equivalences for numerical systems, and lack theoretical guarantees on the size of a fully minimal system. In earlier work, Dean et al. (1997) actually consider an approximate version of bisimulation. For a small positive parameter ε they consider equivalence relations satisfying the property that immediate rewards and stochastic transitions to equivalence classes differ by at most ε . However, the disadvantages already mentioned still apply. More generally, (Li et al., 2006) provide a comprehensive survey and classification of various state abstractions for finite MDPs, including methods based on bisimulation (such as our bisimulation metrics).

Bisimulation metrics have been more extensively studied in the formal verification community. In that setting, the work closest in spirit to our own is (Chen et al., 2012), wherein the authors investigate the complexity of computing bisimilarity and metric bisimilarity for labelled Markov chains. In particular, Theorem 8 in that work relates an undiscounted bisimulation metric to optimal couplings of a given labelled Markov chain. Aside from considering only finite state systems, they allow for states to have differing sets of permissible actions but omit the reward parameter; hence, their work lies outside of the optimal control theory framework on which we focus.

Abate (2012) surveys various approximation metrics for probabilistic bisimulation over Markov processes with general state and action spaces, though here too Markov reward processes are mostly neglected. The author does conclude that a bridge needs to be made between techniques based on computing distances between Markov kernels and techniques based on sampling trajectories from processes under consideration; we believe the current work can help provide that bridge.

A very promising approach appears in (Desharnais et al., 2013) where the authors propose a general algorithm for estimating divergences, distance functions that may fail to satisfy the symmetry and triangle inequality axioms of a pseudometric. They consider divergences that generalize equivalences on probabilistic systems based on tests and observations. In particular, they define a new family of testable equivalences called *k-moment equivalences*; 1-moment equivalence is trace equivalence, as k grows larger k -moment equivalence becomes finer, and all k -moment equivalences as well as their limit equivalence are strictly weaker than bisimilarity. The exciting feature of their work is that the algorithm for estimating a divergence corresponding to a fixed equivalence is based on defining an

MDP whose optimal value function is that divergence, and then using reinforcement learning techniques (Sutton & Barto, 2012) to solve for the optimal value function. While conceptually similar in spirit to our value function representation of bisimulation metrics, this approach differs significantly in how the MDP representing the metric is defined.

5 CONCLUSIONS AND FUTURE WORK

We have shown that the bisimulation metric defined in (Ferns et al., 2011) for an MDP is actually the optimal value function of an optimal coupling of the MDP with itself. This latter formulation is perhaps a more natural conception of distance for MDPs. In any case, all theoretical and practical results from optimal control theory concerning optimal value functions for MDPs can be carried over (based on this result) to the study of bisimulation metrics.

Perhaps the most intriguing implication of Theorem 3.3 is that examining other optimal control theory criteria may lead to different classes of bisimulation metrics perhaps better suited to those optimality tasks. Consider the undiscounted case. What does ρ_c^* represent when c tends to 1? We could set $c = 1$ in Theorem 2.5, as in Theorem 4 of (Chen et al., 2012). The resultant functional $F_1 : \mathfrak{Lsc}_m \rightarrow \mathfrak{Lsc}_m$ defined by $F_1(\rho)(s, s') = \max_{a \in A} \mathcal{K}(\rho)(P_a(s), P_a(s'))$ has a least fixed-point ρ_1^* given by the Knaster-Tarski fixed-point theorem. In fact, in this case the least fixed-point is the everywhere zero pseudometric - unsurprising since in our current setup all actions are allowable in all states and the reward parameter is the only feature that distinguishes states. But how might we interpret such a result more generally? In fact, there is some relation to the infinite-horizon average reward optimality criterion.

Let $\mathcal{M} = (S, \mathcal{B}_S, A, (P_a)_{a \in A}, r)$ be an MDP with the image of r contained in $[0, 1]$ and recall the terminology of Section 2.2. The following definitions can be found in Chapter 5 of (Hernández-Lerma & Lasserre, 1996). Let $\pi \in \Pi$ be a policy on \mathcal{M} . Let $n \in \mathbb{N}$. The *n-stage value function* for π is defined by $J_n(\pi)(s) = \mathbb{E}_s^\pi[\sum_{t=0}^{n-1} r(a_t, x_t)]$ for all $s \in S$, the *average cost value function* for π by $J(\pi)(s) = \limsup_{n \rightarrow \infty} \frac{1}{n} J_n(\pi)(s)$ for all $s \in S$, and the average reward optimal value function by $J^*(s) = \sup_{\pi \in \Pi} J(\pi)(s)$ for all $s \in S$. The solution to the average reward Markov decision problem is a policy π^* such that $J(\pi^*) = J^*$.

Let us assume that \mathcal{M} is finite, i.e., S is finite. The following can be found in Chapter 8 of (Feinberg & Shwartz, 2002), in particular Theorem 8.1, listed below as Theorem 5.1. A policy $\pi \in \Pi$ is said to be *Blackwell optimal* if and only if there exists $\gamma_0 \in (0, 1)$ such that π is γ -optimal for all $\gamma \in (\gamma_0, 1)$.

Remark 2. A stationary Blackwell optimality policy is also average reward optimal, and for such a policy π^* , $\lim_{\gamma \uparrow 1} (1 - \gamma)V_\gamma(\pi^*) = J(\pi^*)$.

Theorem 5.1. In a finite MDP there exists a stationary Blackwell optimal policy.

Let $K \in \Lambda(P, P)$ and $V_c^*(K)$ be the optimal value function for the MDP $\mathcal{M}(K)$ defined in Section 3 with the reward parameter θ^c scaled by $(1 - c)^{-1}$. Then there exists a $K_c^* \in \Lambda(P, P)$, depending on c , such that $\rho_c^* = (1 - c)V_c^*(K_c^*)$. It follows that $\lim_{c \uparrow 1} \rho_c^* = \lim_{c \uparrow 1} (1 - c)V_c^*(K_c^*) \leq \lim_{c \uparrow 1} (1 - c)V_c^*(K) \leq J^*(K)$ for any $K \in \Lambda(P, P)$. Thus, $\lim_{c \uparrow 1} \rho_c^* \leq \inf_{K \in \Lambda(P, P)} J^*(K)$. It remains to be seen whether or not the inequality is strict.

In the general case, the situation is much more complicated. For example, under a variety of conditions not listed here, Lemma 10.4.3 of (Hernández-Lerma & Lasserre, 1999) states the following.

Lemma 5.2. There exists a constant α such that $\alpha = \limsup_{\gamma \uparrow 1} (1 - \gamma)V_\gamma^* \leq J^*$.

It follows that under the same conditions $\limsup_{c \uparrow 1} \rho_c^* \leq \alpha \leq \inf_{K \in \Lambda(P, P)} J^*(K)$. If equality were to hold in this case, then we would have for some $x \in S$, $\alpha = \limsup_{c \uparrow 1} \rho_c^*(x, x) = 0$, so that $\lim_{c \uparrow 1} \rho_c^*$ exists and is everywhere zero, i.e. the resulting equivalence would identify all states. Aside from the unspecified conditions, the distinction with the finite case is that $\lim_{c \uparrow 1} \rho_c^*$ need not exist to begin with.

Similarly, consider the expected total reward criterion. Here we might take the set of lower semicontinuous pseudometrics on S as in Theorem 2.5, but this time bounded with respect to a weighted supremum norm $\|\cdot\|_w$ for some weight function $w : S \times S \rightarrow [1, \infty)$. Thus, an unbounded function f that has a bounded norm with respect to w has its rate of growth bounded by w . Define the functional F by

$$F(\rho)(s, s') = \max_{a \in A} [\theta_a^0(s, s') + \mathcal{K}(\rho)(P_a(s), P_a(s'))].$$

Then if conditions are imposed so that the set of w -bounded lower semicontinuous pseudometrics on S is closed under F , it will have a least fixed-point (extended) pseudometric again corresponding to some expected total reward optimal value function. This line of research is very preliminary.

The major concern of this work along with (Ferns et al., 2014) is to clarify and unify results about the theory of bisimulation metrics in order to provide new avenues of attack for practical applications. An ongoing research goal is to find a more easily computable equivalence than that given by the current bisimulation metrics while maintaining as much as possible the theoretical guarantees. As far as estimating the given family of bisimulation metrics, the current interpretation as optimal value functions suggests

that the most promising approaches involve Monte Carlo techniques, as in (Ferns et al., 2006), (Ferns et al., 2011), and most recently in (Comanici et al., 2012), or advanced approximate linear programming techniques as in (Pazis & Parr, 2013). More to the point, our strong intuition is that state-of-the-art methods for efficient reinforcement learning can be leveraged to develop state-of-the-art methods for efficient bisimulation metric computation, and vice versa. Very interesting recent work in this direction have been done by Bacci et al. (2013), who use greedy heuristics and decomposition techniques to speed up the computation of bisimulation metrics for MDPs. Computational approaches of this flavour should be further investigated.

In order for this approach to be really useful in practice, however, a few topics need to be further addressed by future work.

First, this work is highly dependent on couplings and the coupling method, though we have only just touched upon the subject. The study of couplings in theory and in practice is vast, and a proper discussion is beyond the scope of this work. A good source for the theory of couplings is (Lindvall, 2002). Moreover, as noted in (Chen et al., 2012), it is already known in the discrete case that the set of couplings (called *matchings* in that work) for two probability functions forms a polytope; and that optimizing a linear function over it amounts to optimizing over the finitely many vertices of the polytope (as is done in computing the discrete Kantorovich metric). We hope that this structure can be exploited to improve our theoretical result.

Additionally, we mentioned that the initial applications of bisimulation to MDPs exploited factored or structured representations. It would be fruitful to explore whether or not bisimulation metric reasoning principles can be applied to factored representations without having to flatten the state space. More generally, applying bisimulation metrics to the problem of constructing function approximators for MDP value functions is a very promising future direction, recent work (Comanici & Precup, 2012) has leveraged such metrics to tackle the problem of automatically generating features for function approximation.

Lastly, let us consider the problem of knowledge transfer between MDPs. Suppose $\mathcal{M}_X = (X, \mathcal{B}_X, A, P_X, r(X))$ and $\mathcal{M}_Y = (Y, \mathcal{B}_Y, A, P_Y, r(Y))$ are two MDPs with rewards in the unit interval and that $c \in (0, 1)$ is a discount factor. For $K \in \Lambda(P_X, P_Y)$, consider the coupled MDP $\mathcal{M} = (X \times Y, \mathcal{B}_{X \times Y}, A, K, \theta)$ where $\theta_a(x, y) = (1 - c)|r_a(X)(x) - r_a(Y)(y)|$ for all $x \in X$ and $y \in Y$. Does $\inf_{K \in \Lambda(P_X, P_Y)} V_c^*(K)(x, y)$ measure the bisimilarity of states x and y ? Clearly, there is much work to be done to answer this question.

Annealing Paths for the Evaluation of Topic Models

Abstract

Statistical topic models such as latent Dirichlet allocation have become enormously popular in the past decade, with dozens of learning algorithms and extensions being proposed each year. As these models and algorithms continue to be developed, it becomes increasingly important to evaluate them relative to previous techniques. However, evaluating the predictive performance of a topic model is a computationally difficult task. Annealed importance sampling (AIS), a Monte Carlo technique which operates by annealing between two distributions, has previously been successfully used for topic model evaluation (Wallach et al., 2009b). This technique estimates the likelihood of a held-out document by simulating an annealing process from the prior to the posterior for the latent topic assignments, and using this simulation as an importance sampling proposal distribution.

In this paper we introduce new AIS annealing paths which instead anneal *from one topic model to another*, thereby estimating the *relative* performance of the models. This strategy can exhibit much lower empirical variance than previous approaches, facilitating reliable per-document comparisons of topic models. We then show how to use these paths to evaluate the predictive performance of topic model learning algorithms by efficiently estimating the likelihood at each iteration of the training procedure. The proposed method achieves better held-out likelihood estimates for this task than previous algorithms with, in some cases, an order of magnitude less computation.

1 INTRODUCTION

Topic models such as latent Dirichlet allocation (Blei et al., 2003) have become standard tools for analyzing text cor-

pora, with broad applications in areas such as political science (Grimmer, 2010), sociology (McFarland et al., 2013), conversational dialog (Nguyen et al., 2013), and more. A multitude of extensions to the LDA model have been developed for finding meaningful latent structure in text, along with a variety of strategies for fitting these models to increasingly large corpora.

As these new ideas continue to be proposed in the literature it becomes increasingly important to obtain accurate quantitative evaluations of the different approaches. Among the techniques available for evaluating topic models, the prediction of words in held-out documents (via test log-likelihood or perplexity) is perhaps the single most widely-used method for benchmarking the performance of new topic models and inference algorithms. An important point is that speedups for training these models do not necessarily translate to speedups in evaluating them. For example, there now exist very fast learning algorithms for training topic models based on approximate inference techniques, such as stochastic variational inference (Hoffman et al., 2010, 2013; Foulds et al., 2013), making it possible to learn topic models on corpora with millions of documents. Ironically, however, the time taken to compute test-set metrics for these algorithms can be orders of magnitude greater than the time it takes to train them. The evaluation of the predictive performance of topic models on held-out documents is still painfully slow, and relatively unreliable for individual documents as we will see later in the paper.

More specifically, consider a held-out document d , with word vector $w^{(d)}$, in the context of evaluating the quality of an LDA topic model (or one its many extensions). Given point estimates of topics Φ and a potentially document-specific Dirichlet prior α (if learned), we wish to compute the likelihood of the words in this held-out document, $Pr(w^{(d)}|\Phi, \alpha)$.¹ The direct computation of this quantity involves either an intractable sum over the latent topic assignments $z^{(d)}$, or an intractable integral over the distribution over topics $\theta^{(d)}$. Moreover, this already difficult computation must be performed for every document in

¹Or perplexity, a function of this and document length.

the held-out test set, which frequently contains hundreds to thousands of documents. To address this challenge, a wide variety of approximation strategies for estimating $Pr(w^{(d)}|\Phi, \alpha)$ have been proposed in papers such as those from Wallach et al. (2009b), Buntine (2009) and Scott & Baldridge (2013). Although these methods can lead to significantly more accurate results than naive approaches, the reliable and efficient evaluation of topic models remains a relatively open problem of practical significance.

In this paper we investigate new methods for evaluating topic models based on annealed importance sampling (AIS) (Neal, 2001), a Monte Carlo integration technique which was previously applied to topic model evaluation by Wallach et al. (2009b). Given two probability distributions, AIS produces an estimate of the ratio of their partition functions by annealing between them. Wallach et al. leverage this idea by annealing from the prior over the latent topic assignments $z^{(d)}$ to the posterior, resulting in an estimate of held-out document likelihood. AIS can be very accurate given enough computation time, although the amount of time needed may vary greatly between different choices of annealing paths (Grosse et al., 2013).

The first contribution of this paper is to propose and evaluate an alternative annealing strategy, using two AIS paths which anneal from one topic model to another. This strategy (referred to as ratio-AIS) computes the *ratio* of the likelihoods of two models instead of computing the likelihoods of each model separately. The result is an estimate of the relative performance of the models, with significantly lower empirical variance across runs than previous approaches.² This in turn brings computational benefits, as fewer samples or annealing temperatures may be required to achieve reliable results. The reduced variance comes at the cost of potentially increased bias when insufficient iterations are performed to achieve convergence. However, we also show how to detect such bias by annealing between the topic models in both directions and comparing the results. The consequence of this bias-variance trade-off is that the proposed method is useful in cases where we would like to perform in-depth analysis at the per-document level and when the two topic models are similar to each other. The previous high-variance low-bias methods may still be preferred for general full-corpus comparisons of topic models.

Finally, we show how to use the proposed AIS paths for evaluating topic model learning algorithms by computing held-out likelihood curves over the iterations of the learning procedure. This is achieved by annealing between the topic models at each iteration of the learning algorithm in turn, which allows all previous computation to be reused in each of the likelihood estimates. The proposed method outperforms previous algorithms, in some cases even when

²“Variance” here refers to variance across Monte Carlo estimates of the difference in log-likelihood between models, per document.

it is given an order of magnitude less computation time. Note that although we focus on topic models, the ideas presented here could potentially also be useful for other latent variable models with intractable likelihoods.

2 BACKGROUND

When proposing a new topic model or learning algorithm, it is important to evaluate its performance. When the model is to be used for a certain task it may be possible to evaluate it with respect to an extrinsic, task-specific metric. For example one could evaluate the quality of topics being used as features for a classification algorithm by measuring classification accuracy. More generally, however, given that topic models are generally trained in an unsupervised manner (with a few notable exceptions), a ground-truth evaluation metric is typically not available.

Consequently, a number of intrinsic (i.e. task independent) validation strategies for topic models have been developed in the literature. For example, Chang et al. (2009) proposed the use of elicitations of judgments from humans to evaluate the quality of topic models. Given that obtaining these judgments can be expensive and difficult, Newman et al. (2010) and Mimno et al. (2011) proposed automatic surrogate measures of topic coherence, and showed that these measures, which are typically based on word co-occurrence statistics, are correlated with human judgments.

However, as topic models are statistical models, we also would like to be able to evaluate them as such. In the context of unsupervised machine learning, the standard approach for evaluating a statistical model is to compute the probability of held-out data. Regardless of the utility of the aforementioned methods, it is generally useful to demonstrate good predictive performance in addition to any other extrinsic or intrinsic validation results. Intuitively, as our goal is to fit a statistical model to data, we would like to know both how well we are able to fit the model, and how well the model is able to explain unobserved data.

As in Wallach et al. (2009b), we therefore focus on the computation of $Pr(w^{(d)}|\Phi, \alpha)$, the likelihood of the words $w^{(d)}$ in a held-out document d (or equivalently, perplexity), conditioned on point estimates of the topic-word distributions Φ and (possibly document-specific) priors α , where Φ is a $W \times K$ matrix consisting of K discrete distributions $\Phi^{(k)}$ over the W words in the dictionary, and α is a K -dimensional Dirichlet parameter vector.³ This quantity can be used to evaluate a point estimate of the topics, or in an inner loop to evaluate Bayesian evaluation metrics such as the posterior predictive probability of held-out documents.

³It is standard practice to learn an asymmetric Dirichlet prior α in LDA models, following Wallach et al. (2009a), so we include it as a parameter to evaluate. The prior may also be learned in a document dependent way for models such as DMR (Mimno & McCallum, 2008).

It is in general infeasible to compute $Pr(w^{(d)}|\Phi, \alpha)$ directly, as it involves an intractable sum $\sum_z^{(d)} Pr(w^{(d)}, z^{(d)}|\Phi, \alpha)$ or an intractable integral $\int_{\theta} Pr(w^{(d)}, \theta^{(d)}|\Phi, \alpha)$. The computational difficulty arises because the topic assignments $z^{(d)}$ and distributions over topics $\theta^{(d)}$ for the held-out document are unknown, and so all possible values must be considered. A variety of approximation strategies were considered by Wallach et al. (2009b), the number of which alone is a testament to the difficulty of the problem. The most widely used of these approaches is the “left-to-right” particle filtering algorithm. In the algorithm, a number of particles are maintained, representing topic assignments up to the current word t in the document. In each iteration, these particles are used to draw samples of the topic assignment for the next word $t + 1$, conditioned on the previous words and topic assignments. A resampling step is also performed, making the algorithm’s run time quadratic in the length of the document. The algorithm was analyzed more closely by Buntine (2009), and a faster, but less accurate, variant of the technique was proposed by Scott & Baldridge (2013).

Alternatively, a strategy for side-stepping some of the computational difficulty is to instead estimate (or sample) $z^{(d)}$ or $\theta^{(d)}$ on a subset $w^{(d,1)}$ of the document, and predict only the remaining portion of the document $w^{(d,2)}$, thus estimating $Pr(w^{(d,2)}|w^{(d,1)}, \Phi, \alpha)$. This method is frequently used in practice (e.g. Rosen-Zvi et al. (2004); Wallach et al. (2009a)). However, this “document completion” scenario changes the task somewhat, and is not the gold standard prediction task we would like it to be. It measures the ability of the model to “orient” itself quickly when given partial documents, rather than how likely the overall document is under the model. The widespread use of the document completion strategy may be largely due to its convenient computational properties (leading in turn to its use as a surrogate for fully held-out prediction), rather than being due to any intrinsic benefit of the metric itself.

It is also unclear how the use of document completion as a surrogate for full-document prediction might affect our conclusions, particularly when using topic models which learn the Dirichlet hyper-parameter α as in Wallach et al. (2009a) and Mimno & McCallum (2008). Learning α may help the model to recover $\theta^{(d)}$ better on the training portion of the document, thus increasing the performance of the model for document completion more than in the fully held-out case.

On the other hand, observing more of the document decreases the relative impact of the prior on the posterior distribution, which could reduce the observed improvement due to learning α . Thus, we suspect that document completion may not always be a good surrogate for the full prediction task. It should be noted that many methods for fully held-out prediction can also be adapted for document completion (including those proposed here).

2.1 ANNEALED IMPORTANCE SAMPLING

One of the more accurate strategies investigated by Wallach et al. (2009b) to estimate held-out likelihood was annealed importance sampling (AIS) (Neal, 2001). AIS is a general technique for estimating an expectation of a function of a random variable x with respect to an intractable distribution of interest p_0 . Consider a distribution p_n (which is typically easy to sample from) and a sequence of “intermediate” distributions p_{n-1}, \dots, p_1 leading from p_n to p_0 . AIS works by annealing from p_n towards p_0 by way of the intermediate distributions, and using importance weights to correct for the fact that an annealing process was used instead of sampling directly from p_0 .

Assume that for each intermediate distribution p_j we have a Markov chain with transition operator $T_j(x, x')$ which is invariant to that distribution. We need to be able to sample from these Markov chains, and for each p_j be able to evaluate some function f_j which is proportional to it. In a manner similar to that of traditional importance sampling, AIS produces a collection of samples $x^{(1)}, \dots, x^{(S)}$ with associated importance weights $w^{(1)}, \dots, w^{(S)}$. As with importance sampling, the expectation of interest is estimated using the samples, weighted by the importance weights.

The strategy for drawing each sample $x^{(i)}$ is to begin by drawing a sample x_{n-1} from p_n , then drawing a sequence of points x_{n-2}, \dots, x_0 which “anneal” towards p_0 . Each of the remaining x_j ’s in the sequence are generated from x_{j+1} via T_j . Importance weights $w^{(i)}$ are computed by viewing (x_0, \dots, x_{n-1}) as an augmented state space, and performing importance sampling on this new state space. The above procedure is used as a proposal distribution Q for importance sampling from another distribution P :

$$Q(x_0, \dots, x_{n-1}) \propto f_n(x_{n-1}) \prod_{j=n-1}^1 T_j(x_j, x_{j-1})$$

$$P(x_0, \dots, x_{n-1}) \propto f_0(x_0) \prod_{j=1}^{n-1} \tilde{T}_j(x_{j-1}, x_j),$$

where $\tilde{T}_j(x, x') = T_j(x', x) \frac{f_j(x')}{f_j(x)}$ is the reversal of the transition defined by T_j . This leads to importance weights for each of the samples,

$$w^{(i)} = \frac{P(x_0, \dots, x_{n-1})}{Q(x_0, \dots, x_{n-1})} = \prod_{j=0}^{n-1} \frac{f_j(x_j)}{f_{j+1}(x_j)}. \quad (1)$$

Note that the marginal probability of x_0 under P is $p_0(x_0)$, so after letting $x^{(i)} = x_0$ the procedure correctly carries out importance sampling from p_0 . AIS also provides an estimate for the ratio of normalizing constants for f_0 and f_n . The normalizing constant for P is the same as the normalizing constant for f_0 , and the normalizing constant for Q is the same as the normalizing constant for f_n , and so

the average of the importance weights, $\frac{\sum w^{(i)}}{N}$, converges to $\frac{\int f_0(x)dx}{\int f_n(x)dx}$.

2.2 AIS FOR TOPIC MODELS

Wallach et al. (2009b) showed how to apply the AIS procedure to the problem of calculating LDA likelihoods. The likelihood of a test document for a topic model can be estimated by using AIS to estimate a normalization constant, operating on the latent topic assignments $z^{(d)}$ for the document.⁴ We can set $f_0 = Pr(w^{(d)}, z^{(d)}|\Phi, \alpha)$, $f_n = Pr(z^{(d)}|\alpha)$, with intermediate distributions $f_j = Pr(w^{(d)}|z^{(d)}, \Phi, \alpha)^{\beta_j} f_n$ and the transition operators T_j being the Gibbs sampler for f_j . The ratio of normalizing constants is

$$\begin{aligned} \frac{\sum w^{(i)}}{S} &\approx \frac{\sum_{z^{(d)}} Pr(w^{(d)}, z^{(d)}|\Phi, \alpha)}{\sum_{z^{(d)}} Pr(z^{(d)}|\alpha)} \\ &= \frac{Pr(w^{(d)}|\Phi, \alpha)}{1} = Pr(w^{(d)}|\Phi, \alpha). \end{aligned} \quad (2)$$

The procedure for producing each importance sample, then, is to draw an initial $z^{(d)}$ from the prior, and anneal it towards f_0 by performing $r_j \geq 1$ Gibbs iterations at each intermediate distribution. After repeating this procedure for each sample, the likelihood is estimated as the average of the importance weights. Note that in what follows we define a *run* as the full procedure averaging over importance samples, while a *sample* refers to a single importance sample.

3 ALTERNATIVE ANNEALING PATHS FOR THE EVALUATION OF TOPIC MODELS

The AIS method described above can be very accurate if given enough computation time (Wallach et al., 2009b). However, it is subject to several potentially avoidable sources of variability. Firstly, the method estimates the ratio of the desired quantity $Pr(w^{(d)}|\Phi, \alpha)$ and the denominator $\sum_{z^{(d)}} Pr(z^{(d)}|\alpha)$ in Equation 2, which equals one, introducing stochastic noise on behalf of the denominator even though this is a constant. We would also expect that the prior may typically be very different from the posterior, thereby requiring many annealing iterations to prevent the importance weights $w^{(i)}$ from having a large variance. This has consequences for the efficiency of the sampler, which is reduced by a factor of approximately

⁴The derivation here differs slightly from that of Wallach et al. (2009b). The present derivation suggests that the procedure described in Wallach et al. produces just one importance sample. This may be repeated, finally producing as output the average of the resulting importance weights. In practice however, we found that a single sample with a longer annealing run, as in Wallach et al., may still be the best strategy on a computational budget.

$1 + \text{Var}_q[w^{(i)}/E_q[w^{(i)}]]$ relative to direct sampling from the target density (Neal, 2001).⁵

Making matters worse, we typically must perform the AIS procedure many times across all held-out documents, and therefore have a relatively limited computational budget per document, preventing us from compensating for the high variance by collecting many importance samples with a large number of temperatures. In this section, we introduce new AIS annealing paths for the evaluation of topic models which can have lower variance than the standard approach. We first introduce AIS paths which compare two topic models by annealing between them. We then show how to use these paths for evaluating topic model learning algorithms by computing per-iteration predictive performance efficiently, reusing all previous computation.

3.1 COMPARING TOPIC MODELS BY ANNEALING BETWEEN THEM

The most typical evaluation scenario is model comparison—we want to determine whether a particular model (model 1) performs better at predicting held-out documents than a baseline method (model 2) such as vanilla LDA or a model trained using a previous learning algorithm. Thus, in such situations, the quantity of interest is the *relative* log-likelihood score of the model and the baseline:

$$\begin{aligned} &\log Pr(w^{(d)}|\Phi^{(1)}, \alpha^{(1)}) - \log Pr(w^{(d)}|\Phi^{(2)}, \alpha^{(2)}) \\ &= \log \frac{Pr(w^{(d)}|\Phi^{(1)}, \alpha^{(1)})}{Pr(w^{(d)}|\Phi^{(2)}, \alpha^{(2)})}. \end{aligned} \quad (3)$$

To compute this in the framework proposed by Wallach et al., we must perform the AIS procedure once for each model, incurring the stochastic error twice. To avoid this and the aforementioned sources of variability with that approach, and given that the procedure is already designed to compute a ratio, we propose to instead use AIS to compute Equation 3 directly. Let $f_0(z^{(d)}) = Pr(w^{(d)}, z^{(d)}|\Phi^{(1)}, \alpha^{(1)})$ and $f_n(z^{(d)}) = Pr(w^{(d)}, z^{(d)}|\Phi^{(2)}, \alpha^{(2)})$. Then the desired quantity can be estimated via

$$\begin{aligned} \sum \frac{w^{(i)}}{N} &\approx \frac{\sum_{z^{(d)}} Pr(w^{(d)}, z^{(d)}|\Phi^{(1)}, \alpha^{(1)})}{\sum_{z^{(d)}} Pr(w^{(d)}, z^{(d)}|\Phi^{(2)}, \alpha^{(2)})} \\ &= \frac{Pr(w^{(d)}|\Phi^{(1)}, \alpha^{(1)})}{Pr(w^{(d)}|\Phi^{(2)}, \alpha^{(2)})}. \end{aligned} \quad (4)$$

We will refer to this strategy as “ratio-AIS.” To implement this method, it remains to choose the annealing path, i.e. the sequence of intermediate distributions. We first consider a geometric average $f_j(z^{(d)}) =$

⁵Note that $E_q[w^{(i)}]$ is equal to the ratio of normalizing constants of the target and proposal densities, which in our case is the quantity of interest, e.g. the likelihood.

$f_0(z^{(d)})^{\beta_j} f_n(z^{(d)})^{1-\beta_j}$ of the initial and final distributions, a strategy suggested by Neal (2001) with analogy to simulated annealing, where β_j can be viewed as an ‘‘inverse temperature.’’ To choose a transition operator T_j invariant to f_j , we straightforwardly select the Gibbs sampler. We have importance weights

$$\begin{aligned} w^{(i)} &= \prod_{j=0}^{n-1} \frac{Pr(w^{(d)}, z_j^{(d)} | \Phi^{(1)}, \alpha^{(1)})^{\beta_j}}{Pr(w^{(d)}, z_j^{(d)} | \Phi^{(1)}, \alpha^{(1)})^{\beta_{j+1}}} \\ &\times \prod_{j=0}^{n-1} \frac{Pr(w^{(d)}, z_j^{(d)} | \Phi^{(2)}, \alpha^{(2)})^{1-\beta_j}}{Pr(w^{(d)}, z_j^{(d)} | \Phi^{(2)}, \alpha^{(2)})^{1-\beta_{j+1}}} \\ &= \prod_{j=0}^{n-1} \frac{Pr(w^{(d)}, z_j^{(d)} | \Phi^{(1)}, \alpha^{(1)})^\tau}{Pr(w^{(d)}, z_j^{(d)} | \Phi^{(2)}, \alpha^{(2)})^\tau} \\ \log w^{(i)} &= \frac{1}{n} \sum_{j=0}^{n-1} \log \frac{Pr(w^{(d)}, z_j^{(d)} | \Phi^{(1)}, \alpha^{(1)})}{Pr(w^{(d)}, z_j^{(d)} | \Phi^{(2)}, \alpha^{(2)})}, \quad (5) \end{aligned}$$

assuming $\beta_j - \beta_{j+1} = \tau = n^{-1} \forall j, 0 \leq j < n - 1$. Elegantly, the log importance weights are the average of the log ratios of the probabilities of $w^{(d)}$ and $z^{(d)}$ according to each model. Observe that the same z assignments are used for the numerator and denominator in each of the ratios in Equation 5, further reducing the variance of the estimate relative to the standard AIS strategy.

Although geometric averages are the standard choice for an annealing path, in many cases there exist annealing paths which perform much better. Grosse et al. (2013) introduced an alternative annealing path for exponential families which converges much more quickly, constructed by annealing averages of the moments of the sufficient statistics. The Dirichlet-multinomial distribution $Pr(z^{(d)} | \alpha)$ is not an exponential family so their method does not directly apply to LDA. Nevertheless, we consider an annealing path inspired by their work, where intermediate distributions are constructed by taking convex combinations of the parameters:

$$\begin{aligned} f_j(z^{(d)}) &= Pr(w^{(d)}, z^{(d)} | \Phi_j = \beta_j \Phi^{(1)} + (1 - \beta_j) \Phi^{(2)}, \\ \alpha_j &= \beta_j \alpha^{(1)} + (1 - \beta_j) \alpha^{(2)}). \quad (6) \end{aligned}$$

The intermediate distributions are topic models, so we set T_j to be the corresponding Gibbs sampler. This T_j does not require power operations, providing substantial execution time savings over the geometric path and Equation 2. The importance weights are

$$\begin{aligned} \log w^{(i)} &= \sum_{j=0}^{n-1} \left(\log Pr(w^{(d)}, z_j^{(d)} | \Phi_j, \alpha_j) \right. \\ &\quad \left. - \log Pr(w^{(d)}, z_j^{(d)} | \Phi_{j+1}, \alpha_{j+1}) \right). \quad (7) \end{aligned}$$

To implement this method we need to draw initially from $f_n(z^{(d)})$, which we accomplish via Gibbs sampling. These

initial samples from $f_n(z^{(d)})$ need not be independent for the procedure to work, although we may choose to run independent chains if the cost of burn-in is deemed to be less than the time wasted due to running the annealing on correlated samples. Finally, AIS will be more likely to converge if the initial and target distributions are similar to each other. We therefore align the topics before running the algorithm, using the Hungarian algorithm to minimize the L1 distances between topics. This operation, which is $O(K^3)$, where K is the number of topics, is not a computational bottleneck (relative to performing AIS) and needs only to be performed once per corpus. Pseudo-code for ratio-AIS using the path from Equation 6 is given in Algorithm 1.

Algorithm 1 Ratio-AIS, using the convex path

```

for  $i = 1 : S$  //importance samples
   $\log \omega[i] := 0$ 
   $\Phi^{(next)} := \Phi^{(2)}$ 
   $\alpha^{(next)} := \alpha^{(2)}$ 
  draw  $z^{(i)} \sim Pr(z | \alpha^{(2)})$ 
  for  $j = n - 1, n - 2, \dots, 0$  //temperatures
     $\Phi^{(curr)} := \Phi^{(next)}$ 
     $\alpha^{(curr)} := \alpha^{(next)}$ 
     $\Phi^{(next)} := \beta_j \Phi^{(1)} + (1 - \beta_j) \Phi^{(2)}$ 
     $\alpha^{(next)} := \beta_j \alpha^{(1)} + (1 - \beta_j) \alpha^{(2)}$ 
    for  $a = 1 : r_j$  // $r_{n-1}$  is large, for burn in
      for  $l = 1 : \text{length}(w^{(d)})$  //words
        //draw  $z_l^{(i)}$ 
         $Pr(z_l^{(i)} = k | \cdot) \propto (n_k^{(i)} + \alpha_k^{(curr)}) \Phi_{w_l^{(d)}, k}^{(curr)}$ 
       $\log \omega[i] := \log \omega[i]$ 
       $+ \log Pr(w^{(d)}, z^{(i)} | \Phi^{(next)}, \alpha^{(next)})$ 
       $- \log Pr(w^{(d)}, z^{(i)} | \Phi^{(curr)}, \alpha^{(curr)})$ 
  return  $\log \text{SumExp}(\log \omega) - \log(S)$ 

```

Detecting Convergence Failures

AIS can produce poor estimates if the annealing fails to converge to a high-probability state in the target distribution within the given set of iterations. In general, this may be very difficult to detect. However, in our case we can interchange f_0 and f_n in our AIS strategy to compute the reciprocal of the desired ratio, and compare the reciprocal of this to our estimate. If these two values are wildly different, then we will know that the annealing has failed to converge. This means that we are able to detect convergence failures in many practical cases. In our experiments, we were easily able to catch convergence failures by observing a systematic bias across documents in the results of the different annealing directions (see Section 4).

3.2 EFFICIENTLY EVALUATING TOPIC MODEL LEARNING ALGORITHMS WITH ITERATION-AIS

When evaluating algorithms for learning topic models (or monitoring their convergence), we would ideally like to compute and plot held-out log-likelihood scores per learning iteration (or unit of computation time) for each algorithm under consideration. This is extremely expensive, requiring $|H| \times I \times M$ Monte Carlo approximations of already intractable high-dimensional integrals, where H is the held-out test set, I is the number of iterations of the learning algorithms to evaluate at, and M is the number of competing learning methods.

Fortunately, for many learning algorithms such as the collapsed Gibbs sampler, the topics at successive iterations are similar to each other, and the topics typically vary smoothly from “high temperature” high entropy distributions at early iterations to more complicated later distributions. This suggests using a single AIS path to perform the entire evaluation across all of the iterations, with the topic models at each iteration (or a subset of them) as intermediate distributions. We can accomplish this by annealing from the prior $Pr(z^{(d)}|\alpha^{(1)})$ to the first topic model $Pr(w^{(d)}, z^{(d)}|\Phi^{(1)}, \alpha^{(1)})$ as in Wallach et al. (2009b), and then using ratio-AIS to anneal between successive topic models $Pr(w^{(d)}, z^{(d)}|\Phi^{(t)}, \alpha^{(t)})$. For the topic model at iteration t , the average $S^{-1} \sum_i w^{(i,t)}$ of the importance weights computed up to that point $w^{(i,t)}$ converges to the ratio of normalizing constants,

$$\frac{\sum_{z^{(d)}} Pr(w^{(d)}, z^{(d)}|\Phi^{(t)}, \alpha^{(t)})}{\sum_{z^{(d)}} Pr(z^{(d)}|\alpha^{(1)})} = Pr(w^{(d)}|\Phi^{(t)}, \alpha^{(t)}). \quad (8)$$

With n temperatures per learning iteration k , importance weights can be written recursively as

$$\begin{aligned} \log w^{(i,t)} &= \sum_{t'=1}^t \sum_{j=0}^{n-1} \log \frac{f_{t',j}(z_{t',j})}{f_{t',j+1}(z_{t',j})} \\ &= \log w^{(i,t-1)} + \sum_{j=0}^{n-1} \log \frac{f_{t,j}(z_{t,j})}{f_{t,j+1}(z_{t,j})}. \end{aligned} \quad (9)$$

This method, which we refer to as *iteration-AIS*, exploits all of the computation for selecting z assignments and importance weights from the likelihood estimates at previous learning iterations, leading to successively longer annealing runs, and therefore potentially better likelihood estimates, as k increases.

4 EXPERIMENTS

We explored the performance of the proposed techniques using a corpora of scientific articles from the Association

of Computational Linguistics (ACL) conference⁶ (Radev et al., 2013), and another from the Neural Information Processing Systems (NIPS) conference.⁷ The ACL dataset consists of the 3286 articles from the years 1987 to 2011, while the NIPS corpus contains the 1740 articles published between 1987 and 1999. In each experiment, topic models with 50 topics were fit to each corpus by performing 1000 iterations of collapsed Gibbs sampling using the MALLETT toolkit (McCallum, 2002). Roughly 10% of the documents in each corpus were withheld for testing (130 NIPS articles, and 300 ACL articles). Although cross-validation would have been a preferable option to using a single hold-out set, the computational expense of the experiments prevented this. For example, across all algorithms and learning iterations, Figure 2 required a total of 6.6 million Gibbs iterations for each one of the 300 test articles.

When using AIS we must select the number of temperatures n , the number of importance samples S , and the temperature schedule $\beta_0, \beta_1, \dots, \beta_n$. The variability of an AIS estimator can be reduced by increasing S (due to the law of large numbers) or by increasing n (which reduces the variance of the $w^{(i)}$). In the experiments, we focused on the case where $S = 1$, as in Wallach et al. (2009b). We found in preliminary experiments that $S = 1$ gave essentially exactly the same answer as $S = 100$ importance samples for Ratio-AIS with 10,000 temperatures. For simplicity, we used a uniform spacing of the temperatures β_j .⁸

We also compared to the left-to-right (LR) particle filtering algorithm of Wallach et al. (2009b), using the implementation provided in MALLETT. The left-to-right method requires $N_d(N_d + 1)/2$ word-level Gibbs updates per particle for a document of length N_d . The execution of $p = 2 \times n/(N_d + 1)$ particles corresponds to the same number of Gibbs updates as AIS with n temperatures and $S = 1$. We select the number of LR particles by rounding p to the nearest integer greater than zero.

Ratio-AIS was designed for reliable per-document comparisons. To explore this, we ran each algorithm twice on each document, and reported results comparing the two runs across documents. To remove the effect of document length in the results, instead of reporting the differences in log-likelihood scores for each model we consider instead perplexity scores $\exp(-\frac{\log Pr(w^{(d)}|\Phi, \alpha)}{N_d})$. The ratio of the perplexity of model 1 over the perplexity of model 2 for a document is easily computed from the output of Ratio-AIS as $\exp(\frac{L_2 - L_1}{N_d})$, where L_j is the log-likelihood for model j . We considered two evaluation scenarios: comparing learned topics to perturbed versions of the same top-

⁸Neal (2001) suggests that a geometric spacing of the β_j 's may be beneficial, at least for the geometric annealing path.

ics (Section 4.1), and comparing topic models learned with symmetric and asymmetric Dirichlet priors (Section 4.2). Finally, we evaluated iteration-AIS for estimation of per-iteration likelihood (Section 4.3).

4.1 LEARNED TOPICS VERSUS PERTURBED TOPICS

As the likelihoods we are trying to estimate are intractable, we do not in general have access to ground truth. However, after learning topics Φ on a dataset and then creating a noisy copy of them Φ' , we have good reason to believe that the original topics Φ are better than the copy. This style of experiment was previously performed by Wallach et al. (2009b). We took the word-topic assignments learned by MALLET, and created Φ' by re-assigning 5% of them to new word-topic assignments uniformly at random.⁹

Ratios of the perplexities for the two models were computed with both cheap (100 temperatures) and expensive runs (10,000 temperatures). Overall results are given in Table 1, and per-document results for the ACL dataset are plotted in Figure 1.¹⁰ The two ratio-AIS paths were both the most accurate and the most consistent methods, in both temperature regimes.

In the cheap regime, the ratio-AIS points are slightly off-diagonal in Figure 1, with one annealing direction giving systematically lower results, representing a detectable bias due to convergence failure in at least one annealing direction. Nevertheless, these results have much lower variance, and the bias disappears in the expensive regime. Surprisingly, the standard AIS method performed extremely poorly, with most data points falling outside of the boundaries of the figure, which are tight around the results of the other methods. Using many importance samples would very likely mitigate this, at greater computational cost. It should be noted that the task of comparing two very similar topic models is difficult for standard methods, but is relatively easy for ratio-AIS due to the distance to anneal between the distributions being smaller.

4.2 SYMMETRIC VERSUS ASYMMETRIC DIRICHLET PRIORS

Learning asymmetric α hyperparameters can improve the predictive performance of topic models (e.g., Wallach et al. (2009a)). To explore this, on each corpus we learned a topic model with asymmetric α , and a model where α was fixed to be flat but its concentration parameter was learned. The AIS and LR algorithms were used to compare the resulting models, using runs with 1000 temperatures and 10,000 temperatures.

⁹MALLET’s left-to-right takes as input a count matrix, so the perturbed topics must be representable as counts.

¹⁰Results for the NIPS corpus are similar, and are provided in Foulds (2014).

It was found that in the “cheap” 1000 temperature regime, the ratio-AIS estimates were the most closely correlated with left-to-right estimates in the expensive regime, the best available proxy for ground truth (Table 2, top).¹¹ In all cases the ratio-AIS paths had one to two orders of magnitude lower empirical variances in the estimates of per-document perplexity ratios than the previous methods, with the convex path having the least variance (Table 2, middle). Ratio-AIS therefore achieves the original goal of greatly reducing the variance of per-document comparisons of topic models. This is particularly important if we want to perform detailed analysis at a per-document level, such as exploring the effect of covariates on topic model performance. In such a scenario, the previous methods have unacceptably high variance for a reasonable level of computation (see also Figure 1), while the ratio-AIS estimates of relative performance have very small empirical variance with just one importance sample.

Unfortunately, this reduction comes at a price of potentially increased bias in the estimated perplexity ratio when given insufficient computation. Topic models which learn an asymmetric α tend to perform better than those with a symmetric α (Wallach et al., 2009a), and the previous methods detected a larger advantage for the asymmetric approach (Table 2, bottom). The direction of the ratio-AIS annealing path also made a difference to the outcome. In particular, the forward direction of annealing did not detect an overall advantage to the asymmetric hyper-parameter model. On the other hand, the difference per direction allowed us to detect a convergence failure, which is difficult to do in general. Also note that for the task in Section 4.1, the overall perplexity ratios were very consistent between annealing directions, and showed a clearer difference between models than the baseline algorithms did – see Foulds (2014).

4.3 EVALUATING TOPIC MODELS PER ITERATION

The iteration-AIS annealing path evaluates the performance of topic model learning algorithms on a per-iteration basis. We explored its performance using the convex path with 1000 and 10,000 temperatures per learned model, annealing between the models at every 10th learning iteration. At the first learning iteration $\Phi^{(1)}$, the algorithms were given an extra 1000 temperatures to compensate for the cold-start from the prior.

Results on ACL are shown in Figure 2. It was found that iteration-AIS estimated higher log-likelihoods than left-to-right and standard AIS in both temperature regimes (Figure 2, left). The main failure mode of these algorithms is to underestimate the likelihood by failing to find high probability regions, so higher values are likely to be better

¹¹The standard AIS estimate of the perplexity ratios had too high a variance to be used (see Table 2).

(Wallach et al., 2009b). Consistent with this observation, the iteration-AIS likelihood curve at 1000 temperatures coincided with the likelihood curves of the baselines when they were given ten times more computation. The proposed method also exhibited much lower variance in the likelihood estimates (Figure 2, right). This is expected, as the effective number of annealing temperatures is higher, which is known to reduce the variance of the importance weights (Neal, 2001). Similar results were observed on NIPS (see Foulds (2014) for these and other additional results).

The baselines reported decreasing held-out likelihood in later iterations, while iteration-AIS did not. Such a decrease could be due to over-fitting, but is more likely to be caused by convergence failures due to the topics becoming more complex. As evidence for this, the dip in likelihood was smaller with increased computation, and all methods exhibited higher variance in the likelihood estimates for later learning iterations (Figure 2, right, computed based on two evaluations of the likelihood per document, and averaged across documents). The prior probability of the topic models also decreased from around iteration 300 (the same point where standard AIS began to report a decrease in performance), and this is likely to make inference more difficult (see Foulds (2014)).

5 CONCLUSIONS

We have introduced ratio-AIS, a strategy for comparing topic models, and empirically evaluated its performance relative to previous methods using two datasets. Ratio-AIS was found to have low empirical variance, making it useful for document-level analysis. It should be noted that importance sampling can suffer from bias with a finite number of

samples, e.g. approaches such as those described by Wallach et al. (2009b) will typically underestimate the likelihood. For ratio-AIS this results in the potential for a bias that favors a particular model when an insufficient number of samples or temperatures is used, due to the directional nature of the approach. Such a convergence failure of a Monte Carlo algorithm is in general very difficult to detect, but in the proposed method the bias is frequently easily detectable by comparing the results of two Monte Carlo runs. When applied to the evaluation of the per-iteration performance of topic model training algorithms (iteration-AIS), the method outperforms traditional approaches even when given an order of magnitude less computation. Based on our results, we recommend ratio-AIS for document-level analysis, or in cases where the topics are very similar to each other. The method should be performed using both annealing directions as a convergence sanity check, at least for a subset of the held-out documents. Left-to-right is still generally preferred for corpus-level perplexity comparisons, unless per-iteration curves are desired, in which case we recommend that iteration-AIS be used.

For future work, it is straightforward to adapt ratio-AIS to the document completion task. It may also be possible to find other AIS paths with better mixing properties, and the ideas in this work may be applicable to other latent variable models such as RBMs. See Foulds (2014) for a discussion on these ideas, as well as on the use of ratio-AIS with multiple topic models, and where the models differ in the number of topics or in their parametric forms.

Abstract

We propose an active learning method for discovering low-dimensional structure in high-dimensional Gaussian process (GP) tasks. Such problems are increasingly frequent and important, but have hitherto presented severe practical difficulties. We further introduce a novel technique for approximately marginalizing GP hyperparameters, yielding marginal predictions robust to hyperparameter misspecification. Our method offers an efficient means of performing GP regression, quadrature, or Bayesian optimization in high-dimensional spaces.

1 INTRODUCTION

We propose a method to actively learn, simultaneously, about a function and a low-dimensional embedding of its input domain. High dimensionality has stymied the progress of model-based approaches to many common machine learning tasks. In particular, although Bayesian nonparametric modeling with Gaussian processes (GPs) (Rasmussen & Williams, 2006) has become popular for regression, classification, quadrature (O’Hagan, 1991), and global optimization (Brochu et al., 2010), such approaches remain intractable for large numbers of input variables (with the exception of local optimization (Hennig & Kiefel, 2012)). An old idea for the solution to this problem is the exploitation of low-dimensional structure; the most tractable such case is that of a linear embedding. Throughout this text, we consider a function $f(x): \mathbb{R}^D \rightarrow \mathbb{R}$ of a high-dimensional variable $x \in \mathbb{R}^D$ (for notational simplicity, x will be assumed to be a row vector). The assumption is that f , in reality, only depends on the variable $u := xR^T$, of much lower dimensionality $d \ll D$, through a linear embedding $R \in \mathbb{R}^{d \times D}$. We are interested in an algorithm that simultaneously learns R and f , and does so in an active way. That is, it iteratively selects informative locations x_* in a box-bounded region $\mathcal{X} \subset \mathbb{R}^D$, and collects associated obser-

ventions y_* of $f_* := f(x_*)$ corrupted by i.i.d. Gaussian noise: $p(y_* | f_*) = \mathcal{N}(y_*; f_*, \sigma^2)$.

The proposed method comprises three distinct steps (Algorithm 1): constructing a probability distribution over possible embeddings (*learning the embedding R*); using this belief to determine a probability distribution over the function itself (*learning the function f*), and then choosing evaluation points to best inform these beliefs (*active selection*). To learn the embedding, we use a Laplace approximation on the posterior over R to quantify the uncertainty in the embedding (Section 2). To learn the function, we develop a novel approximate means of marginalizing over Gaussian process hyperparameters (including those parameterizing embeddings), to provide predictions robust to hyperparameter misspecification (Section 3). This sub-algorithm is more generally applicable to many Gaussian process tasks, and to the marginalization of hyperparameters other than embeddings, and so represents a core contribution of this paper. Finally, for active selection, we extend previous work (Houlsby et al., 2011) to select evaluations that maximize the expected reduction in uncertainty about R (Section 4).

Estimators for R in wide use include LASSO (Tibshirani, 1996) and the Dantzig selector (Candes & Tao, 2007), both of which assume $d = 1$. These are passive methods estimating the linear embedding from a fixed dataset. This paper develops an algorithm that *actively* learns R for the domain of a Gaussian process. The goal is to use few function evaluations to intelligently explore and identify R . Notice that although the embedding is assumed to be linear, the function f itself will be allowed to be nonlinear via the GP prior.

This problem is related to, but distinct from, dimensionality reduction (Lawrence, 2012), for which active learning has recently been proposed (Iwata et al., 2013). Dimensionality reduction is also known as visualization or blind source separation, and is solved using, e.g., principal component analysis (PCA), factor analysis, or latent variable models. As in dimensionality reduction, we consider the problem of finding a low-dimensional representation of an input or feature matrix $X \in \mathbb{R}^{N \times D}$; unlike dimensionality reduction, we do so given an associated vector of training

Algorithm 1 Simultaneous active learning of functions and their linear embeddings (pseudocode)

return $q(R), q(f)$.

outputs or labels $y \in \mathbb{R}^N$, containing information about which inputs are most relevant to a function. The problem of discovering linear embeddings of GPs was discussed by Snelson & Ghahramani (2006) for the passive case. Active supervised learning has been widely investigated (MacKay, 1992b; Guestrin et al., 2005; Houlby et al., 2011); our work hierarchically extends this idea to additionally identify the embedding. A special case of our method (the case of a diagonal R) is the hitherto unconsidered problem of *active* automatic relevance determination (MacKay, 1992a; Neal, 1995; Williams & Rasmussen, 1996).

Identifying embeddings is relevant for numerous Gaussian process applications, notably regression, classification, and optimization. Within Bayesian optimization, much recent work has focused on high-dimensional problems (Hutter et al., 2011; Chen et al., 2012; Carpentier & Munos, 2012; Bergstra & Bengio, 2012; Hutter, 2009). Recently, Wang et al. (2013) proposed using randomly generated linear embeddings. In contrast, our active learning strategy can provide an initialization phase that selects objective function evaluations so as to best learn low-dimensional structure. This permits the subsequent optimization of high-dimensional objectives over only the learned low-dimensional embedding.

Alongside this paper, we are releasing open-source software implementing our contributions. A simple MATLAB implementation of Algorithm 1, built on the Gaussian Process for Machine Learning (GPML) Toolbox,¹ is freely available.² An independent, GPML-compatible implementation of the MGP (Section 3) is also available.³

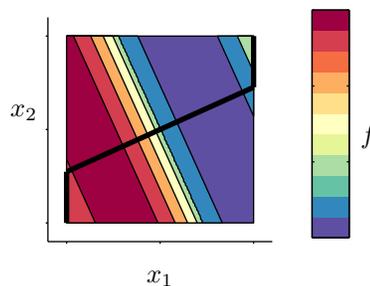

Figure 1: A function f with a one-dimensional linear embedding and its box-bounded domain \mathcal{X} . Searching over the thick black lines captures all variation of the function. Our aim is to learn this embedding, represented by embedding matrix $R \in \mathbb{R}^{1 \times 2}$, by selecting evaluations of f in some search space.

2 LINEAR EMBEDDINGS OF GAUSSIAN PROCESSES

In many applications, like image analysis, D can be in the order of thousands or millions. But even $D = 10$ is a high dimensionality for common Gaussian process models, not only from a computational, but also from an informational, perspective. Because standard GP covariance functions stipulate that function values separated by more than a few input length scales are negligibly correlated, for high D , almost all of \mathcal{X} is uncorrelated with observed data. Hence data is effectively ignored during most predictions, and learning is impossible. Practical experience shows, however, that many functions are insensitive to some of their inputs (Wang et al., 2013), thus have low *effective* dimensionality (Figure 1). Our goal is to discover an $R \in \mathbb{R}^{d \times D}$ such that, for low-dimensional $\mathcal{U} \subset \mathbb{R}^d$, $u = xR^\top$, $\forall u \in \mathcal{U}$, $x \in \mathcal{X}$ and $f(x) = \tilde{f}(u)$ for a new function, $\tilde{f}: \mathcal{U} \rightarrow \mathbb{R}$. The discussion here will be restricted to predefined d ; in reality, this is likely to be defined as the maximum number of dimensions that can be feasibly considered in light of computational constraints. If the actual d is lower than this limit, R can be padded with rows of zeros.

We adopt a GP prior on \tilde{f} with mean and covariance functions $\tilde{\mu}$ and $\tilde{\kappa}$, respectively. The linear embedding induces another GP prior $p(f) = \mathcal{GP}(f; \mu, \kappa)$, where $\mu(x) = \tilde{\mu}(xR^\top)$ and $\kappa(x, x') = \tilde{\kappa}(xR^\top, x'R^\top)$. For example, if $\tilde{\kappa}$ is the well-known isotropic exponentiated-quadratic (squared-exponential, radial basis function, Gaussian) covariance, $\tilde{\kappa}(u, u') := \gamma^2 \exp[-\frac{1}{2}(u - u')(u - u')^\top]$ with output scale γ , κ on f is the Mahalanobis exponentiated-quadratic covariance

$$\kappa(x, x') = \gamma^2 \exp\left[-\frac{1}{2}(x - x')R^\top R(x - x')^\top\right]. \quad (1)$$

If $d = D = 1$, then $R \in \mathbb{R}$ is an inverse length scale. We will return to this one-dimensional example later to build intuition. A further special case is a diagonal R (assuming

$d = D$), in which case κ is the automatic relevance determination (ARD) covariance (Neal, 1995), widely used to identify the most-important inputs.

Given an appropriate R with acceptably small d , learning about f is possible even for large D , because the regression problem is reduced to the manageable space \mathbb{R}^d . This can remain true even in the case of an uncertain R : in particular, assume a prior $p(R) = \mathcal{N}(R; \hat{R}, \Sigma)$. Thus, recalling that $u = xR^\top$, and using standard Gaussian identities, if $d = 1$, $p(u | x) = \mathcal{N}(u; x\hat{R}^\top, x\Sigma x^\top)$. If $d > 1$, Σ is $\text{Cov}[\text{vect}R]$, resulting in another Gaussian for $p(u | x)$ that is only slightly more involved than in the $d = 1$ case. As such, regression on f reduces to GP regression on \hat{f} , whose domain is the much smaller $\mathcal{U} \subset \mathbb{R}^d$, but with uncertain, Gaussian-distributed, inputs. Unlike the work of McHutchon & Rasmussen (2011), giving an existing approach to GP regression with uncertain inputs, the Gaussian over the inputs here is correlated; the location of a point is correlated with all others via mutual dependence on R . And unlike the setting considered by Girard & Murray-Smith (2005), there is no natural ordering of this domain enabling an iterative procedure. The following section describes a novel means of regression with uncertain embedding R .

2.1 APPROXIMATING THE POSTERIOR ON R

The log-likelihood of R , after N observations forming a dataset $\mathcal{D} := (X, y) \in \mathbb{R}^{N \times D} \times \mathbb{R}^N$, is

$$\begin{aligned} \log p(y | X, R) &= \log \mathcal{N}(y; \mu_X, K_{XX} + \sigma^2 \mathbb{I}) \\ &= -1/2[(y - \mu_X)^\top (K_{XX} + \sigma^2 \mathbb{I})^{-1} (y - \mu_X) \\ &\quad + \log |K_{XX} + \sigma^2 \mathbb{I}| + N \log 2\pi]. \end{aligned} \quad (2)$$

As $\mu_X := \mu(X)$ and $K_{XX} := \kappa(X, X)$ have nonlinear dependence upon R , so does $p(y | X, R)$. Even a simplistic prior on the elements of R thus gives a complicated posterior. We will use a Laplace approximation for $p(R | \mathcal{D})$ to attain a tractable algorithm. To construct a Gaussian approximation, $\mathcal{N}(R; \hat{R}, \Sigma) \simeq p(R | \mathcal{D})$, we find a mode of the posterior of $p(R | \mathcal{D})$ and set this mode as the mean \hat{R} of our approximate distribution. The covariance of the Gaussian approximation is taken as the inverse Hessian of the negative logarithm of the posterior evaluated at \hat{R} ,

$$\Sigma^{-1} = -\nabla \nabla^\top \log p(R | \mathcal{D}) \Big|_{R=\hat{R}}. \quad (3)$$

2.1.1 Computational Cost

How costly is it to construct the Laplace approximation of Equation (3)? Since D may be a large number, active learning should have low cost in D . This section shows that the required computations can be performed in time linear in D , using standard approximate numerical methods. It is a technical aspect that readers not interested in details may want to skip over.

Up to normalization, the log posterior is the sum of log prior and log likelihood (2). The former can be chosen very simplistically; the latter has gradient and Hessian given by, defining $G := \kappa_{XX} + \sigma^2 \mathbb{I}$ and $\Gamma := G^{-1}(y - \mu_X)$,

$$\begin{aligned} -2 \frac{\partial \log p(y | X, R)}{\partial \theta} &= -\Gamma^\top \frac{\partial \kappa_{XX}}{\partial \theta} \Gamma + \text{Tr} \left[G^{-1} \frac{\partial \kappa_{XX}}{\partial \theta} \right]; \\ -2 \frac{\partial^2 \log p(y | X, R)}{\partial \theta \partial \eta} &= 2\Gamma^\top \frac{\partial \kappa_{XX}}{\partial \eta} G^{-1} \frac{\partial \kappa_{XX}}{\partial \theta} \Gamma \\ &\quad - \text{Tr} \left[G^{-1} \frac{\partial \kappa_{XX}}{\partial \eta} G^{-1} \frac{\partial \kappa_{XX}}{\partial \theta} \right] \\ &\quad - \Gamma^\top \frac{\partial^2 \kappa_{XX}}{\partial \theta \partial \eta} \Gamma + \text{Tr} \left[G^{-1} \frac{\partial^2 \kappa_{XX}}{\partial \theta \partial \eta} \right]. \end{aligned} \quad (4)$$

Together with the analogous expressions for a prior $p(R)$, these expressions can be used to find a maximum of the posterior distribution (e.g., via a quasi-Newton method), and the Hessian matrix required for the Laplace approximation to $p(R | \mathcal{D})$. The computational cost of evaluating these expressions depends on the precise algebraic form of the kernel κ . For the exponentiated quadratic kernel of Equation (1), careful analysis shows that the storage cost for the Hessian of (2) is $\mathcal{O}(N^2 d D)$, and its structure allows its multiplication with a vector in $\mathcal{O}(N^2 d D)$. The corresponding derivations are tedious and not particularly enlightening. To give an intuition, consider the most-involved term in (4): Using the short-hand $\Delta_\ell^{ij} := x_{i\ell} - x_{j\ell}$, a straightforward derivation gives the form

$$\begin{aligned} H_{k\ell, ab}^1 &:= - \sum_{ij} \Gamma_i \frac{\partial^2 \kappa(x_i, x_j)}{\partial R_{k\ell} \partial R_{ab}} \Gamma_j \\ &= \sum_{ijop} R_{ko} \Delta_o^{ij} \Delta_\ell^{ij} \Gamma_i \kappa(x_i, x_j) \Gamma_j R_{ap} \Delta_p^{ij} \Delta_b^{ij} \\ &\quad - \sum_{ij} \delta_{ka} \Delta_b^{ij} \Gamma_i \kappa(x_i, x_j) \Gamma_j \Delta_\ell^{ij}. \end{aligned}$$

Multiplication of this term with some vector g_{ab} (resulting from stacking the elements of the $D \times d$ matrix g into a vector) requires storage of the $d \times N \times N$ array $R\Delta$ with elements $(R\Delta)_k^{ij}$, the $D \times N \times N$ array Δ with elements Δ_ℓ^{ij} , and the $N \times N$ matrix $\Gamma \Gamma^\top \otimes K$. Multiplication then takes the form

$$\begin{aligned} [H^1 g]_{k\ell} &= \sum_{j=1}^N \sum_{i=1}^N (R\Delta)_k^{ij} \Delta_\ell^{ij} \Gamma_i \Gamma_j \kappa_{x_i x_j} \\ &\quad \times \underbrace{\left[\sum_{a=1}^d (R\Delta)_a^{ij} \left[\sum_{b=1}^D \Delta_b^{ij} g_{ab} \right] \right]}_{\text{compute once in } \mathcal{O}(N^2 d D), \text{ store in } \mathcal{O}(N^2)}. \end{aligned} \quad (5)$$

Since the $N \times N$ matrix in the square brackets is independent of $k\ell$, it can be reused in the dD computations required to evaluate the full matrix–vector product, so the overall computation cost of this product is $\mathcal{O}(N^2 d D)$. The other required terms are of similar form. This means that approximate inversion of the Hessian, using an iterative solver like

the Lanczos or conjugate gradient methods, is achievable in time linear in D . The methods described here are computationally feasible even for high-dimensional problems. Our implementation of the active method, released along with this text, does not yet allow this kind of scalability, but the derivations above show that it is feasible in principle.

3 APPROXIMATE MARGINALIZATION OF GAUSSIAN PROCESS HYPERPARAMETERS

To turn the approximate Gaussian belief on R into an approximate Gaussian process belief on f , the active learning algorithm (constructed in Section 4) requires an (approximate) means of integrating over the belief on R . The elements of R form hyperparameters of the GP model. The problem of dealing with uncertainty in Gaussian process hyperparameters is a general one, also faced by other, non-active, Gaussian process regression models. This section presents a novel means of approximately integrating over the hyperparameters of a GP. The most widely used approach to learning GP hyperparameters is type-II maximum likelihood estimation (evidence maximization), or maximum *a posteriori* (MAP) estimation, which both approximate the likelihood as a delta function. However, ignoring the uncertainty in the hyperparameters in this way can lead to pathologies (MacKay, 2003).

For compact notation, all hyperparameters to be marginalized will be subsumed into a vector θ . We will denote as $m_{f|\mathcal{D},\theta}(x)$ the GP posterior mean prediction for $f(x)$ conditioned on data \mathcal{D} and θ , and similarly as $V_{f|\mathcal{D},\theta}(x)$ the posterior variance V of $f(x)$ conditioned on \mathcal{D} and θ .

We seek an approximation to the intractable posterior for $f_* = f(x_*)$, which requires marginalization over θ :

$$p(f_* | \mathcal{D}) = \int p(f_* | \mathcal{D}, \theta) p(\theta | \mathcal{D}) d\theta. \quad (6)$$

Assume a Gaussian conditional, $p(\theta|\mathcal{D}) = \mathcal{N}(\theta; \hat{\theta}, \Sigma)$, on the hyperparameters, such as the approximate distribution over R constructed in the preceding section. To make the integral in (6) tractable, we seek a linear approximation

$$p(f_*|\mathcal{D}, \theta) = \mathcal{N}(f_*; m_{f|\mathcal{D},\theta}(x_*), V_{f|\mathcal{D},\theta}(x_*)) \quad (7)$$

$$\simeq q(f_*; \theta) := \mathcal{N}(f_*; a^\top \theta + b, \nu^2), \quad (8)$$

using free parameters a, b, ν^2 to optimize the fit. The motivation for this approximation is that it yields a tractable marginal, $p(f_*|\mathcal{D}) \simeq \mathcal{N}(f_*; a^\top \hat{\theta} + b, \nu^2 + a^\top \Sigma a)$. Further, the posterior for θ typically has quite narrow width, over which $p(f_*|\mathcal{D}, \theta)$'s dependence on θ can be reasonably approximated. We choose the variables a, b, ν^2 by matching a local expansion of $q(f_* | \theta)$ to $p(f_*|\mathcal{D}, \theta)$. The expansion will be performed at $\theta = \hat{\theta}$, and at a $f_* = \hat{f}_*$ to be determined.

Specifically, we match as

$$\left. \frac{\partial}{\partial f_*} q(f_*; \theta) \right|_{\hat{\theta}, \hat{f}_*} = \left. \frac{\partial}{\partial f_*} p(f_*|\mathcal{D}, \theta) \right|_{\hat{\theta}, \hat{f}_*}; \quad (9)$$

$$\left. \frac{\partial}{\partial \theta_i} q(f_*; \theta) \right|_{\hat{\theta}, \hat{f}_*} = \left. \frac{\partial}{\partial \theta_i} p(f_*|\mathcal{D}, \theta) \right|_{\hat{\theta}, \hat{f}_*}; \quad (10)$$

$$\left. \frac{\partial^2}{\partial f_*^2} q(f_*; \theta) \right|_{\hat{\theta}, \hat{f}_*} = \left. \frac{\partial^2}{\partial f_*^2} p(f_*|\mathcal{D}, \theta) \right|_{\hat{\theta}, \hat{f}_*}; \quad (11)$$

$$\left. \frac{\partial^2}{\partial f_* \partial \theta_i} q(f_*; \theta) \right|_{\hat{\theta}, \hat{f}_*} = \left. \frac{\partial^2}{\partial f_* \partial \theta_i} p(f_*|\mathcal{D}, \theta) \right|_{\hat{\theta}, \hat{f}_*}. \quad (12)$$

An alternative set of constraints could be constructed by including second derivatives with respect to θ . But this would require computation scaling as $\mathcal{O}((\#\theta)^2)$, prohibitive for large numbers of hyperparameters, such as the $D \times d$ required to parameterize R for large D . We define

$$\hat{m} := m_{f|\mathcal{D}, \hat{\theta}} \quad \text{and} \quad \frac{\partial \hat{m}}{\partial \theta_i} := \left. \frac{\partial m_{f|\mathcal{D}, \theta}}{\partial \theta_i} \right|_{\theta = \hat{\theta}}, \quad (13)$$

along with analogous expressions for \hat{V} and $\frac{\partial \hat{V}}{\partial \theta_i}$. Turning to solving for a, b, ν^2 and f_* , note that, firstly, (9) implies that $a^\top \hat{\theta} + b = \hat{m}$, and that (11) implies that $\nu^2 = \hat{V}$. Rearranging (10) and (12), respectively, we have

$$2a_i = \frac{\partial \hat{V}}{\partial \theta_i} \left(\frac{1}{\hat{f}_* - \hat{m}} - \frac{\hat{f}_* - \hat{m}}{\hat{V}} \right) + 2 \frac{\partial \hat{m}}{\partial \theta_i}; \quad (14)$$

$$2a_i = 2 \frac{\partial \hat{V}}{\partial \theta_i} \frac{\hat{f}_* - \hat{m}}{\hat{V}} + 2 \frac{\partial \hat{m}}{\partial \theta_i}. \quad (15)$$

(14) and (15) can be solved only for

$$a_i = a_{i\pm} := \pm \frac{1}{\sqrt{3\hat{V}}} \frac{\partial \hat{V}}{\partial \theta_i} + \frac{\partial \hat{m}}{\partial \theta_i}; \quad (16)$$

$$f_* = \hat{f}_{*\pm} := \hat{m}(x_*) \pm \sqrt{\frac{\hat{V}(x_*)}{3}}. \quad (17)$$

In particular, note that the intuitive choice $f_* = \hat{m}(x_*)$, for which $\frac{\partial}{\partial f_*} p(f_*|\mathcal{D}, \theta) = 0$, gives q inconsistent constraints related to its variation with θ . Introducing the separation of $(\hat{V}(x_*)/3)^{1/2}$ provides optimal information about the curvature of $p(f_*|\mathcal{D}, \theta)$ with θ . Hence there are two possible values, $\hat{f}_{*\pm}$, to expand around, giving a separate Gaussian approximation for each. We average over the two solutions, giving an approximation that is a mixture of two Gaussians. We then further approximate this as a single moment-matched Gaussian.

The consequence of this approximation is that

$$p(f_* | \mathcal{D}) \simeq \mathcal{N}(f_*; \tilde{m}_{f|\mathcal{D}}(x_*), \tilde{V}_{f|\mathcal{D}}(x_*)), \quad (18)$$

where the marginal mean for f_* is $\tilde{m}_{f|\mathcal{D}}(x_*) := \hat{m}(x_*)$,

and the marginal variance is

$$\begin{aligned} \tilde{V}_{f|\mathcal{D}}(x_*) &:= \frac{4}{3} \hat{V}(x_*) + \frac{\partial \hat{m}(x_*)^\top}{\partial \theta} \Sigma \frac{\partial \hat{m}(x_*)}{\partial \theta} \\ &+ \frac{1}{3 \hat{V}(x_*)} \frac{\partial \hat{V}(x_*)^\top}{\partial \theta} \Sigma \frac{\partial \hat{V}(x_*)}{\partial \theta}. \end{aligned} \quad (19)$$

Figure 2 provides an illustration of our approximate marginal GP (henceforth abbreviated as MGP).

Our approach is similar to that of Osborne et al. (2012) (BBQ), for which $\tilde{V}_{f|\mathcal{D}} = V_{f|\mathcal{D}, \hat{\theta}} + \frac{\partial \hat{m}}{\partial \theta}^\top \Sigma \frac{\partial \hat{m}}{\partial \theta}$. However, BBQ ignores the variation of the predictive variance with changes in hyperparameters.

To compare the two methods, we generated (from a GP) $10 \times D$ random function values, \mathcal{D} , where D is the problem dimension. We then trained a GP with zero prior mean and ARD covariance on that data, and performed prediction for $10 \times D$ test data. Test points, (x_*, y_*) , were generated a small number (drawn from $\mathcal{U}(1, 3)$) of input scales away from a training point in a uniformly random direction. The MGP and BBQ were used to approximately marginalize over all GP hyperparameters (the output scale and D input scales), computing posteriors for the test points. We considered $D \in \{5, 10, 20\}$ and calculated the mean symmetrized Kullback–Leibler divergence (SKLD) over fifty random repetitions of each experiment. We additionally tested on two real datasets:⁴ yacht hydrodynamics (Gerritsma et al., 1981) and (centered) concrete compressive strength (Yeh, 1998). In these two, a random selection of 50 and 100 points, respectively, was used for training and the remainder for testing. All else was as above, with the exception that ten random partitions of each dataset were considered.

We evaluate performance using the SKLD between approximate posteriors and the “true” posterior (obtained using a run of slice sampling (Neal, 2003) with 10^5 samples and 10^4 burn-in); the better the approximate marginalization, the smaller this divergence. We additionally measured the average negative predictive log-likelihood, $-\mathbb{E}[\log p(y_* | x_*, \mathcal{D})]$, on the test points (x_*, y_*) . Results are displayed in Table 1; it can be seen that the MGP provides both superior predictive likelihoods and posteriors closer to the “true” distributions. The only exception is found on the yacht dataset, where the MGP’s SKLD score was penalized for having predictive variances that were consistently slightly larger than the “true” variances. However, these conservative variances, in better accommodating test points that were unexpectedly large or small, led to better likelihoods than the consistently over-confident MAP and BBQ predictions.

4 ACTIVE LEARNING OF GAUSSIAN PROCESS HYPERPARAMETERS

Now we turn to the question of actively selecting observation locations to hasten our learning of R . We employ an active learning strategy due to Houlsby et al. (2011), known as *Bayesian active learning by disagreement* (BALD). The idea is that, in selecting the location x of a function evaluation f to learn parameters θ , a sensible utility function is the expected reduction in the entropy of θ ,

$$v(x) := H(\Theta) - H(\Theta | F) = H(F) - H(F | \Theta), \quad (20)$$

also equal to the mutual information $I(\Theta; F)$ between f and θ . Mutual information, unlike differential entropies, is well-defined: the BALD objective is insensitive to changes in the representation of f and θ . The right-hand side of (20), the expected reduction in the entropy of f given the provision of θ , is particularly interesting. For our purposes, θ will parameterize $R \in \mathbb{R}^{d \times D}$; that is, θ is very high-dimensional, making the computation of $H(\Theta)$ computationally demanding. In contrast, the calculation of the entropy of $f \in \mathbb{R}$ is usually easy or even trivial. The right-hand side of (20) is particularly straightforward to evaluate under the approximation of Section 3, for which $p(f | \mathcal{D}, \theta)$ and the marginal $p(f | \mathcal{D})$ are both Gaussian. Further, under this approximation, $p(f | \mathcal{D}, \theta)$ has variance $\nu^2 = \hat{V}$ that is independent of θ , hence, $H(F | \Theta) = H(F | \Theta = \hat{\theta})$. We henceforth consider the equivalent but transformed utility function

$$v'(x) = \tilde{V}_{f|\mathcal{D}}(x) \left(V_{f|\mathcal{D}, \hat{\theta}}(x) \right)^{-1}. \quad (21)$$

The MGP approximation has only a slight influence on this objective – Figure 2 compares it to a full MCMC-derived marginal. With reference to (19), (21) encourages evaluations where the posterior mean and covariance functions are most sensitive to changes in θ (Figure 3), normalized by the variance in f : such points are most informative about the hyperparameters. An alternative to BALD is found in *uncertainty sampling*. Uncertainty sampling selects the location with highest variance, that is, its objective is simply $H(F)$, the first term in the BALD objective. This considers only the variance of a single point, whereas the BALD objective rewards points that assist in the learning of embeddings, thereby reducing the variance associated with all points. An empirical comparison of our method against uncertainty sampling follows below.

4.1 ACTIVE LEARNING OF LINEAR EMBEDDINGS FOR GAUSSIAN PROCESSES

To apply BALD to learning the linear embedding of a Gaussian process, we consider the case $R \subset \theta$; the GP hyperparameters define the embedding described in Section 2. Figure 4 demonstrates an example of active learning for the embedding of a two-dimensional function.

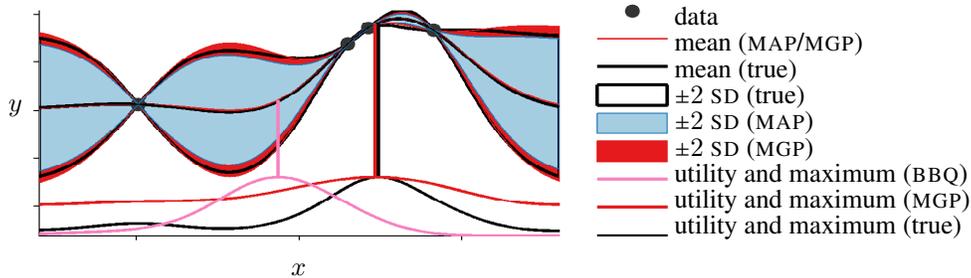

Figure 2: Approximate marginalization (MGP) of covariance hyperparameters θ increases the predictive variance to closely match the “true” posterior (obtained using slice sampling with 10^5 samples). BBQ (Osborne et al., 2012) provides a standard deviation differing from the MAP standard deviation by less than 3.1% everywhere, and would hence be largely invisible on this plot. The bottom of the figure displays the (normalized) mutual information $I(\Theta; F(x))$ (equal to the BALD utility function $v(x)$) for the various methods, and their maxima, giving the optimal positions for the next function evaluations. The MGP position is very close to the true position.

Table 1: Mean negative log-likelihood for test points and mean SKLD (nats) between approximate and true posteriors. Both metrics were averaged over test points, as well as over fifty and ten random repeats for synthetic and real experiments, respectively.

problem	dim	$-\mathbb{E}[\log p(y_* x_*, \mathcal{D})]$			SKLD		
		MAP	BBQ	MGP	MAP	BBQ	MGP
synthetic	5	3.58	2.67	1.73	0.216	0.144	0.0835
synthetic	10	3.57	3.10	1.86	0.872	0.758	0.465
synthetic	20	1.46	1.41	0.782	1.01	0.947	0.500
yacht	6	123.0	97.8	56.8	0.0322	0.0133	0.0323
concrete	8	$2.96 \cdot 10^9$	$2.96 \cdot 10^9$	$1.67 \cdot 10^9$	0.413	0.347	0.337

The latent model of lower dimension renders optimizing an objective with domain \mathcal{X} (e.g., $f(x)$, or the BALD objective) feasible even for high-dimensional \mathcal{X} . Instead of direct search over \mathcal{X} , one can choose a $u \in \mathcal{U}$, requiring search over only the low-dimensional \mathcal{U} , and then evaluate the objective at an $x \in \mathcal{X}$ for which $u = x R^\top$. A natural choice is the x which is most likely to actually map to u under R , that is, the x for which $p(u | x)$ is as tight as possible. For example, we could minimize $\log \det \text{cov}[u | x]$, subject to $\mathbb{E}[u | x] = x \hat{R}^\top$, by solving the appropriate program. For $d = 1$, this is a quadratic program that minimizes the variance $x \Sigma x^\top$ under the equality constraint. Finally, we evaluate the objective at the solution.

For simplicity, we will henceforth assume $\mathcal{X} = [-1, 1]^D$. For any box-bounded problem, there is an invertible affine transformation mapping the box to this \mathcal{X} ; this then requires only that R is composed with this transformation. Further, define the signature of the i th row of R to be $[\text{sign}(R_{i1}), \text{sign}(R_{i2}), \dots]$. Then, for the i th coordinate, the maximum and minimum value obtained by mapping the corners of \mathcal{X} through R are achieved by the corner matching this signature and its negative. This procedure defines the extreme corners of the search volume \mathcal{U} .

Consider the typical case in which we take $\tilde{\mu}$ as constant and $\tilde{\kappa}$ as isotropic (e.g., the exponentiated quadratic (1)). Since $p(f | X, R)$ is then invariant to orthogonal transformations of R in \mathbb{R}^d , there is no unique embedding. In the special case $d = 1$, R and $-R$ are equivalent. For most means and covariances there will be similar symmetries, and likely ever more of them as d increases.⁵ We therefore evaluate the performance of our algorithms not by comparing estimated to true R s, which is difficult due to these symmetries, but rather in the direct predictive performance for f .

4.2 ACTIVE LEARNING OF LINEAR EMBEDDINGS EXPERIMENTS

We now present the results of applying our proposed method for learning linear embeddings on both real and synthetic data with dimension up to $D = 318$. Given a function $f: \mathcal{X} \rightarrow \mathbb{R}$ with a known or suspected low-dimensional embedding, we compare the following methods for sequentially

⁵An alternative would be to place a prior on the *Stiefel manifold* rather than directly on R ; the Stiefel manifold accounts for most of these symmetries Minka (2000). This would require the rows of R to be orthogonal.

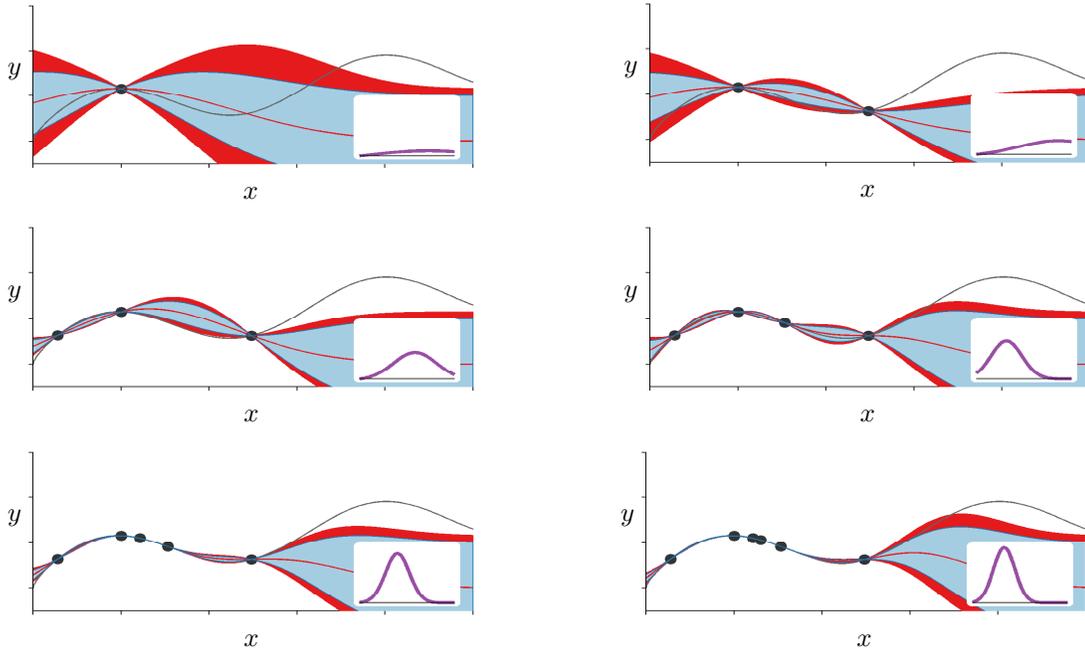

Figure 3: Active learning of the length scale of a one-dimensional GP (beginning at the top left and continuing across and then down): the next sample is taken where the MAP and approximate variances maximally disagree, normalized by the MAP variance. Samples are taken at a variety of separations to refine belief about the length scale. The inset plots (all of which share axes) display the approximate posteriors over log-length scales, which tighten with increasing numbers of samples. The legend is identical to that of Figure 2.

selecting $N = 100$ observations from the domain $[-1, 1]^D$: random sampling (RAND), a Latin hypercube design (LH), uncertainty sampling (UNC), and BALD. UNC and BALD use identical models (Laplace approximation on R followed by MGP) and hyperparameter priors. We also compare with LASSO, choosing the regularization parameter by minimizing squared loss on the training data. The functions that these methods are compared on are:

- Synthetic in-model data drawn from a GP matching our model with an embedding drawn from our prior, for $d \in \{2, 3\}$ and $D \in \{10, 20\}$.
- The Branin function, a popular test function for global optimization ($d = 2$), embedded in $D \in \{10, 20\}$ via an embedding drawn from our prior.
- The temperature data⁶ described in Snelson & Ghahramani (2006) ($D = 106$), with $d = 2$. The associated prediction problem concerns future temperature at a weather station, given the output of a circulation model. The training and validation points were combined to form the dataset, comprising 10 675 points.
- The normalized “communities and crime” (C&C)

⁶<http://theoval.cmp.uea.ac.uk/~gcc/competition>.

dataset from the UCI Machine Learning Repository⁷ ($D = 96$), with $d = 2$. The task here is to predict the number of violent crimes per capita in a set of US communities given historical data from the US Census and FBI. The LEMAS survey features were discarded due to missing values, as was a single record missing the “AsianPerCap” attribute, leaving 1 993 points.

- The “relative location of CT slices on axial axis” dataset from the UCI Machine Learning Repository⁸ ($D = 318$), with $d = 2$. The task is to use features extracted from slices of a CT scan to predict its vertical location in the human body. Missing features were replaced with zeros. Only axial locations in the range $[50, 60]$ were used. Features that did not vary over these points were discarded, leaving 3 071 points.

The CT slices and communities and crime datasets are, respectively, the highest- and third-highest-dimensional regression datasets available in the UCI Machine Learning Repository with real attributes; in second place is an unnormalized version of the C&C dataset.

⁷<http://archive.ics.uci.edu/ml/datasets/Communities+and+Crime>.

⁸<http://archive.ics.uci.edu/ml/datasets/Relative+location+of+CT+slices+on+axial+axis>.

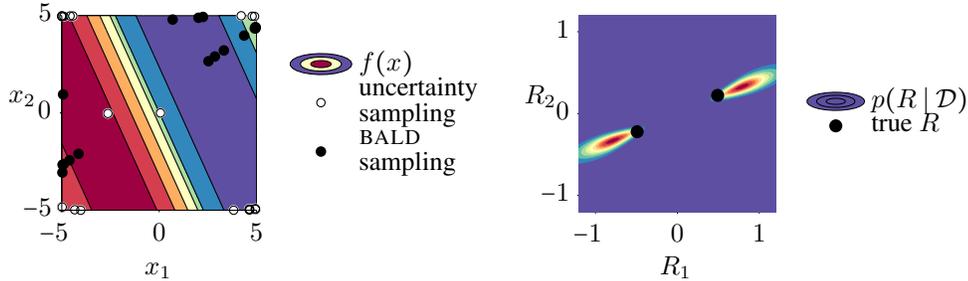

Figure 4: Left: Twenty samples selected by uncertainty sampling and BALD for a function f with a one-dimensional linear embedding. Note that uncertainty sampling prefers corner locations, to maximize the variance in $u, x\Sigma x^\top$, and hence the variance in f ; these points are less useful for learning f and its embedding than those selected by BALD. Right: the posterior over embeddings returned by the BALD samples, concentrated near the true embedding (equivalent under negation).

Table 2: The combination of MGP and BALD actively learns embeddings whose predictive performance improves on alternatives. Average negative log predictive probability and average RMSE on test functions for various D and d .

dataset	D/d	$-\mathbb{E}[\log p(y_* x_*, \hat{R})]$				RMSE

CT slices	318/2	1.30	—	1.26	1.16	0.878	—	0.845	0.767	0.900

For the synthetic and Branin problems, where the true embedding R was chosen explicitly, we report averages over five separate experiments differing only in the choice of R . On these datasets, the UNC and BALD methods selected points by successively maximizing their respective objectives on a set of 20 000 fixed points in the input domain, 10 000 selected uniformly in $[-1, 1]^D$ and 10 000 selected uniformly in the unit D -sphere. For a given D , these points were fixed across methods and experimental runs. This choice allows us to compare methods based only on their objectives and not the means of optimizing them.

For the real datasets (temperature, communities and crimes, and CT slices), each method selected from the available points; LH is incapable of doing so and so is not considered on these datasets. The real datasets were further processed by transforming all features to the box $[-1, 1]^D$ via the “subtract min, divide by max” map and normalizing the outputs to have zero mean and unit variance. For the synthetic problems, we added i.i.d. Gaussian observation noise with variance $\sigma^2 = (0.1)^2$. For the remaining problems, the datapoints were used directly (assuming that these real measurements already reflect noise).

After each method selected 100 observations, we compare the quality of the learned embeddings by fixing the hyper-

parameters of a GP to the MAP embedding at termination and measuring predictive performance. This is intended to emulate a fixed-budget embedding learning phase followed by an experiment using only the most likely R . We chose $N = 100$ training points and 1 000 test points uniformly at random from those available; these points are common to all methods. We report root-mean-square error (RMSE) and the average negative predictive log-likelihood on the test points. The RMSE measures predictive accuracy, whereas the log-likelihood additionally captures the accuracy of variance estimates. This procedure was repeated 10 times for each experiment; the reported numbers are averages.

The embedding prior $p(R)$ was set to be i.i.d. zero-mean Gaussian with standard deviation $5/4 D^{-1}$. This choice roughly implies that we expect $[-1, 1]^D$ to map approximately within $[-2.5, 2.5]^d$, a box five length scales on each side, under the unknown embedding. This prior is extremely diffuse and does not encode any structure of R beyond preferring low-magnitude values. At each step, the mode of the log posterior over R was found using using L-BFGS, starting from both the previous best point and one random restart drawn from $p(R)$.

The results are displayed in Table 2. The active algorithm achieves the most accurate predictions on all but one prob-

lem, including each of the real datasets, according to both metrics. These results strongly suggest an advantage for actively learning linear embeddings.

5 CONCLUSIONS

Active learning in regression tasks should include hyperparameters, in addition to the function model itself. Here we studied simultaneous active learning of the function and a low-dimensional linear embedding of its input domain. We also developed a novel means of approximately integrating over the hyperparameters of a GP model. The resulting algorithm addresses needs in a number of domains, including Bayesian optimization, Bayesian quadrature, and also the underlying idea of nonparametric Gaussian regression itself. Empirical evaluation demonstrates the efficacy of the resulting algorithm on both synthetic and real problems in up to 318 dimensions, and an analysis of computational cost shows that the algorithm can, at least in principle, be scaled to problems of much larger dimensionality as well.

Estimating Causal Effects by Bounding Confounding

Philipp Geiger, Dominik Janzing, Bernhard Schölkopf

Abstract

Assessing the causal effect of a treatment variable X on an outcome variable Y is usually difficult due to the existence of unobserved common causes. Without further assumptions, observed dependences do not even prove the existence of a causal effect from X to Y . It is intuitively clear that strong statistical dependences between X and Y do provide evidence for X influencing Y if the influence of common causes is known to be weak. We propose a framework that formalizes effect versus confounding in various ways and derive upper/lower bounds on the effect in terms of a priori given bounds on confounding. The formalization includes information theoretic quantities like information flow and causal strength, as well as other common notions like effect of treatment on the treated (ETT). We discuss several scenarios where upper bounds on the strength of confounding can be derived. This justifies to some extent human intuition which assumes the presence of causal effect when strong (e.g. close to deterministic) statistical relations are observed.

1 INTRODUCTION

In many situations one wants to estimate the causal effect from an observable X to an observable Y , e.g. if/to what extent smoking causes lung cancer. It is widely agreed that randomized experiments constitute the gold standard for inferring the causal effect. The reason for this is that an ideal randomized experiment excludes the possibility of a (partially) unobserved confounding cause U . However, in many cases conducting randomized experiments would be very expensive or impossible. In these cases, if we do not have

any additional knowledge on the setting, then inference of the (precise or approximate) causal effect is generally deemed impossible. In case we have additional knowledge however, it may be possible to *estimate* the causal effect, i.e. derive (upper and/or lower) *bounds* for it. For instance it is well known that if we observe an instrumental variable Z together with X and Y , those bounds can be derived (see e.g. [Pearl, 2000]).

1.1 THE FORMAL FRAMEWORK

To make our discussion as precise as possible we will from this point on use the framework for causality developed in [Pearl, 2000]. Particularly we will make use of the do-calculus formalizing interventions on variables. (It should be mentioned though that we slightly deviate from Pearl's definition of the do-operator as we will further explicate in Section 2.1.)

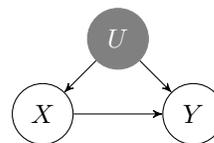

Figure 1: Causal DAG for the confounding scenario (gray means unobserved).

The causal DAG in Figure 1 formalizes the causal structure underlying U, X, Y . Note that we allow U and in some cases also X, Y to be multivariate. Furthermore keep in mind that in some scenarios discussed in the paper we assume U to be partially observed. Our general goal is to estimate the causal effect from X to Y . Formally, this means that we want to estimate $P(Y|\text{do } X=x)$ or related quantities such as the effect of treatment on the treated (ETT) [Pearl, 2000] or the causal strength from X to Y [Janzing et al., 2013]. Without further assumptions, these quantities are impossible to estimate. To give an extreme example, one can imagine observing the deterministic

relationship $P(y|x) = \delta_{yx}$, with δ_{yx} denoting the Kronecker delta. This observation can be induced by two completely different underlying causal structures, the first one being that Y in fact is produced by copying X , the second one being that both X and Y are copied from U without X having any causal effect on Y .

1.2 RELATED WORK

Several approaches have been developed to identify or estimate causal effects in spite of hidden confounders.

Back-door/front-door criterion (see [Pearl, 2000, 2009]): This approach applies for the case where some variables on the confounding path or between X and Y are measured and we know the causal structure underlying all variables together. There are several criteria that allow to decide whether the causal effect from X to Y is identifiable. Furthermore, formulas are available to calculate the effect in these cases. Besides the natural limitation namely requiring a lot of information on additional variables and structures, one drawback of this method is that it cannot be used if X is deterministically coupled to the back-door variable.

Instrumental variables (see e.g. [Pearl, 2000, Angrist et al., 1996, Efron and Feldman, 1991]): In the simplest case, the causal DAG in Figure 1 is augmented by a parentless node Z with an arrow to X . An important example are clinical trials with partial compliance. The additional Z allows to infer bounds on the average causal effect. One drawback of this method is that it yields a convex optimization problem with the number of equations growing exponentially with the cardinality of X . Furthermore, to apply this method one needs to know $p(X, Y|Z)$ while in Section 4.2 we present a scenario where $p(Z)$ (additional to $p(X, Y)$) helps to estimate the causal effect.

Regression discontinuity design (see e.g. [Thistlewaite and Campbell, 1960, Imbens and Lemieux, 2008, Lee and Lemieux, 2010]): This framework is applicable to cases where an additional observable Z mediating between U and X is measured and X is a deterministic function of Z that contains a discontinuity. Under the assumption of linearity of the remaining structural equations, the effect from X to Y , i.e. the linear coefficient, can be identified. One limitation of this method is that it needs the discontinuity and a high slope alone does not suffice.

1.3 OUR APPROACH

The approach we suggest to estimate causal effects in spite of confounding consists of two parts: In the *first part* (Section 3) we propose various possibilities to formalize the following notions:

- *Observed dependence*: the dependence of Y on X that we can observe based on $p(X, Y)$.
- *Back-door dependence*: the “spurious association” [Pearl, 2000] between X and Y due to the confounder U .
- *Causal effect*: what happens to Y upon intervening on X ; this includes notions of conditional causal effect such as the ETT.

For all formalizations we present inequalities (see Table 1 for an overview) which turn out to always have the following prototypical form:

$$\left[\begin{array}{c} \text{back-door} \\ \text{dependence} \end{array} \right] \geq d \left(\left[\begin{array}{c} \text{observed} \\ \text{dependence} \end{array} \right], \left[\begin{array}{c} \text{causal} \\ \text{effect} \end{array} \right] \right)$$

(where the $d(\cdot, \cdot)$ stands for deviation measure). In some of these results, observed dependence, back-door dependences, and causal effect are real numbers and $d(\cdot, \cdot)$ simply stands for the usual difference which allows us to convert the prototypical form into

$$\left[\begin{array}{c} \text{causal} \\ \text{effect} \end{array} \right] \geq \left[\begin{array}{c} \text{observed} \\ \text{dependence} \end{array} \right] - \left[\begin{array}{c} \text{back-door} \\ \text{dependence} \end{array} \right],$$

which may be more convenient for applications.

In order to draw conclusions on the true causal effect using the inequalities from the first part, one needs to have knowledge on the back-door dependence. Therefore, in the *second part* (Section 4), we demonstrate how in various situations one can come up with bounds on the back-door dependence. Based on these together with the observed dependence one can then infer bounds on the true causal effect.

Before getting started, in Section 2, we present several definitions which are needed throughout the paper.

2 PREREQUISITES

Keep in mind the following definitions and results throughout the paper.

2.1 DEFINITION OF CAUSAL MODEL AND do-OPERATOR

As already mentioned we essentially use the framework developed in [Pearl, 2000] to discuss causal relations. Let $V = \{X_1, \dots, X_n\}$ be a set of random variables. A *causal model* M w.r.t. V consists of a DAG G , noise variables N_i for each i with a joint distribution P that makes them jointly independent, and structural equations $X_i := f_i(\text{PA}_i^G, N_i)$ for each i , where PA_i^G denotes the parents of X_i in G .

Table 1: Formalizing observed dependence (O), back-door dependence (B), causal effect (C) and deviation measure (d). $\mathfrak{C}_{X \rightarrow Y}$ denotes the strength of the influence of X on Y in the sense of [Janzing et al., 2013], $I(X \rightarrow Y|\text{do } U)$ is the information flow by [Ay and Polani, 2008], $D[\cdot|\cdot]$ denotes Kullback-Leibler divergence [Cover and Thomas, 1991]. The symbol do is the do-operator defined by [Pearl, 2000].

Sec.	O/B/C/d formalized by ...
3.1	O $I(X : Y)$
	B $I(U : X), \mathfrak{C}_{U \rightarrow X}$
	C $\mathfrak{C}_{X \rightarrow Y}$
	d difference
3.2	O $I(X : Y)$
	B $I(U : X)$
	C $I(X \rightarrow Y \text{do } U)$
	d difference
3.3	O $p(Y X=x)$
	B $I(X : U), \min\{\mathfrak{C}_{U \rightarrow X}, \mathfrak{C}_{U \rightarrow Y}\}$
	C $p(Y \text{do } X=x)$
	d $D[\cdot \cdot]$
3.4	O $\mathbb{E}[d_x \log p(Y X=x)^2]$
	B $\mathbb{E}[\partial_2 \log p(Y X=x, \text{do } X=x)^2]$
	C $\mathbb{E}[\partial_1 \log p(Y X=x, \text{do } X=x)^2]$
	d difference
3.5	O $\mathbb{E}[Y X=x'] - \mathbb{E}[Y X=x]$
	B $\mathbb{E}[Y X=x', \text{do } X=x]$ $-\mathbb{E}[Y X=x, \text{do } X=x]$
	C $\mathbb{E}[Y X=x', \text{do } X=x']$ $-\mathbb{E}[Y X=x', \text{do } X=x]$
	d difference
3.6	O $d_x \mathbb{E}[Y X=x]$
	B $\partial_1 \mathbb{E}[Y X=x, \text{do } X=x]$
	C $\partial_2 \mathbb{E}[Y X=x, \text{do } X=x]$
	d difference

Now we define the *do-operator*. Given any $X_i \in V$ the post-intervention causal model $M_{\text{do } X_i=x'}$ is obtained from M in the following way: For each child X_j of X_i , we replace the structural equation $X_j = f_j(\text{PA}_j^G \setminus X_i, X_i, N_j)$ by $X_j = f_j(\text{PA}_j^G \setminus X_i, x', N_j)$. Note that the random variable X_i stays in the model it just no longer has children. (This is the point where we deviate from [Pearl, 2000]. Note the analogy to the splitting of nodes in [Richardson and Robins, 2013, Robins et al., 2007], where X_i is replaced with two deterministically coupled variables, one being adjacent to the parents of X_i and one to the children of X_i . Then we refer to an intervention on the latter one while the first one is kept.)

The new set of structural equations of $M_{\text{do } X_i=x'}$

together with the noise variables N_i for all i induce a new joint distribution on X_1, \dots, X_n which we denote by $P(X_1, \dots, X_n|\text{do } X=x')$. In particular, given M contains the variables X and Y , quantities such as $P(Y|X=x, \text{do } X=x')$ are well defined. (Note that $P(Y|X=x, \text{do } X=x')$, based on our definition of $M_{\text{do } X=x'}$, coincides with the counterfactual distribution $P(Y_{x'}|X=x)$ as defined in [Pearl, 2000].)

2.2 DISTRIBUTIONS AND DENSITIES

Throughout the paper we will work with U, X, Y with discrete as well as with continuous ranges.

Unless noted otherwise we make the following fundamental assumption regarding the distributions of the random variables in a causal model M with causal DAG G : for each $X_j \in V$, the random variable $f_j(\text{pa}_j, N_j)$ has a density w.r.t. the Lebesgue measure (in the continuous case) or w.r.t. the counting measure (in the discrete case) respectively, denoted by $q_j(x_j; \text{pa}_j)$ for each value pa_j of PA_j (note that we have to slightly deviate from this assumption in Section 4.1 though). This assumption implies the following simple lemma, which is only formulated for the case $n = 3$, since we only need this case in the present paper. A proof can be found in the supplement.

Lemma 1. *Under the assumption made above, the joint distribution of X_1, X_2, X_3 induced by a causal model M or any post-interventional model $M_{\text{do } X_i=x}$ has a density w.r.t. the Lebesgue measure (in the continuous case) or counting measure (in the discrete case), respectively. Moreover, this density factorizes according to the causal DAG belonging to the respective model.*

Regarding any causal model M with causal DAG as depicted in Figure 1, also the following simple statement holds true. The proof is obvious but we present it in the supplement anyway. Note that the lemma is similar to [Pearl, 2000, Corollary 7.3.2], but better tailored for our definition of $M_{\text{do } X=x}$.

Lemma 2. *For all x we have*

$$p(Y|X=x, \text{do } X=x) = p(Y|X=x),$$

$$\mathbb{E}[Y|X=x, \text{do } X=x] = \mathbb{E}[Y|X=x].$$

3 THE RELATION BETWEEN OBSERVED DEPENDENCE, BACK-DOOR DEPENDENCE AND CAUSAL EFFECT

In this section we present various possibilities to formalize the notions of observed dependence, back-door dependence and causal effect. For all formalizations

we prove that the back-door dependence is equal to or upper bounds the deviation between the observed dependence and the actual causal effect.

Subsections 3.1, 3.2 apply to X, Y, U with finite range. Subsections 3.3, 3.5 apply to X, Y, U with arbitrary range. Subsections 3.4 and 3.6 apply to X with continuous range.

Keep in mind that $H(\cdot)$ denotes the Shannon entropy, $I(\cdot : \cdot)$ ($I(\cdot : \cdot | \cdot)$) the (conditional) mutual information, and $D[\cdot \| \cdot]$ the Kullback-Leibler divergence, all based on logarithms with base 2. For details see [Cover and Thomas, 1991].

3.1 ESTIMATING THE CAUSAL STRENGTH FROM X TO Y

The basic quantities in this section are:

- observed dep.: $I(X : Y)$,
- back-door dep.: $I(X : U)$, $\mathfrak{C}_{U \rightarrow X}$,
- causal effect: $\mathfrak{C}_{X \rightarrow Y}$.

We consider the case of U, X, Y having finite range. [Janzing et al., 2013] proposed a definition for the causal strength of a set of arrows in a causal DAG.

We briefly want to repeat this definition for the special case of measuring the strength of a single arrow. For a set of observables $V = \{X_1, \dots, X_n\}$, a DAG G' with V as the set of nodes and a joint distribution $p(X_1, \dots, X_n)$ and for any arrow $X_i \rightarrow X_j$ in G' we first define the distribution $p_{X_i \rightarrow X_j}$ corresponding to deleting $X_i \rightarrow X_j$ from the graph and feeding X_j with an independent copy of X_i instead, see also [Ay and Krakauer, 2007]:

$$p_{X_i \rightarrow X_j}(x_j | \text{pa}_{X_j}^{X_i \rightarrow X_j}) := \sum_{x'_i} p(x'_i) p(y | x'_i, \text{pa}_{X_j}^{X_i \rightarrow X_j}),$$

$$p_{X_i \rightarrow X_j}(x_k | \text{pa}_{X_k}^{X_i \rightarrow X_j}) := p(x_k | \text{pa}_{X_k}), \text{ for all } k \neq j,$$

$$p_{X_i \rightarrow X_j}(x_1, \dots, x_n) := \prod_{k=1}^n p_{X_i \rightarrow X_j}(x_k | \text{pa}_{X_k}^{X_i \rightarrow X_j}),$$

where $\text{pa}_{X_k}^{X_i \rightarrow X_j}$ denotes (values of) the set of parents of X_k in the modified graph G' without arrow $X_i \rightarrow X_j$ (obviously this actually only makes a change for pa_{X_j}). Now we are able to define the *causal strength* $\mathfrak{C}_{X_i \rightarrow X_j}$ by the impact of the edge deletion:

$$\mathfrak{C}_{X_i \rightarrow X_j} := D[p(X_1, \dots, X_n) \| p_{X_i \rightarrow X_j}(X_1, \dots, X_n)].$$

Let us get back to our specific confounding scenario (the causal DAG in Figure 1). For general DAGs, [Janzing et al., 2013] shows $\mathfrak{C}_{X \rightarrow Y} \geq I(X : Y | PA_Y \setminus X)$, that is, the information Y contains about X given its other parents is a lower bound for causal

strength (they argue that this property would be desirable for other information-theoretic measures of causal strength as well). Hence in our confounding scenario (Figure 1) we have $\mathfrak{C}_{X \rightarrow Y} \geq I(X : Y | U)$. Also keep in mind that $\mathfrak{C}_{U \rightarrow X} = I(U : X)$ in our setting.

Lemma 3. *We have*

$$I(X : Y | U) \geq I(X : Y) - I(X : U). \quad (1)$$

Proof. The statement follows from the fact that $I(X : Y | U) + I(X : U) = I(X : U, Y) \geq I(X : Y)$. \square

We consider $I(X : Y)$ as a measure of *observed dependence* between X and Y . The following theorem shows that the *back-door dependence* $\mathfrak{C}_{U \rightarrow X}$ bounds the difference between the observed dependence and the true *causal effect* $\mathfrak{C}_{X \rightarrow Y}$.

Theorem 1. *We have*

$$\mathfrak{C}_{U \rightarrow X} \geq I(X : Y) - \mathfrak{C}_{X \rightarrow Y}. \quad (2)$$

Proof. This follows from Lemma 3 together with the fact that $\mathfrak{C}_{X \rightarrow Y} \geq I(X : Y | U)$ and $\mathfrak{C}_{U \rightarrow X} = I(X : U)$ in our confounding scenario (i.e. the DAG in Figure 1). \square

3.2 ESTIMATING THE INFORMATION FLOW FROM X TO Y

The basic quantities in this section are:

- observed dep.: $I(X : Y)$,
- back-door dep.: $I(X : U)$,
- causal effect: $I(X \rightarrow Y | do U)$.

Another information theoretic quantity to measure the causal effect of X on Y is the *information flow* proposed by [Ay and Polani, 2008]. In our setting (the causal DAG in Figure 1) it is defined as

$$\begin{aligned} I(X \rightarrow Y | do U) := & \sum_u p(u) \sum_x p(x | do U=u) \sum_y p(y | do X=x, do U=u) \\ & \times \log \frac{p(y | do X=x, do U=u)}{\sum_{x'} p(y | do X=x', do U=u) p(x' | do U=u)}. \end{aligned}$$

Since $p(y | do X=x, do U=u) = p(y | x, u)$ in our setting, we simply have $I(X \rightarrow Y | do U) = I(X : Y | U)$.

So we can establish a theorem for the information flow similar to the one for the causal strength. it follows immediately from Lemma 3.

Theorem 2. *We have*

$$I(X : U) \geq I(X : Y) - I(X \rightarrow Y | do U). \quad (3)$$

3.3 BOUNDING THE KULLBACK-LEIBLER DIVERGENCE BETWEEN $p(Y|X=x)$ AND $p(Y|\text{do } X=x)$

The basic quantities in this section are:

- observed dep.: $p(Y|X=x)$,
- back-door dep.: $I(X : U)$, $\min\{\mathfrak{C}_{U \rightarrow X}, \mathfrak{C}_{U \rightarrow Y}\}$,
- causal effect: $p(Y|\text{do } X=x)$.

In some sense, $p(Y|\text{do } X=x)$ is the most fundamental characterization of the *causal effect* from X to Y , while $p(Y|X=x)$ can be seen as the corresponding characterization of their *observed dependence*. In this section we show that the deviation between these two objects can be bounded by quantities which measure the *back-door dependence*, $I(X : U)$ and $\min\{\mathfrak{C}_{U \rightarrow X}, \mathfrak{C}_{U \rightarrow Y}\}$. We formalize the notion of deviation here by

$$\begin{aligned} & D[p(Y|X) \| p(Y|\text{do } X)] \\ & := \sum_x p(x) D[p(Y|x) \| p(Y|\text{do } X=x)]. \end{aligned}$$

Theorem 3. *We have*

$$\begin{aligned} D[p(Y|X) \| p(Y|\text{do } X)] & \leq \min\{\mathfrak{C}_{U \rightarrow X}, \mathfrak{C}_{U \rightarrow Y}\} \\ & \leq I(X : U). \end{aligned}$$

Proof. First note that

$$\begin{aligned} p_{U \rightarrow X}(u, x, y) & = p(u)p(x)p(y|u, x) \text{ and} \\ p_{U \rightarrow Y}(u, x, y) & = p(u)p(x|u) \sum_{u'} p(y|u, x)p(u'). \end{aligned}$$

This implies

$$\begin{aligned} p(y|\text{do } X=x) & = p_{U \rightarrow X}(y|X=x) \text{ and} \\ p(y|\text{do } X=x) & = p_{U \rightarrow Y}(y|X=x). \end{aligned}$$

Therefore, using the chain rule for Kullback-Leibler divergence,

$$\begin{aligned} D[p(Y|X) \| p(Y|\text{do } X)] & = D[p(Y|X) \| p_{U \rightarrow X}(Y|X)] \\ & \leq D[p(X, Y) \| p_{U \rightarrow X}(X, Y)] = \mathfrak{C}_{U \rightarrow X} (= I(U : X)). \end{aligned}$$

Similarly one can derive $D[p(Y|X) \| p(Y|\text{do } X)] \leq \mathfrak{C}_{U \rightarrow Y}$. \square

The above theorem makes a statement w.r.t. the divergence between $p(Y|x)$ and $p(Y|\text{do } X=x)$ averaged over all values x of X . But it is also possible to derive a pointwise version:

Theorem 4. *For all x*

$$D[p(Y|x) \| p(Y|\text{do } x)] \leq D[p(U|x) \| p(U)],$$

with equality iff $p(u|x) = p(u)$ for all u .

Proof. By the log sum inequality we have

$$\begin{aligned} & p(y|x) \log \frac{p(y|x)}{p(y|\text{do } x)} \\ & = \left(\sum_u p(y|x, u)p(u|x) \right) \log \frac{\sum_u p(y|x, u)p(u|x)}{\sum_u p(y|x, u)p(u)} \\ & \leq \sum_u p(y|x, u)p(u|x) \log \frac{p(y|x, u)p(u|x)}{p(y|x, u)p(u)} \quad (4) \\ & = \sum_u p(y, u|x) \log \frac{p(u|x)}{p(u)}. \end{aligned}$$

Equality holds in (4) iff $p(y|x, u)p(u|x) = cp(y|x, u)p(u)$ for all u and some constant c , i.e. iff $p(u|x) = p(u)$ for all u . Summing over all y yields the claimed inequality. \square

Note that taking the average w.r.t. X in Theorem 4 is another way to prove the first part of Theorem 3. With a similar proof we can also derive the following inequality w.r.t. the ‘‘inverse mutual information’’ $D[p(U)p(X) \| p(U, X)]$ (as opposed to the usual mutual information $I(U : X) = D[p(U, X) \| p(U)p(X)]$). For this purpose let us define

$$\begin{aligned} & D[p(Y|\text{do } X) \| p(Y|X)] \\ & := \sum_x p(x) \sum_y p(y|\text{do } X=x) \log \frac{p(y|\text{do } X=x)}{p(y|X=x)}. \end{aligned}$$

Corollary 1. *We have*

$$D[p(Y|\text{do } X) \| p(Y|X)] \leq D[p(U)p(X) \| p(U, X)].$$

To assess which bound is relevant for a scenario, we recall that for two distributions p and q , $D[p \| q]$ diverges when $q = 0$ and $p > 0$ on a set of Lebesgue measure greater than 0. If the observed dependence $p(Y|X)$ is deterministic, $p(Y|\text{do } X)$ needs to be deterministic if $D[p(Y|\text{do } X) \| p(Y|X)]$ is finite.

3.3.1 An example for bounding the average causal effect from X to Y

Often one is interested in estimating the *average causal effect* $\mathbb{E}[Y|\text{do } X=x'] - \mathbb{E}[Y|\text{do } X=x]$ for two values x, x' of X [Pearl, 2000], in particular because this quantity is easy to interpret. In what follows, we want to give an example how one can derive bounds on this quantity based on Theorem 3. It is important to mention however, that the assumptions we make are very restrictive. The purpose of the example is only to show that information theoretic bounds on the back-door dependence *can*, under appropriate assumptions, imply bounds for the average causal effect.

Let X be binary, $p(Y|x) = \mathcal{N}(\mu_x, \sigma^2)$, and $p(Y|\text{do } X=x) = \mathcal{N}(\mu_{\text{do } x}, \sigma_{\text{do}}^2)$, for $x = 0, 1$ (hence particularly $\mathbb{E}[Y|\text{do } X=x] = \mu_{\text{do } x}$).¹

In this case we can calculate (have in mind that \ln is the natural logarithm)

$$\begin{aligned} & p(X=0)(\mu_0 - \mu_{\text{do } 0})^2 + p(X=1)(\mu_1 - \mu_{\text{do } 1})^2 \\ &= 2\sigma_{\text{do}}^2 \left(\mathbb{D}[p(Y|X)] \| p(Y|\text{do } X) - \ln \frac{\sigma_{\text{do}}^2}{\sigma^2} - \frac{\sigma^2}{2\sigma_{\text{do}}^2} + \frac{1}{2} \right) \\ &\leq 2\sigma_{\text{do}}^2 \left(\min\{\mathfrak{C}_{U \rightarrow X}, \mathfrak{C}_{U \rightarrow Y}\} - \ln \frac{\sigma_{\text{do}}^2}{\sigma^2} - \frac{\sigma^2}{2\sigma_{\text{do}}^2} + \frac{1}{2} \right). \end{aligned} \quad (5)$$

Now assume we fix $\min\{\mathfrak{C}_{U \rightarrow X}, \mathfrak{C}_{U \rightarrow Y}\}$ and σ_{do}^2 . Keep in mind that μ_0, μ_1, σ^2 are observed. Then we can derive upper and lower bounds on the average causal effect $\mu_{\text{do } 1} - \mu_{\text{do } 0}$ by maximizing and minimizing it, respectively, under the constraints on the pair $(\mu_{\text{do } 1}, \mu_{\text{do } 0})$ imposed by inequality (5).

3.4 ESTIMATING THE FISHER INFORMATION

The basic quantities in this section are:

- observed dep.: $\mathcal{F}_{Y|X}(x)$,
- back-door dep.: $\mathcal{F}_{Y|X, \text{do } X}^1(x, x)$,
- causal effect: $\mathcal{F}_{Y|X, \text{do } X}^2(x, x)$.

In the following, $\partial_i f(x, x')$, $i = 1, 2$, denotes the partial derivative w.r.t. the i th argument of f evaluated at position (x, x') . And $\text{d}_x g(x)$ denotes the total derivative of $g(x)$ w.r.t. x at position x , in particular $\text{d}_x f(x, x) = \text{d}_x g(x)$ for $g(x) := f(x, x)$.

Given a family of distributions depending on continuous parameters, *Fisher information* provides a natural way to quantify the sensitivity of a probability distribution to infinitesimal parameter changes. It plays an important role for the error made when estimating the true parameter value from empirical data [Rao, 1945]. Here we quantify causal influence by the sensitivity of $p(Y|\text{do } x)$ to small changes of x . This can be considered as a ‘‘local’’ measure of causal strength in the neighborhood of x . We introduce the following notation:

$$\begin{aligned} \mathcal{F}_{Y|X}(x) &:= \int (\text{d}_x \log p(y|X=x))^2 p(y|X=x) dy, \\ \mathcal{F}_{Y|X, \text{do } X}^i(x, x') &:= \\ &\int (\partial_i \log p(y|X=x, \text{do } X=x'))^2 p(y|X=x, \text{do } X=x') dy, \end{aligned}$$

¹Note, however, that both $p(Y|X=0)$ and $p(Y|X=1)$ being Gaussian actually provides some evidence for the absence of confounding since a confounder will often destroy this simple structure of $P(Y|X)$ [Janzing et al., 2011].

for $i = 1, 2$.

Theorem 5. *For all x*

$$\sqrt{\mathcal{F}_{Y|X}(x)} - \sqrt{\mathcal{F}_{Y|X, \text{do } X}^2(x, x)} \leq \sqrt{\mathcal{F}_{Y|X, \text{do } X}^1(x, x)}.$$

A proof can be found in the supplement.

3.5 ESTIMATING THE EFFECT OF TREATMENT ON THE TREATED FROM X TO Y

The basic quantities in this section are:

- observed dep.: $\mathbb{E}[Y|X=x'] - \mathbb{E}[Y|X=x]$,
- back-door dep.: $\mathbb{E}[Y|X=x', \text{do } X=x] - \mathbb{E}[Y|X=x, \text{do } X=x]$,
- causal effect: $\mathbb{E}[Y|X=x', \text{do } X=x'] - \mathbb{E}[Y|X=x', \text{do } X=x]$.

Following [Pearl, 2000], we define the quantity

$$\mathbb{E}[Y|X=x', \text{do } X=x'] - \mathbb{E}[Y|X=x', \text{do } X=x]$$

as the *effect of treatment on the treated*. As the name already suggests, the idea behind this quantity is to measure the deviation between the average response of the treated subjects and the average response of these same subjects had they not been treated. The following result w.r.t. the effect of treatment on the treated follows from Lemma 2.

Theorem 6. *We have for all x, x'*

$$\begin{aligned} & \mathbb{E}[Y|X=x'] - \mathbb{E}[Y|X=x] \\ &= \mathbb{E}[Y|X=x', \text{do } X=x'] - \mathbb{E}[Y|X=x', \text{do } X=x] \\ &\quad + \mathbb{E}[Y|X=x', \text{do } X=x] - \mathbb{E}[Y|X=x, \text{do } X=x]. \end{aligned}$$

Note that in mediation analysis [Pearl, 2001, Avin et al., 2005, Robins and Greenland, 1992] a similar splitting into direct and indirect effect is used. However mediation analysis addresses the problem of defining direct and indirect *causal* effects and not back-door dependences.

We briefly want to discuss the other quantities that appear in the theorem. Obviously, $\mathbb{E}[Y|X=x'] - \mathbb{E}[Y|X=x]$ measures the *observed dependence* of Y on X . Now keep in mind that in $M_{\text{do } X=x}$, X has no causal effect on Y anymore and hence Y statistically depends on X solely via U . Therefore the difference

$$\mathbb{E}[Y|X=x', \text{do } X=x] - \mathbb{E}[Y|X=x, \text{do } X=x]$$

measures the strength of the *back-door dependence* of Y on X .

3.6 ESTIMATING THE DIFFERENTIAL EFFECT OF TREATMENT ON THE TREATED FROM X TO Y

The basic quantities in this section are:

- observed dep.: $d_x \mathbb{E}[Y|X=x]$,
- back-door dep.: $\partial_1 \mathbb{E}[Y|X=x, \text{do } X=x]$,
- causal effect: $\partial_2 \mathbb{E}[Y|X=x, \text{do } X=x]$.

First note that by $\partial_i \mathbb{E}[Y|X=x, \text{do } X=x']$ we mean $\partial_i f(x, x')$ for $f(x, x') := \mathbb{E}[Y|X=x, \text{do } X=x']$ (recall that ∂_i denotes the partial derivative w.r.t. the i th argument). In the case of continuous random variables U, X, Y we want to consider the following quantity (if it exists i.e. if the conditional expectation is differentiable)

$$\partial_2 \mathbb{E}[Y|X=x, \text{do } X=x],$$

which we call *differential effect of treatment on the treated* or simply *differential effect* in cases where this does not lead to confusions. It is the analog to the discrete effect of treatment on the treated (see Section 3.5) for the case of infinitesimal interventional changes on X ; we simply replaced a difference by a derivative.

Similar to Theorem 6 we can establish the following result. It follows from the chain rule for derivatives together with Lemma 2.

Theorem 7. *For all x*

$$\begin{aligned} d_x \mathbb{E}[Y|X=x] &= \partial_1 \mathbb{E}[Y|X=x, \text{do } X=x] \\ &\quad + \partial_2 \mathbb{E}[Y|X=x, \text{do } X=x]. \end{aligned}$$

The interpretation of this theorem is similar to the one for Theorem 6. Obviously, $d_x \mathbb{E}[Y|X=x]$ is the *observed dependence*, whereas the quantity $\partial_1 \mathbb{E}[Y|X=x, \text{do } X=x]$ measures the *back-door dependence* of Y on X . So the observed dependence of Y on X splits into the causal effect plus the back-door dependence.

4 PROTOTYPICAL SCENARIOS WITH BOUNDS ON THE BACK-DOOR DEPENDENCE

In this section we present several prototypical scenarios where bounds on the back-door dependence between X and Y can be derived. Together with our results from Section 3 these bounds help to estimate causal effect from X to Y .

4.1 A QUALITATIVE TOY EXAMPLE

We want to give an example that demonstrates how human intuition concerning observed dependence and causal effect relates to the theorems from Section 3.

Assume there is a drug that is indicated for a specific disease. We observe some not too small number of people with the disease and see that some of them take the drug and some do not. We find that all persons who took the drug recovered on the same day whereas none of the persons not taking the drug recovered that fast. For each sick person let X denote the date he or she takes the drug and Y the date he or she recovers. Since these are only observations, we cannot exclude that there is a confounder U , i.e. we assume the usual causal DAG (Figure 1). We estimate the distribution of Y given X by the empirical distribution, i.e. $p(y|x) = \delta_{yx}$, where δ_{yx} denotes the Kronecker delta.

Given the above setting probably most people would argue that there has to be some effect from the drug to the immediate healing of those people who took it. However, formally and without further assumptions $p(Y|x)$ alone does not even tell us if there is a causal link from X to Y at all. With the help of Theorem 3 though, we can formally reason as follows. We make the weak additional assumption that X cannot be completely determined by U which we formalize by $I(U : X) < H(X)$. It seems implausible that there exists a common cause of X and Y that determines both, the exact date X a person takes the drug and the recovering date Y . E.g. the wealth of a person may strongly influence both, the treatment he or she takes and how quickly he or she recovers (via the general health condition), however it seems not plausible that the wealth determines the exact day of taking the drug and of recovering.

For a proof by contradiction we may assume that there is no causal effect from X to Y , i.e. $p(Y|\text{do } X=x) = p(Y|\text{do } X=x')$ for all x, x' . Then

$$\begin{aligned} D[p(Y|X)||p(Y|\text{do } X=x)] &= \sum_x p(x) D[p(Y|X=x)||p(Y|\text{do } X=x)] \\ &= \sum_x p(x) \sum_y \delta_{yx} \log \frac{\delta_{yx}}{P(Y=y|\text{do } X=x)} \\ &= \sum_x p(x) \log \frac{1}{p(Y=x|\text{do } X=0)} \geq H(X), \end{aligned}$$

where the last inequality is due to Gibb's inequality [Cover and Thomas, 1991].

On the other hand, due to Theorem 3 we have

$$D[p(Y|X)||p(Y|\text{do } X)] \leq I(X : U) < H(X),$$

which yields the contradiction. Hence we could formally show that there has to be some causal effect from X to Y , $p(Y|\text{do } X=x) \neq p(Y|\text{do } X=x')$ for some x, x' . Note that the above argumentation completely

transfers to any other situation where $p(y|x) = \delta_{yx}$, particularly any other range of X and Y .

4.2 PARTIAL RANDOMIZATION SCENARIO

We first discuss a formal scenario, then an application example, and afterwards we discuss how the scenario and our result is related to the instrumental variable design [Pearl, 2000].

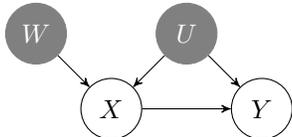

Figure 2: The partial randomization causal DAG.

4.2.1 THE FORMAL PROTOTYPE

We consider a scenario where we have measured X and Y , and where hidden variables U and W are present and we know the distribution of W . The underlying causal structure of all variables looks like the causal DAG depicted in Figure 2. We assume that W is binary. Furthermore we assume that in this scenario $I(U : X|W = 0) = 0$. The intuition behind this assumption is that W decides whether X is influenced by U ($W = 1$) or not. This scenario implies the following inequality. A proof can be found in the supplement.

Proposition 1. *In the given scenario we have $I(U : X) \leq H(X)p(W=1)$.*

Now we can employ our results from Sections 3.1 through 3.3. We obtain the following bounds:

$$I(X : Y) - \mathfrak{C}_{X \rightarrow Y} \leq H(X)p(W=1), \quad (6)$$

$$I(X : Y) - I(X \rightarrow Y|\text{do } U) \leq H(X)p(W=1), \quad (7)$$

$$D[p(Y|X)||p(Y|\text{do } X)] \leq H(X)p(W=1). \quad (8)$$

Note that under strong assumptions, one can also apply the result from Section 3.3.1 to estimate the average causal effect $\mathbb{E}[Y|\text{do } X=x'] - \mathbb{E}[Y|\text{do } X=x]$ for two values x, x' of X .

4.2.2 ADVERTISEMENT LETTER EXAMPLE

Assume we are managers of a mail order company, and want to know the effect of sending advertisement letters on the ordering behavior of the recipients. We have a data set of (X, Y) pairs with X denoting whether a letter was sent to a specific person and let Y denote the total costs of the products ordered by this

person afterwards (within some fixed time span). Assume we have enough data to estimate $p(X, Y)$. Furthermore, assume that so far there were already imperfect guidelines based on rough intuition on whom to send letters and whom not. These guidelines introduce a potential confounder U since letters were more likely sent to potential customers with properties that made them also more likely to order something (if the guidelines were not complete nonsense). It is known however that only some employees stuck to these guidelines. Let W denote whether a letter was sent out in compliance with these guidelines ($W = 1$) or not.

Based on an estimate of how many employees complied with the guidelines, we also have an estimate of $p(W = 1)$, i.e. the fraction of letters that was sent out in compliance with the guidelines. Based on Proposition 1, we know that $I(U : X) \leq H(X)p(W=1)$. Hence we have an upper bound on the back-door dependence of Y on X . Particularly we can apply inequalities (6) to (8) and, under strong additional assumptions, the result w.r.t. the average causal effect from Section 3.3.1.

For example by (6) we have $I(X : Y) - H(X)p(W=1) \leq \mathfrak{C}_{X \rightarrow Y}$. Now assume $H(X) \approx 1$ (we sent a letter to roughly every second person in our register) and $p(W=1) \approx 0.5$ (only half the employees stuck to the guidelines). Then if we observe a strong dependence of Y on X , say $I(X : Y) \approx 0.75$, then we can conclude that $\mathfrak{C}_{X \rightarrow Y} \gtrsim 0.25$, i.e. our advertisement letters have a significant effect on the potential customers.

4.2.3 DIFFERENCE TO INSTRUMENTAL VARIABLE DESIGN

We already mentioned the instrumental variable design [Pearl, 2000] in Section 1. In this design it is assumed that an additional variable W is observed such that the causal structure of all variables together is as depicted in Figure 2, except that W is not hidden. The prototypical application scenario for this design are clinical trials with partial compliance. [Pearl, 2000] describes a method to derive bounds on the average causal effect $\mathbb{E}[Y|\text{do } X=1] - \mathbb{E}[Y|\text{do } X=0]$. This analysis heavily depends on the range of X, Y , and W and involves convex optimization in 15-dimensional space already for the case where all variables are binary (since U can be assumed to attain 16 different values).

The advantage of our approach lies in the fact that the ranges of the variables may be arbitrary without increasing the complexity – for the cost of getting less tight bounds than an explicit modeling, of course. One can get bounds for the case where neither X nor

Y are binary, e.g., in a drug testing scenario with different doses and descriptions of health conditions that are more complex than just reporting recovery or not. Moreover, we do not need complete knowledge of $p(Y, X|W)$ provided that we have some knowledge on W that provides upper bounds on $I(X:U)$.

4.3 A VARIANT OF THE REGRESSION DISCONTINUITY DESIGN

We already mentioned the regression discontinuity design (RDD) [Thistlewaite and Campbell, 1960, Imbens and Lemieux, 2008, Lee and Lemieux, 2010] in Section 1. It is a quasi-experimental design that can help to estimate the causal effect from X to Y in cases where an additional variable Z is measured and the underlying causal DAG of all variables together is as depicted in Figure 3. The design usually requires that X is a deterministic function of Z that contains a discontinuity, that all remaining structural equations are linear, and that $\mathbb{E}[U|Z = z]$ is continuous in z . (Note that the causal DAG in Figure 3 is a special case of the general confounding scenario depicted in Figure 1, which can be seen by replacing U in Figure 1 by $U' := (U, Z)$.)

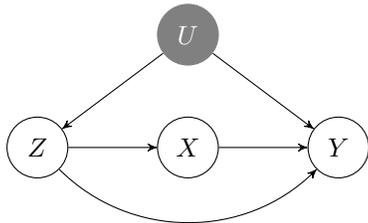

Figure 3: The causal DAG for the RDD and our variant of it.

We now want to consider a scenario inspired by the RDD, which allows to bound the back-door dependence in the sense of Section 3.6 and thus makes Theorem 7 applicable to estimate the causal effect $\partial_2 \mathbb{E}[Y|X=x, \text{do } X=x]$, i.e. the differential effect of treatment on the treated. The scenario differs from the RDD in that neither a discontinuity in the structural equation for X , nor linearity of the remaining structural equations is required.

Assume the causal DAG in Figure 3. Furthermore assume that $X = f_X(Z)$ for a function f_X that is differentiable. (This is the point where our scenario differs from RDD.) Suppose f_X is invertible, $g := f_X^{-1}$. It can easily be seen that this implies

$$\begin{aligned} \partial_1 \mathbb{E}[Y|X=x, \text{do } X=x] \\ = \partial_1 \mathbb{E}[Y|Z=g(x), \text{do } X=x]g'(x). \end{aligned}$$

Note that $\partial_1 \mathbb{E}[Y|Z=g(x), \text{do } X=x]$ means the deriva-

tive of $\mathbb{E}[Y|Z=z, \text{do } X=x]$ w.r.t. z at position $(g(x), x)$. Applying Theorem 7 yields

$$\begin{aligned} d_x \mathbb{E}[Y|X=x] - \partial_2 \mathbb{E}[Y|X=x, \text{do } X=x] \\ = \partial_1 \mathbb{E}[Y|Z=g(x), \text{do } X=x]g'(x). \end{aligned}$$

Hence if for any position x_0 of X we assume a bound on the strength of the “back-door” dependence of Y on Z , $\partial_1 \mathbb{E}[Y|Z=g(x_0), \text{do } X=x_0]$, and if $|g'(x_0)|$ is comparably small (which is the case when $|f'_X(g(x_0))|$ is big), then we can bound the difference between observed dependence and causal effect at position x_0 .

For instance, if we consider the observed dependence $d_x \mathbb{E}[Y|X=x]$ as a realistic scale based on which one can constrain $\partial_1 \mathbb{E}[Y|Z=g(x), \text{do } X=x]$, formally

$$|\partial_1 \mathbb{E}[Y|Z=g(x), \text{do } X=x]| \leq c |d_x \mathbb{E}[Y|X=x]|,$$

for some c , then one can bound the modulus of the causal effect from below:

$$\begin{aligned} |\partial_2 \mathbb{E}[Y|Z=g(x), \text{do } X=x]| \\ \geq (1 - c|g'(x)|) |d_x \mathbb{E}[Y|X=x]|. \end{aligned}$$

Obviously one weakness of the above argument is that the estimation of the causal effect heavily depends on the bound that we assume w.r.t. the “back-door” dependence of Y on Z , $\partial_1 \mathbb{E}[Y|Z=g(x), \text{do } X=x]$. However, this can be seen as a quantitative analogon to the qualitative assumption of the RDD that $\mathbb{E}[U|Z = z]$ is continuous in z .

Keep in mind that our results on Fisher information (Section 3.4) can be used in the case where X is not a deterministic function of Z that changes rapidly but instead the conditional probability $p(X|z)$ changes fast at some $z = z_0$.

5 CONCLUSIONS

In this paper, we analyzed a simple intuition linking observation and causation: if the observed dependence is strong and the effect of confounding is known to be weak, then we can infer a causal effect. We did this by employing a number of different notions for measuring dependence and causation, leading to different theoretical bounds. We do not argue that at present, there is a single formalization that best captures all aspects of this intuition, rather, we try to shed light on properties of the various notions by applying them to the same fundamental problem. While bounding confounding appears easier based on information theoretic quantities, expressing the influence from the treatment to the outcome variable by e.g. the effect of treatment on the treated (ETT) seems more relevant for practical purposes. We discussed several prototypical scenarios where bounds on confounding can be derived.

Abstract

Recent work on Bayesian optimization has shown its effectiveness in global optimization of difficult black-box objective functions. Many real-world optimization problems of interest also have constraints which are unknown *a priori*. In this paper, we study Bayesian optimization for constrained problems in the general case that noise may be present in the constraint functions, and the objective and constraints may be evaluated independently. We provide motivating practical examples, and present a general framework to solve such problems. We demonstrate the effectiveness of our approach on optimizing the performance of online latent Dirichlet allocation subject to topic sparsity constraints, tuning a neural network given test-time memory constraints, and optimizing Hamiltonian Monte Carlo to achieve maximal effectiveness in a fixed time, subject to passing standard convergence diagnostics.

1 INTRODUCTION

Bayesian optimization (Mockus et al., 1978) is a method for performing global optimization of unknown “black box” objectives that is particularly appropriate when objective function evaluations are expensive (in any sense, such as time or money). For example, consider a food company trying to design a low-calorie variant of a popular cookie. In this case, the design space is the space of possible recipes and might include several key parameters such as quantities of various ingredients and baking times. Each evaluation of a recipe entails computing (or perhaps actually measuring) the number of calories in the proposed cookie. Bayesian optimization can be used to propose new candidate recipes such that good results are found with few evaluations.

Now suppose the company also wants to ensure the *taste* of the cookie is not compromised when calories are reduced.

Therefore, for each proposed low-calorie recipe, they perform a taste test with sample customers. Because different people, or the same people at different times, have differing opinions about the taste of cookies, the company decides to require that at least 95% of test subjects must like the new cookie. This is a constrained optimization problem:

$$\min_{\mathbf{x}} c(\mathbf{x}) \text{ s.t. } \rho(\mathbf{x}) \geq 1 - \epsilon,$$

where \mathbf{x} is a real-valued vector representing a recipe, $c(\mathbf{x})$ is the number of calories in recipe \mathbf{x} , $\rho(\mathbf{x})$ is the fraction of test subjects that like recipe \mathbf{x} , and $1 - \epsilon$ is the minimum acceptable fraction, i.e., 95%.

This paper presents a general formulation of constrained Bayesian optimization that is suitable for a large class of problems such as this one. Other examples might include tuning speech recognition performance on a smart phone such that the user’s speech is transcribed within some acceptable time limit, or minimizing the cost of materials for a new bridge, subject to the constraint that all safety margins are met.

Another use of constraints arises when the search space is known *a priori* but occupies a complicated volume that cannot be expressed as simple coordinate-wise bounds on the search variables. For example, in a chemical synthesis experiment, it may be known that certain combinations of reagents cause an explosion to occur. This constraint is not unknown in the sense of being a discovered property of the environment as in the examples above—we do not want to discover the constraint boundary by trial and error explosions of our laboratory. Rather, we would like to specify this constraint using a boolean noise-free oracle function that declares input vectors as valid or invalid. Our formulation of constrained Bayesian optimization naturally encapsulates such constraints.

1.1 BAYESIAN OPTIMIZATION

Bayesian optimization proceeds by iteratively developing a global statistical model of the unknown objective function. Starting with a prior over functions and a likelihood, at each

iteration a posterior distribution is computed by conditioning on the previous evaluations of the objective function, treating them as observations in a Bayesian nonlinear regression. An *acquisition function* is used to map beliefs about the objective function to a measure of how promising each location in input space is, if it were to be evaluated next. The goal is then to find the input that maximizes the acquisition function, and submit it for function evaluation.

Maximizing the acquisition function is ideally a relatively easy proxy optimization problem: evaluations of the acquisition function are often inexpensive, do not require the objective to be queried, and may have gradient information available. Under the assumption that evaluating the objective function is expensive, the time spent computing the best next evaluation via this inner optimization problem is well spent. Once a new result is obtained, the model is updated, the acquisition function is recomputed, and a new input is chosen for evaluation. This completes one iteration of the Bayesian optimization loop.

For an in-depth discussion of Bayesian optimization, see Brochu et al. (2010b) or Lizotte (2008). Recent work has extended Bayesian optimization to multiple tasks and objectives (Krause and Ong, 2011; Swersky et al., 2013; Zuluaga et al., 2013) and high dimensional problems (Wang et al., 2013; Djolonga et al., 2013). Strong theoretical results have also been developed (Srinivas et al., 2010; Bull, 2011; de Freitas et al., 2012). Bayesian optimization has been shown to be a powerful method for the meta-optimization of machine learning algorithms (Snoek et al., 2012; Bergstra et al., 2011) and algorithm configuration (Hutter et al., 2011).

1.2 EXPECTED IMPROVEMENT

An acquisition function for Bayesian optimization should address the exploitation vs. exploration tradeoff: the idea that we are interested both in regions where the model believes the objective function is low (“exploitation”) and regions where uncertainty is high (“exploration”). One such choice is the Expected Improvement (EI) criterion (Mockus et al., 1978), an acquisition function shown to have strong theoretical guarantees (Bull, 2011) and empirical effectiveness (e.g., Snoek et al., 2012). The expected improvement, $EI(\mathbf{x})$, is defined as the expected amount of improvement over some target t , if we were to evaluate the objective function at \mathbf{x} :

$$EI(\mathbf{x}) = \mathbb{E}[(t - y)_+] = \int_{-\infty}^{\infty} (t - y)_+ p(y | \mathbf{x}) dy, \quad (1)$$

where $p(y | \mathbf{x})$ is the predictive marginal density of the objective function at \mathbf{x} , and $(t - y)_+ \equiv \max(0, t - y)$ is the improvement (in the case of minimization) over the target t . EI encourages both exploitation and exploration because it is large for inputs with a low predictive mean (exploitation) and/or a high predictive variance (exploration). Of-

ten, t is set to be the minimum over previous observations (e.g., Snoek et al., 2012), or the minimum of the expected value of the objective (Brochu et al., 2010a). Following our formulation of the problem, we use the minimum expected value of the objective such that the probabilistic constraints are satisfied (see Section 1.5, Eq., 6).

When the predictive distribution under the model is Gaussian, EI has a closed-form expression (Jones, 2001):

$$EI(\mathbf{x}) = \sigma(\mathbf{x}) (z(\mathbf{x})\Phi(z(\mathbf{x})) + \phi(z(\mathbf{x}))) \quad (2)$$

where $z(\mathbf{x}) \equiv \frac{t - \mu(\mathbf{x})}{\sigma(\mathbf{x})}$, $\mu(\mathbf{x})$ is the predictive mean at \mathbf{x} , $\sigma^2(\mathbf{x})$ is the predictive variance at \mathbf{x} , $\Phi(\cdot)$ is the standard normal CDF, and $\phi(\cdot)$ is the standard normal PDF. This function is differentiable and fast to compute, and can therefore be maximized with a standard gradient-based optimizer. In Section 3 we present an acquisition function for constrained Bayesian optimization based on EI.

1.3 OUR CONTRIBUTIONS

The main contribution of this paper is a general formulation for constrained Bayesian optimization, along with an acquisition function that enables efficient optimization of such problems. Our formulation is suitable for addressing a large class of constrained problems, including those considered in previous work. The specific improvements are enumerated below.

First, our formulation allows the user to manage uncertainty when constraint observations are noisy. By reformulating the problem with probabilistic constraints, the user can directly address this uncertainty by specifying the required confidence that constraints are satisfied.

Second, we consider the class of problems for which the objective function and constraint function need not be evaluated jointly. In the cookie example, the number of calories might be predicted very cheaply with a simple calculation, while evaluating the taste is a large undertaking requiring human trials. Previous methods, which assume joint evaluations, might query a particular recipe only to discover that the objective (calorie) function for that recipe is highly unfavorable. The resources spent simultaneously evaluating the constraint (taste) function would then be very poorly spent. We present an acquisition function for such problems, which incorporates this user-specified cost information.

Third, our framework, which supports an arbitrary number of constraints, provides an expressive language for specifying arbitrarily complicated restrictions on the parameter search spaces. For example if the total memory usage of a neural network must be within some bound, this restriction could be encoded as a separate, noise-free constraint with very low cost. As described above, evaluating this low-cost constraint would take priority over the more expensive con-

straints and/or objective function.

1.4 PRIOR WORK

There has been some previous work on constrained Bayesian optimization. Gramacy and Lee (2010) propose an acquisition function called the integrated expected conditional improvement (IECI), defined as

$$\text{IECI}(\mathbf{x}) = \int_{\mathcal{X}} [\text{EI}(\mathbf{x}') - \text{EI}(\mathbf{x}'|\mathbf{x})] h(\mathbf{x}') d\mathbf{x}'. \quad (3)$$

In the above, $\text{EI}(\mathbf{x}')$ is the expected improvement at \mathbf{x}' , $\text{EI}(\mathbf{x}'|\mathbf{x})$ is the expected improvement at \mathbf{x}' given that the objective has been observed at \mathbf{x} (but without making any assumptions about the observed value), and $h(\mathbf{x}')$ is an arbitrary density over \mathbf{x}' . In words, the IECI at \mathbf{x} is the expected reduction in EI at \mathbf{x}' , under the density $h(\mathbf{x}')$, caused by observing the objective at \mathbf{x} . Gramacy and Lee use IECI for constrained Bayesian optimization by setting $h(\mathbf{x}')$ to the probability of satisfying the constraint. This formulation encourages evaluations that inform the model in places that are likely to satisfy the constraint.

Zuluaga et al. (2013) propose the Pareto Active Learning (PAL) method for finding Pareto-optimal solutions when multiple objective functions are present and the input space is a discrete set. Their algorithm classifies each design candidate as either Pareto-optimal or not, and proceeds iteratively until all inputs are classified. The user may specify a confidence parameter determining the tradeoff between the number of function evaluations and prediction accuracy. Constrained optimization can be considered a special case of multi-objective optimization in which the user’s utility function for the “constraint objectives” is an infinite step function: constant over the feasible region and negative infinity elsewhere. However, PAL solves different problems than those we intend to solve, because it is limited to discrete sets and aims to classify each point in the set versus finding a single optimal solution.

Snoek (2013) discusses constrained Bayesian optimization for cases in which constraint violations arise from a failure mode of the objective function, such as a simulation crashing or failing to terminate. The author introduces the weighted expected improvement acquisition function, namely expected improvement weighted by the predictive probability that the constraint is satisfied at that input.

1.5 FORMALIZING THE PROBLEM

In Bayesian optimization, the objective and constraint functions are in general unknown for two reasons. First, the functions have not been observed everywhere, and therefore we must interpolate or extrapolate their values to new inputs. Second, our observations may be noisy; even after multiple observations at the same input, the true function is

not known. Accounting for this uncertainty is the role of the model, see Section 2.

However, before solving the problem, we must first define it. Returning to the cookie example, each taste test yields an estimate of $\rho(\mathbf{x})$, the fraction of test subjects that like recipe \mathbf{x} . But uncertainty is always present, even after many measurements. Therefore, it is impossible to be certain that the constraint $\rho(\mathbf{x}) \geq 1 - \epsilon$ is satisfied for any \mathbf{x} . Likewise, the objective function can only be evaluated point-wise and, if noise is present, it may never be determined with certainty.

This is a stochastic programming problem: namely, an optimization problem in which the objective and/or constraints contain uncertain quantities whose probability distributions are known or can be estimated (see e.g., Shapiro et al., 2009). A natural formulation of these problems is to minimize the objective function *in expectation*, while satisfying the constraints *with high probability*. The condition that the constraint be satisfied with high probability is called a *probabilistic constraint*. This concept is formalized below.

Let $f(\mathbf{x})$ represent the objective function. Let $\mathcal{C}(\mathbf{x})$ represent the *constraint condition*, namely the boolean function indicating whether or not the constraint is satisfied for input \mathbf{x} . For example, in the cookie problem, $\mathcal{C}(\mathbf{x}) \iff \rho(\mathbf{x}) \geq 1 - \epsilon$. Then, our probabilistic constraint is

$$\Pr(\mathcal{C}(\mathbf{x})) \geq 1 - \delta, \quad (4)$$

for some user-specified minimum confidence $1 - \delta$.

If K constraints are present, for each constraint $k \in (1, \dots, K)$ we define $\mathcal{C}_k(\mathbf{x})$ to be the constraint condition for constraint k . Each constraint may also have its own tolerance δ_k , so we have K probabilistic constraints of the form

$$\Pr(\mathcal{C}_k(\mathbf{x})) \geq 1 - \delta_k. \quad (5)$$

All K probabilistic constraints must ultimately be satisfied at a solution to the optimization problem.¹

Given these definitions, a general class of constrained Bayesian optimization problems can be formulated as

$$\min_{\mathbf{x}} \mathbb{E}[f(\mathbf{x})] \text{ s.t. } \forall k \Pr(\mathcal{C}_k(\mathbf{x})) \geq 1 - \delta_k. \quad (6)$$

The remainder of this paper proposes methods for solving problems in this class using Bayesian optimization. Two key ingredients are needed: a model of the objective and constraint functions (Section 2), and an acquisition function that determines which input \mathbf{x} would be most beneficial to observe next (Section 3).

¹Note: this formulation is based on individual constraint satisfaction for all constraints. Another reasonable formulation requires the (joint) probability that *all* constraints are satisfied to be above some single threshold.

2 MODELING THE CONSTRAINTS

2.1 GAUSSIAN PROCESSES

We use Gaussian processes (GPs) to model both the objective function $f(\mathbf{x})$ and the constraint functions. A GP is a generalization of the multivariate normal distribution to arbitrary index sets, including infinite length vectors or functions, and is specified by its positive definite covariance kernel function $K(\mathbf{x}, \mathbf{x}')$. GPs allow us to condition on observed data and tractably compute the posterior distribution of the model for any finite number of query points. A consequence of this property is that the marginal distribution at any single point is univariate Gaussian with a known mean and variance. See Rasmussen and Williams (2006) for an in-depth treatment of GPs for machine learning.

We assume the objective and all constraints are independent and model them with independent GPs. Note that since the objective and constraints are all modeled independently, they need not all be modeled with GPs or even with the same types of models as each other. Any combination of models suffices, so long as each one represents its uncertainty about the true function values.

2.2 THE LATENT CONSTRAINT FUNCTION, $g(\mathbf{x})$

In order to model constraint conditions $\mathcal{C}_k(\mathbf{x})$, we introduce real-valued latent *constraint functions* $g_k(\mathbf{x})$ such that for each constraint k , the constraint condition $\mathcal{C}_k(\mathbf{x})$ is satisfied if and only if $g_k(\mathbf{x}) \geq 0$.² Different observation models lead to different likelihoods on $g(\mathbf{x})$, as discussed below. By computing the posterior distribution of $g_k(\mathbf{x})$ for each constraint, we can then compute $\Pr(\mathcal{C}_k(\mathbf{x})) = \Pr(g_k(\mathbf{x}) \geq 0)$ by simply evaluating the Gaussian CDF using the predictive marginal mean and variance of the GP at \mathbf{x} .

Different constraints require different definitions of the constraint function $g(\mathbf{x})$. When the nature of the problem permits constraint observations to be modeled with a Gaussian likelihood, the posterior distribution of $g(\mathbf{x})$ can be computed in closed form. If not, approximations or sampling methods are needed (see Rasmussen and Williams, 2006, p. 41-75). We discuss two examples below, one of each type, respectively.

2.3 EXAMPLE I: BOUNDED RUNNING TIME

Consider optimizing some property of a computer program such that its running time $\tau(\mathbf{x})$ must not exceed some

²Any inequality constraint $g(\mathbf{x}) \leq g_0$ or $g(\mathbf{x}) \geq g_1$ can be represented this way by transforming to a new variable $\hat{g}(\mathbf{x}) \equiv g_0 - g(\mathbf{x}) \geq 0$ or $\hat{g}(\mathbf{x}) \equiv g(\mathbf{x}) - g_1 \geq 0$, respectively, so we set the right-hand side to zero without loss of generality.

value τ_{\max} . Because $\tau(\mathbf{x})$ is a measure of time, it is non-negative for all \mathbf{x} and thus not well-modeled by a GP prior. We therefore choose to model time in logarithmic units. In particular, we define $g(\mathbf{x}) = \log \tau_{\max} - \log \tau$, so that the condition $g(\mathbf{x}) \geq 0$ corresponds to our constraint condition $\tau \leq \tau_{\max}$, and place a GP prior on $g(\mathbf{x})$. For every problem, this transformation implies a particular prior on the original variables; in this case, the implied prior on $\tau(\mathbf{x})$ is the log-normal distribution. In this problem we may also posit a Gaussian likelihood for observations of $g(\mathbf{x})$. This corresponds to the generative model that constraint observations are generated by some true latent function corrupted with i.i.d. Gaussian noise. As with the prior, this choice implies something about the original function $\tau(\mathbf{x})$, in this case a log-normal likelihood. The basis for these choices is their computational convenience. Given a Gaussian prior and likelihood, the posterior distribution is also Gaussian and can be computed in closed form using the standard GP predictive equations.

2.4 EXAMPLE II: MODELING COOKIE TASTINESS

Recall the cookie optimization, and let us assume that constraint observations arrive as a set of counts indicating the numbers of people who did and did not like the cookies. We call these *binomial constraint observations*. Because these observations are discrete, they are not modeled well by a GP prior. Instead, we model the (unknown) binomial probability $\rho(\mathbf{x})$ that a test subject likes cookie \mathbf{x} , which is linked to the observations through a binomial likelihood.³ In Section 1.5, we selected the constraint condition $\rho(\mathbf{x}) \geq 1 - \epsilon$, where $1 - \epsilon$ is the user-specified threshold representing the minimum allowable probability that a test subject likes the new cookie. Because $\rho(\mathbf{x}) \in (0, 1)$ and $g(\mathbf{x}) \in \mathbb{R}$, we define $g(\mathbf{x}) = s^{-1}(\rho(\mathbf{x}))$, where $s(\cdot)$ is a monotonically increasing sigmoid function mapping $\mathbb{R} \rightarrow (0, 1)$ as in logistic or probit regression.⁴ In our implementation, we use $s(z) = \Phi(z)$, the Gaussian CDF. The likelihood of $g(\mathbf{x})$ given the binomial observations is then the binomial likelihood composed with s^{-1} . Because this likelihood is non-Gaussian, the posterior distribution cannot be computed in closed form, and therefore approximation or sampling methods are needed.

2.5 INTEGRATING OUT THE GP HYPERPARAMETERS

Following Snoek et al. (2012), we use the Matérn 5/2 kernel for the Gaussian process prior, which corresponds to the

³We use the notation $\rho(\mathbf{x})$ both for the fraction of test subjects who like recipe \mathbf{x} and for its generative interpretation as the probability that a subject likes recipe \mathbf{x} .

⁴When the number of binomial trials is one, this model is called Gaussian Process Classification.

assumption that the function being modeled is twice differentiable. This kernel has $D + 1$ hyperparameters in D dimensions: one characteristic length scale per dimension, and an overall amplitude. Again following Snoek et al. (2012), we perform a fully-Bayesian treatment by integrating out these kernel hyperparameters with Markov chain Monte Carlo (MCMC) via slice sampling (Neal, 2000).

When the posterior distribution cannot be computed in closed form due to a non-Gaussian likelihood, we use elliptical slice sampling (Murray et al., 2010) to sample $g(\mathbf{x})$. We also use the prior whitening procedure described in Murray and Adams (2010) to avoid poor mixing due to the strong coupling of the latent values and the kernel hyperparameters.

3 ACQUISITION FUNCTIONS

3.1 CONSTRAINT WEIGHTED EXPECTED IMPROVEMENT

Given the probabilistic constraints and the model for a particular problem, it remains to specify an acquisition function that leads to efficient optimization. Here, we present an acquisition function for constrained Bayesian optimization under the Expected Improvement (EI) criterion (Section 1.2). However, the general framework presented here does not depend on this specific choice and can be used in conjunction with any improvement criterion.

Because improvement is not possible when the constraint is violated, we can define an acquisition function for constrained Bayesian optimization by extending the expectation in Eq. 1 to include the additional constraint uncertainty. This results in a constraint-weighted expected improvement criterion, $a(\mathbf{x})$:

$$a(\mathbf{x}) = \text{EI}(\mathbf{x}) \Pr(\mathcal{C}(\mathbf{x})) \tag{7}$$

$$= \text{EI}(\mathbf{x}) \prod_{k=1}^K \Pr(\mathcal{C}_k(\mathbf{x})) \tag{8}$$

where the second line follows from the assumed independence of the constraints. The gradient of this acquisition function is readily computed and therefore this acquisition function can be maximized in the same manner as standard EI. In practice we maximize it following the method in Snoek et al. (2012).

Then, the full acquisition function $a(\mathbf{x})$, after integrating out the GP hyperparameters, is given by

$$a(\mathbf{x}) = \int \text{EI}(\mathbf{x}|\theta)p(\theta|\mathbf{D})p(\mathcal{C}(\mathbf{x})|\mathbf{x}, \mathbf{D}', \omega)p(\omega|\mathbf{D}')d\theta d\omega,$$

where θ is the set of GP hyperparameters for the objective function model, ω is the set of GP hyperparameters for the constraint model(s), $\mathbf{D} = \{\mathbf{x}_n, y_n\}_{n=1}^N$ are the previous

objective function observations, and \mathbf{D}' are the constraint function observations.

3.2 FINDING THE FEASIBLE REGION

The acquisition function given above is not defined when at least one probabilistic constraint is violated for all \mathbf{x} , because in this case the EI target does not exist and therefore EI cannot be computed. In this case we take the acquisition function to include only the second factor,

$$a(\mathbf{x}) = \prod_{k=1}^K \Pr(g_k(\mathbf{x}) \geq 0) \tag{9}$$

Intuitively, if the probabilistic constraint is violated everywhere, we ignore the objective function and try to satisfy the probabilistic constraint until it is satisfied somewhere. This acquisition function may also be used if no objective function exists, i.e., if the problem is just to search for any feasible input. This feasibility search is purely exploitative: it searches where the probability of satisfying the constraints is highest. This is possible because the true probability of constraint satisfaction is either zero or one. Therefore, as the algorithm continues to probe a particular region, it will either discover that the region is feasible, or the probability will drop and it will move on to a more promising region.

3.3 DECOUPLED OBSERVATIONS

In some problems, the objective and constraint functions may be evaluated independently. We call this property the *decoupling* of the objective and constraint functions. In decoupled problems, we must choose to evaluate either the objective function or one of the constraint functions at each iteration of Bayesian optimization. As discussed in Section 1.3, it is important to identify problems with this decoupled structure, because often some of the functions are much more expensive to evaluate than others. Bayesian optimization with decoupled constraints is a form of multi-task Bayesian optimization (Swersky et al., 2013), in which the different black-boxes or *tasks* are the objective and decoupled constraint(s), represented by the set $\{\text{objective}, 1, 2, \dots, K\}$ for K constraints.

3.3.1 Chicken and Egg Pathology

One possible acquisition function for decoupled constraints is the expected improvement of individually evaluating each task. However, the myopic nature of the EI criterion causes a pathology in this formulation that prevents exploration of the design space. Consider a situation, with a single constraint, in which some feasible region has been identified and thus the current best input is defined, but a large unexplored region remains. Evaluating only the objective in this region could not cause improvement as our

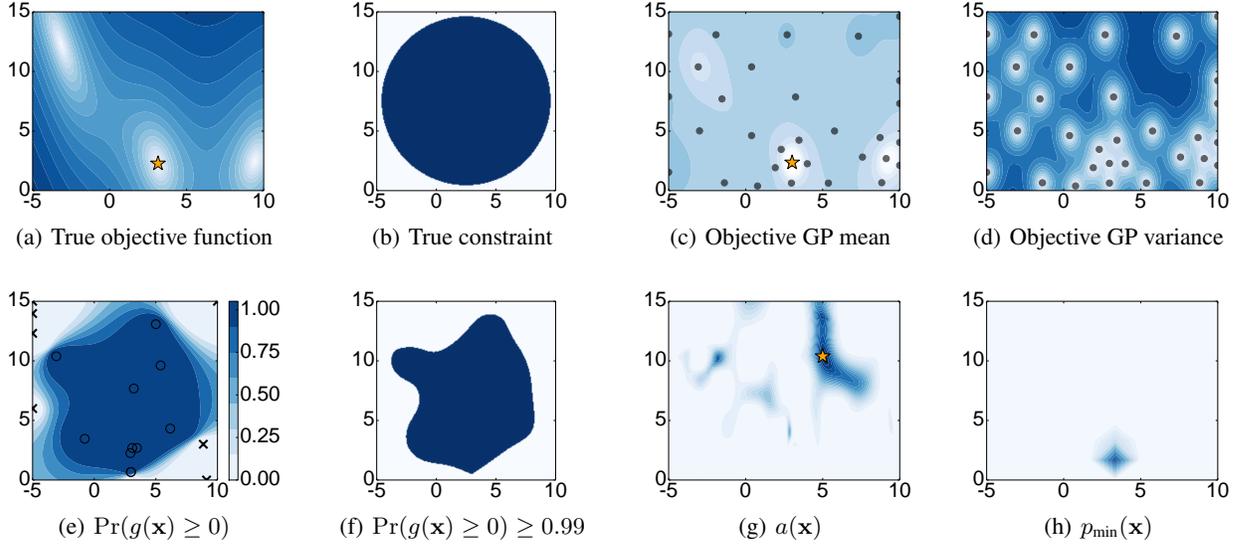

Figure 1: Constrained Bayesian optimization on the 2D Branin-Hoo function with a disk constraint, after 50 iterations (33 objective evaluations and 17 constraint evaluations): (a) Branin-Hoo function, (b) true constraint, (c) mean of objective function GP, (d) variance of objective function GP, (e) probability of constraint satisfaction, (f) probabilistic constraint, $\Pr(g(\mathbf{x}) \geq 0) \geq 0.99$, (g) acquisition function, $a(\mathbf{x})$, and (h) probability distribution over the location of the minimum, $p_{\min}(\mathbf{x})$. Lighter colors indicate lower values. Objective function observations are indicated with black circles in (c) and (d). Constraint observations are indicated with black \times 's (violations) and o's (satisfactions) in (e). Orange stars: (a) unique true minimum of the constrained problem, (c) best solution found by Bayesian optimization, (g) input chosen for the next evaluation, in this case an objective evaluation because $\Delta S_o(\mathbf{x}) > \Delta S_c(\mathbf{x})$ at the next observation location \mathbf{x} .

belief about $\Pr(g(\mathbf{x}) \geq 0)$ will follow the prior and not exceed the threshold $1 - \delta$. Likewise, evaluating only the constraint would not cause improvement because our belief about the objective will follow the prior and is unlikely to become the new best. This is a causality dilemma: we must learn that *both* the objective and the constraint are favorable for improvement to occur, but this is not possible when only a single task is observed. This difficulty suggests a non-myopic acquisition function which assesses the improvement after a sequence of objective and constraint observations. However, such a multi-step acquisition function is intractable in general (Ginsbourger and Riche, 2010).

Instead, to address this pathology, we propose to use the coupled acquisition function (Eq. 7) to select an input \mathbf{x} for observation, followed by a second step to determine which task will be evaluated at \mathbf{x} . Following Swersky et al. (2013), we use the entropy search criterion (Hennig and Schuler, 2012) to select a task. However, our framework does not depend on this choice.

3.3.2 Entropy Search Criterion

Entropy search works by considering $p_{\min}(\mathbf{x})$, the probability distribution over the location of the minimum of the objective function. Here, we extend the definition of p_{\min} to be the probability distribution over the location of the solution to the constrained problem. Entropy search seeks

the action that, in expectation, most reduces the relative entropy between $p_{\min}(\mathbf{x})$ and an uninformative base distribution such as the uniform distribution. Intuitively speaking, we want to reduce our uncertainty about p_{\min} as much as possible at each step, or, in other words, maximize our information gain at each step. Following Hennig and Schuler (2012), we choose $b(\mathbf{x})$ to be the uniform distribution on the input space. Given this choice, the relative entropy of p_{\min} and b is the differential entropy of p_{\min} up to a constant that does not affect the choice of task. Our decision criterion is then

$$T^* = \arg \min_T \mathbb{E}_y \left[S \left(p_{\min}^{(y_T)} \right) - S(p_{\min}) \right], \quad (10)$$

where T is one of the tasks in $\{\text{objective}, 1, 2, \dots, K\}$, T^* is the selected task, $S(\cdot)$ is the differential entropy functional, and $p_{\min}^{(y_T)}$ is p_{\min} conditioned on observing the value y_T for task T . When integrating out the GP covariance hyperparameters, the full form is

$$T^* = \arg \min_T \int S \left(p_{\min}^{(y_T)} \right) p(y_T | \theta, \omega) dy_T d\theta d\omega \quad (11)$$

where y_T is a possible observed outcome of selecting task T and θ and ω are the objective and constraint GP hyperparameters respectively.⁵

⁵For brevity, we have omitted the base entropy term (which does not affect the decision T^*) and the explicit dependence of p_{\min} on θ and ω .

3.3.3 Entropy Search in Practice

Solving Eq. 11 poses several practical difficulties, which we address here in turn. First, estimating $p_{\min}(\mathbf{x})$ requires a discretization of the space. In the spirit of Hennig and Schuler (2012), we form a discretization of N_d points by taking the top N_d points according to the weighted expected improvement criterion. Second, p_{\min} cannot be computed in closed form and must be either estimated or approximated. Swersky et al. (2013) use Monte Carlo sampling to estimate p_{\min} by drawing samples from the GP on the discretization set and finding the minimum. We use the analogous method for constrained optimization: we sample from the objective function GP and all K constraint GPs, and then find the minimum of the objective for which the constraint is satisfied for all K constraint samples.

3.3.4 Incorporating cost information

Following Swersky et al. (2013), we incorporate information about the relative cost of the tasks by simply scaling the acquisition functions by these costs (provided by the user). In doing so, we pick the task with the most information gain per unit cost. If λ_A is the cost of observing task A , then Eq. 10 becomes

$$A^* = \arg \min_A \frac{1}{\lambda_A} \mathbb{E}_y \left[S \left(p_{\min}^{(y_A)} \right) - S(p_{\min}) \right]. \quad (12)$$

4 EXPERIMENTS

4.1 BRANIN-HOO FUNCTION

We first illustrate constrained Bayesian optimization on the Branin-Hoo function, a 2D function with three global minima (Fig. 1(a)). We add a decoupled disk constraint $(\mathbf{x}_1 - 2.5)^2 + (\mathbf{x}_2 - 7.5)^2 \leq 50$, shown in Fig. 1(b). This constraint eliminates the upper-left and lower-right solutions, leaving a unique global minimum at $\mathbf{x} = (\pi, 2.275)$, indicated by the orange star in Fig. 1(a). After 33 objective function evaluations and 17 constraint evaluations, the best solution is (3.01, 2.36), which satisfies the constraint and has value 0.48 (true best value = 0.40).

4.2 ONLINE LDA WITH SPARSE TOPICS

Online Latent Dirichlet Allocation (LDA, Hoffman et al., 2010) is an efficient variational formulation of a popular topic model for learning topics and corresponding word distributions given a corpus of documents. In order for topics to have meaningful semantic interpretations, it is desirable for the word distributions to exhibit sparsity. In this experiment we optimize the hyperparameters of online LDA subject to the constraint that the entropy of the per-topic word distribution averaged over topics is less than $\log_2 200$ bits, which is achieved, for example by allocating uniform density over 200 words. We used the online LDA

implementation from Agarwal et al. (2011) and optimized five hyperparameters corresponding to the number of topics (from 2 to 100), two Dirichlet distribution prior base measures (from 0 to 2), and two learning rate parameters (rate from 0.1 to 1, decay from 10^{-5} to 1). As a baseline, we compare with unconstrained Bayesian optimization in which constraint violations are set to the worst possible value for this LDA problem. Fig. 2(a) shows that constrained Bayesian optimization significantly outperforms the baseline and the IECI method from Gramacy and Lee (2010) (see Section 1.4). Intuitively, the baseline is poor because the GP has difficulty modeling the sharp discontinuities caused by the large values.

4.3 MEMORY-LIMITED NEURAL NET

In the final experiment, we optimize the hyperparameters of a deep neural network on the MNIST handwritten digit classification task in a memory-constrained scenario. We optimize over 11 parameters: 1 learning rate, 2 momentum parameters (initial and final), the number of hidden units per layer (2 layers), the maximum norm on model weights (for 3 sets of weights), and the dropout regularization probabilities (for the inputs and 2 hidden layers). We optimize the classification error on a withheld validation set under the constraint that the total number of model parameters (weights in the network) must be less than one million. This constraint is decoupled from the objective and inexpensive to evaluate, because the number of weights can be calculated directly from the parameters, without training the network. We train the neural network using momentum-based stochastic gradient descent which is notoriously difficult to tune as training can diverge under various combinations of the momentum and learning rate. When training diverges, the objective function cannot be measured. Reporting the constraint violation as a large objective value performs poorly because it introduces sharp discontinuities that are hard to model (Fig. 2). This necessitates a second noisy, binary constraint which is violated when training diverges, for example when the both the learning rate and momentum are too large. The network is trained⁶ for 25,000 weight updates and the objective is reported as classification error on the standard validation set. Our Bayesian optimization routine can thus choose between two decoupled tasks, evaluating the memory constraint or the validation error after a full training run. Evaluating the validation error can still cause a constraint violation when the training diverges, which is treated as a binary constraint in our model. Fig. 2(b) shows a comparison of our constrained Bayesian optimization against a baseline standard Bayesian optimization where constraint violations are treated as resulting in a random classifier (90% error). Only the objective evaluations are presented, since

constraint evaluations are extremely inexpensive compared to an entire training run. In the event that training diverges on an objective evaluation, we report 90% error. The optimized net has a learning rate of 0.1, dropout probabilities of 0.17 (inputs), 0.30 (first layer), and 0 (second layer), initial momentum 0.86, and final momentum 0.81. Interestingly, the optimization chooses a small first layer (size 312) and a large second layer (size 1772).

4.4 TUNING MCMC

Hamiltonian Monte Carlo (HMC) is a popular MCMC sampling technique that takes advantage of gradient information for rapid mixing. However, HMC contains several parameters that require careful tuning. The two basic parameters are the number of leapfrog steps τ , and the step size ϵ . HMC may also include a mass matrix which introduces $\mathcal{O}(D^2)$ additional parameters in D dimensions, although the matrix is often chosen to be diagonal (D parameters) or a multiple of the identity matrix (1 parameter) (Neal, 2011). In this experiment, we optimize the performance of HMC using Bayesian optimization; see Mahendran et al. (2012) for a similar approach. We optimize the following parameters: τ , ϵ , a mass parameter, and the frac-

tion of the allotted computation time spent burning in the chain.

Our experiment measures the number of effective samples (ES) in a fixed computation time; this corresponds to finding chains that minimize estimator variance. We impose the constraints that the generated samples must pass the Geweke (Geweke, 1992) and Gelman-Rubin (Gelman and Rubin, 1992) convergence diagnostics. In particular, we require the worst (largest absolute value) Geweke test score across all variables and chains to be at most 2.0, and the worst (largest) Gelman-Rubin score between chains and across all variables to be at most 1.2. We use PyMC (Patil et al., 2010) for the convergence diagnostics and the LaplacesDemon R package to compute effective sample size. The chosen thresholds for the convergence diagnostics are based on the PyMC and LaplacesDemon documentation. The HMC integration may also diverge for large values of ϵ ; we treat this as an additional constraint, and set $\delta = 0.05$ for all constraints. We optimize HMC sampling from the posterior of a logistic regression binary classification problem using the German credit data set from the UCI repository (Frank and Asuncion, 2010). The data set contains 1000 data points, and is normalized to have unit

Table 1: Tuning Hamiltonian Monte Carlo.

Experiment	burn-in	# steps, τ	step size, ϵ	mass	# samples	accept rate	effective samples
Baseline	10%	100	0.047	1	8.3×10^3	85%	1.1×10^3
BayesOpt	3.8%	2	0.048	1.55	3.3×10^5	70%	9.7×10^4

variance. We initialize each chain randomly with D independent draws from a Gaussian distribution with mean zero and standard deviation 10^{-3} . For each set of inputs, we compute two chains, each with 5 minutes of computation time on a single core of a compute node.

Fig. 3 shows constraint surfaces discovered by Bayesian optimization for a simpler experiment in which only τ and ϵ are varied; burn-in is fixed at 10% and the mass is fixed at 1. These diagrams yield interpretations of the feasible region; for example, Fig. 3(d) shows that the numerical integration diverges for values of ϵ above $\approx 10^{-1}$. Table 1 shows the results of our 4-parameter optimization after 50 iterations, compared with a baseline that is reflective of a typical HMC configuration: 10% burn in, 100 leapfrog steps, and the step size chosen to yield an 85% proposal accept rate. Each row in the table was produced by averaging 5 independent runs with the given parameters. The optimization chooses to perform very few ($\tau = 2$) leapfrog steps and spend relatively little time (3.8%) burning in the chain, and chooses an acceptance rate of 70%. In contrast, the baseline spends much more time generating each proposal ($\tau = 100$), which produces many fewer total samples and, correspondingly, significantly fewer effective samples.

5 CONCLUSION

In this paper we extended Bayesian optimization to constrained optimization problems. Because constraint observations may be noisy, we formulate the problem using probabilistic constraints, allowing the user to directly express the tradeoff between cost and risk by specifying the confidence parameter δ . We then propose an acquisition function to perform constrained Bayesian optimization, including the case where the objective and constraint(s) may be observed independently. We demonstrate the effectiveness of our system on the meta-optimization of machine learning algorithms and sampling techniques. Constrained optimization is a ubiquitous problem and we believe this work has applications in areas such as product design (e.g. designing a low-calorie cookie), machine learning meta-optimization (as in our experiments), real-time systems (such as a speech recognition system on a mobile device with speed, memory, and/or energy usage constraints), or any optimization problem in which the objective function and/or constraints are expensive to evaluate and possibly noisy.

Abstract

The distance dependent Chinese restaurant process (ddCRP) provides a flexible framework for clustering data with temporal, spatial, or other structured dependencies. Here we model multiple groups of structured data, such as pixels within frames of a video sequence, or paragraphs within documents from a text corpus. We propose a hierarchical generalization of the ddCRP which clusters data within groups based on distances between data items, and couples clusters across groups via distances based on aggregate properties of these local clusters. Our hddCRP model subsumes previously proposed hierarchical extensions to the ddCRP, and allows more flexibility in modeling complex data. This flexibility poses a challenging inference problem, and we derive a MCMC method that makes coordinated changes to data assignments both within and between local clusters. We demonstrate the effectiveness of our hddCRP on video segmentation and discourse modeling tasks, achieving results competitive with state-of-the-art methods.

1 INTRODUCTION

The recent explosive growth of image and video repositories, and of structured data collections more broadly, motivates methods for the unsupervised discovery of informative latent structures. Image sequences of course exhibit strong spatio-temporal dependencies: objects typically occupy blocks of spatially contiguous pixels, and their movements induce strong dependencies among video frames. Nevertheless, many previous nonparametric models for visual data have mostly ignored such relationships, relying on careful feature engineering to make local likelihoods informative (Sudderth et al., 2008; Haines & Xiang, 2012). While accounting for spatial dependencies can be technically challenging, it produces image partitions which much more accurately reflect real-world scene structure (Orbanz

& Buhmann, 2008; Sudderth & Jordan, 2008). However, these methods treat images as an unordered, or *exchangeable*, collection; they thus fail to capture the strong temporal dependencies found in video sequences.

Blei & Frazier (2011) proposed the *distance dependent Chinese restaurant process* (ddCRP) as a flexible distribution over partitions of data with temporal, spatial, or other non-exchangeable structure. The ddCRP represents partitions via links between data instances: each observation links to one other, and the probability of linking to nearby instances is higher. Closeness is measured according to a distance which may be arbitrarily specified to capture domain knowledge. The connected components of the induced link graph then partition the dataset into clusters. Previous work has used the ddCRP to effectively cluster data with sequential, temporal, or spatial structure (Ghosh et al., 2011; Socher et al., 2011; Ghosh et al., 2012).

In this paper, we propose a *hierarchical ddCRP* (hddCRP) that captures local relationships like these, but also uses distances among latent clusters to extract further global dependencies. After an initial ddCRP partitioning, local clusters are grouped via additional links that depend on a user-specified measure of cluster similarity. This framework allows the hddCRP to model relationships that depend on *aggregate* properties of clusters such as size and shape, which may be difficult to capture with likelihoods alone. Given arbitrary cluster and data affinity functions, which need not arise from true distance metrics, the hddCRP always defines a valid joint probability distribution on partitions.

The hddCRP is a hierarchical generalization of the ddCRP which unifies and generalizes existing models. Simpler hierarchical extensions of the ddCRP employing restricted distance functions (Ghosh et al., 2011; Kim & Oh, 2011), as well as the “Chinese restaurant franchise” representation of the *hierarchical Dirichlet process* (HDP, Teh et al. (2006)), are special cases of the hddCRP. The HDP and related dependent Dirichlet process models (MacEachern, 1999) define dependent random measures from which allocations of data to clusters are sampled, indirectly inducing dependencies in the resulting partitions. For example,

Griffin & Steel (2006), Dunson & Park (2008), Rao & Teh (2009), and Lin et al. (2010) define priors which encourage “close” data points to have similar allocation distributions.

In contrast, the hddCRP directly specifies distributions over partitions via a flexible set of user-specified affinity functions. This allows structural constraints on clusters, such as connectivity (Ghosh et al., 2011), to be directly enforced. The hddCRP does not require its “distance” functions to be true metrics or have any special properties, and thus provides an extremely flexible framework for modeling complex data. Alternative models based on latent Gaussian processes (Duan et al., 2007; Sudderth & Jordan, 2008) require appropriate positive-definite kernel functions, whose specification can be challenging in non-Euclidean spaces (e.g., of object shapes). By working directly with discrete partitions, rather than latent continuous measures, the hddCRP also allows more computationally efficient inference.

The hddCRP generative process defined in Section 2 is simple, but the data-level and cluster-level link variables are strongly coupled in the posterior. Section 3 develops a *Markov chain Monte Carlo* (MCMC) method that makes coordinated changes to links at both levels, and thus more effectively explores clustering hypotheses. This sampler is also a novel inference algorithm for the HDP that makes large changes to the partition structure, without needing to explicitly craft split or merge proposals (Jain & Neal, 2004; Wang & Blei, 2012). By reasoning about data and cluster links, our sampler changes cluster allocations at varying resolutions, perturbing both memberships of data instances to local clusters and clusters to global components.

In Section 4, we demonstrate the versatility of the hddCRP by applying it to the problems of video segmentation and discourse analysis. In addition to having diverse data types (video sequences versus text documents), these two problems exhibit very different kinds of relationships among data instances and latent clusters. Nevertheless, our hddCRP model and inference framework easily applies to both domains by selecting appropriate data and cluster-level affinity functions. In both domains, explicit modeling of dependencies between latent clusters boosts performance over models that ignore such relationships.

2 HIERARCHICAL DISTANCE DEPENDENT CLUSTERS

The distance-dependent CRP (Blei & Frazier, 2011) defines a distribution over partitions indirectly via distributions over links between data instances. A data point i has an associated link variable c_i which links to another data instance j , or itself, according to the following distribution:

$$p(c_i = j \mid A, \alpha) \propto \begin{cases} A_{ij} & i \neq j, \\ \alpha & i = j. \end{cases} \quad (1)$$

The *affinity* $A_{ij} = f(d(i, j))$ depends on a user-specified *distance* $d(i, j)$ between pairs of data points, and a mono-

tonically decreasing *decay function* $f(d)$ which makes links to nearby data more likely. The resulting link structure induces a partition, where two data instances are assigned to the same cluster if and only if one is reachable from the other by traversing the link edges. Larger self-affinity parameters α favor partitions with more clusters.

2.1 THE HIERARCHICAL ddCRP

We propose a novel generative model that applies the ddCRP formalism twice, first for clustering data within each group into local clusters, and then for coupling the local clusters across groups. Like the ddCRP, our hddCRP defines a valid distribution over partitions of a dataset. It places higher probability mass on partitions that group nearby data points into latent clusters, *and* couple similar local clusters into global components. Examples of these data and cluster links are illustrated in Figure 1.

Consider a collection of G groups, where group g contains N_g observations. We denote the i^{th} data point of group g by x_{gi} , and the full dataset by \mathbf{x} . The data link variable c_{gi} for x_{gi} is sampled from a group-specific ddCRP:

$$p(c_{gi} = gj \mid \alpha_g, A^g) \propto \begin{cases} A_{ij}^g & i \neq j, \\ \alpha_g & i = j. \end{cases} \quad (2)$$

At this first level of link variables, we set the probability of linking observations in different groups to zero. The connected components of the links $c_g = \{c_{gi} \mid i = 1, \dots, N_g\}$ then determine the local clustering for group g .

Data links $\mathbf{c} = \{c_1, \dots, c_G\}$ across all groups divide the dataset into group-specific local clusters $T(\mathbf{c})$. The hddCRP then associates each cluster $t \in T(\mathbf{c})$ with a cluster link k_t drawn from a global ddCRP distribution:

$$p(k_t = s \mid \alpha_0, A^0(\mathbf{c})) \propto \begin{cases} A_{ts}^0(\mathbf{c}) & t \neq s, \\ \alpha_0 & t = s. \end{cases} \quad (3)$$

Here α_0 is a global self-affinity parameter, and $A^0(\mathbf{c})$ is the set of pairwise affinities between the elements of $T(\mathbf{c})$. We let $A_{ts}^0(\mathbf{c}) = f_0(d_0(t, s, \mathbf{c}))$, where $d_0(t, s, \mathbf{c})$ is a “distance” based on arbitrary properties of clusters t and s , and $f_0(d_0)$ a decreasing decay function. The connected components of $\mathbf{k} = \{k_t \mid t \in T(\mathbf{c})\}$ then couple local clusters into global components shared across groups. Let z_{gi} denote the component associated with observation i in group g , and $\mathbf{z} = \{z_{gi} \mid g = 1, \dots, G; i = 1, \dots, N_g\}$. Data instances x_{gi} and x_{hj} are clustered ($z_{gi} = z_{hj}$) if and only if they are reachable via some combination of data and cluster links.

Given this partition structure, we endow component m with likelihood parameters $\phi_m \sim G_0(\lambda)$, and generate observations $x_{gi} \sim p(x_{gi} \mid \phi_{z_{gi}})$. Let $M(\mathbf{c}, \mathbf{k})$ equal the number of global components induced by the cluster links \mathbf{k} and data links \mathbf{c} . Because data links \mathbf{c} are conditionally independent given $A^{1:G}$, and cluster links \mathbf{k} are conditionally independent given \mathbf{c} and the cluster affinities $A^0(\mathbf{c})$, the hddCRP

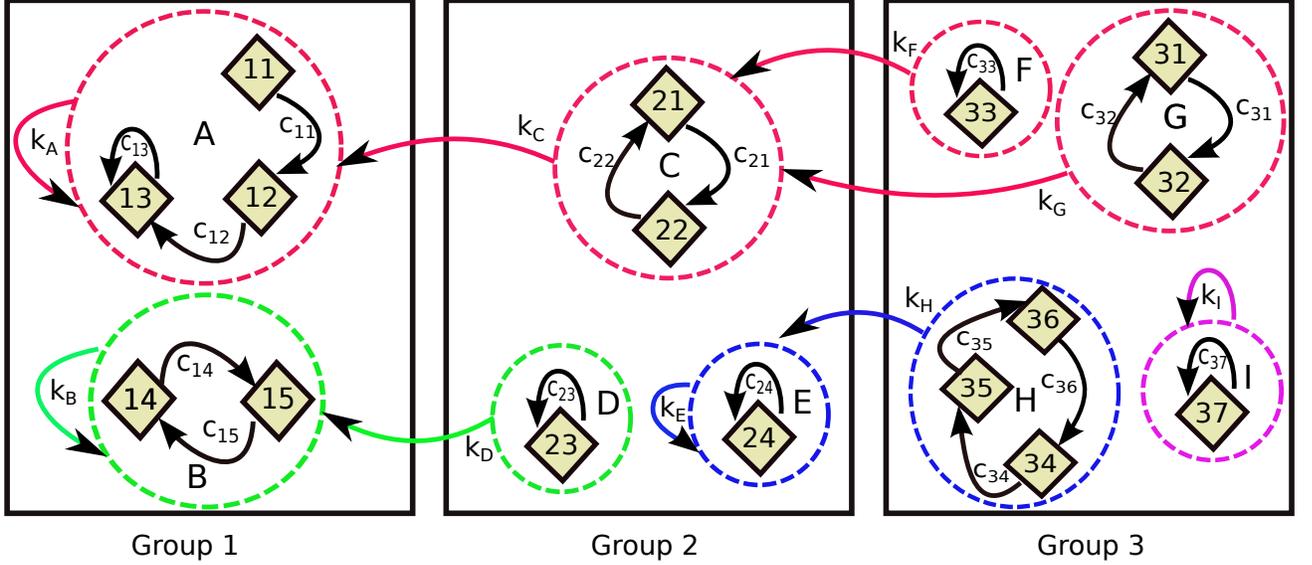

Figure 1: An example link variable configuration for a hierarchical ddCRP model of three groups (rectangles). Observed data points (customers, depicted as diamonds) link to other data points in the same group (black arrows), producing local clusters (dashed circles, labeled A through I). Cluster links (colored arrows) then join clusters to produce (in this case, four) global mixture components.

joint distribution on partitions and observations equals

$$p(\mathbf{x}, \mathbf{k}, \mathbf{c} \mid \alpha_{1:G}, \alpha_0, A^{1:G}, A^0, \lambda) = \prod_{m=1}^{M(\mathbf{c}, \mathbf{k})} p(x_{\mathbf{z}=m} \mid \lambda) \prod_{g=1}^G \prod_{i=1}^{N_g} p(c_{gi} \mid \alpha_g, A^g) \prod_{k_t \in \mathbf{k}} p(k_t \mid \mathbf{c}, \alpha_0, A^0(\mathbf{c})) \quad (4)$$

The set of data in component m is denoted by $x_{\mathbf{z}=m}$, and

$$p(x_{\mathbf{z}=m} \mid \lambda) = \int \prod_{gi|z_{gi}=m} p(x_{gi} \mid \phi_m) dG_0(\phi_m \mid \lambda), \quad (5)$$

where λ are hyperparameters specifying the prior distribution G_0 . Our inference algorithms assume this integral is tractable, as it always is when an exponential family likelihood is coupled with an appropriate conjugate prior. We emphasize that for arbitrary data and cluster affinities, the sequential hddCRP generative process defines a valid joint distribution $p(\mathbf{x}, \mathbf{k}, \mathbf{c}) = p(\mathbf{c})p(\mathbf{k} \mid \mathbf{c})p(\mathbf{x} \mid \mathbf{k}, \mathbf{c})$.

2.2 RELATED HIERARCHICAL MODELS

The hddCRP subsumes several recently proposed hierarchical extensions to the ddCRP, as well as the HDP itself, by defining appropriately restricted data affinities and local cluster affinities. Blei & Frazier (2011) show that the CRP is recovered from the ddCRP by arranging data in an arbitrary sequential order, and defining affinities as

$$A_{ij} = \begin{cases} 1 & \text{if } i < j, \\ 0 & \text{if } i > j. \end{cases} \quad (6)$$

Data points link to all previous observations with equal probability, and thus the probability of joining any existing cluster is proportional to the number of other data points already in that cluster. The probability of creating a new

cluster is proportional to the self-connection weight α . The resulting distribution on partitions can be shown to be invariant to the chosen sequential ordering of the data, and thus the standard CRP is *exchangeable* (Pitman, 2002).

Hierarchical Chinese Restaurant Process (hCRP) The hCRP representation of the HDP, which Teh et al. (2006) call the ‘‘Chinese restaurant franchise’’, is recovered from the hddCRP by first defining group-specific affinities as in Eq. (6). We then arrange local clusters (tables, in the CRF metaphor) t sequentially with distances $A_{ts}^0(\mathbf{c}) = 1$ if $t < s$, and $A_{ts}^0(\mathbf{c}) = 0$ if $t > s$. Just as the two-level hCRP arises from a sequence of CRPs, the hddCRP is defined from a sequence of two ddCRP models.

Naive Hierarchical ddCRP (naive-hddCRP) The image segmentation model of Ghosh et al. (2011) clusters data within each group via a ddCRP based on an informative distance (in their experiments, spatial distance between image pixels). A standard CRP, as in the upper level of the HDP, is then used to combine these clusters into larger segments. Inference is substantially simpler for this special case, because cluster distances do not depend on properties of the data assigned to those clusters.

Distance Dependent Chinese Restaurant Franchise An alternate approach to capturing group-specific metadata uses a standard CRP to locally cluster data, but then uses the group labels to define affinities between clusters. Kim & Oh (2011) use this model to learn topic models of time-stamped documents. By constraining cluster affinities to depend on group labels, but not properties of the data assigned to within-group clusters, inference is simplified.

3 MCMC INFERENCE

The posterior distribution over the data and cluster links $p(\mathbf{c}, \mathbf{k} \mid \mathbf{x}, \alpha_{1:G}, \alpha_0, A^{1:G}, A^0, \lambda)$ is intractable, and we thus explore it via a Metropolis-Hastings MCMC method. Our approach generalizes the non-hierarchical ddCRP Gibbs sampler of Blei & Frazier (2011), which iteratively samples single data links conditioned on the observations and other data links. Evolving links lead to splits, merges, and other large changes to the partition structure. In the hddCRP, local clusters belong to global components, and these component memberships must be sampled as well.

3.1 MARKOV CHAIN STATE SPACE

The number of possible non-empty subsets (clusters) of N data points is $2^N - 1$. The state space of our Markov chain consists of the data links \mathbf{c} , and the set of *all* possible cluster links \mathcal{K} , one for each candidate non-empty cluster. For instance, given three observations $\{h, i, j\}$ the set of non-empty subsets is $\mathcal{T} = \{\{h\}, \{i\}, \{j\}, \{hi\}, \{ij\}, \{jh\}, \{hij\}\}$, and the corresponding set of possible cluster links is $\mathcal{K} = \{k_h, k_i, k_j, k_{hi}, k_{ij}, k_{jh}, k_{hij}\}$, where $|\mathcal{K}| = 2^3 - 1$.

For any configuration of \mathbf{c} , a strict subset of \mathcal{T} will have data associated with it. We call this the *active set*. For instance, if $c_h = h, c_i = i, c_j = j$, then only the clusters $\{\{h\}, \{i\}, \{j\}\}$ and the corresponding links $\{k_h, k_i, k_j\}$ are active. Given \mathbf{c} , we split \mathcal{K} into the active set \mathbf{k} , and the remaining inactive cluster links $\tilde{\mathbf{k}} = \mathcal{K} \setminus \mathbf{k}$. We account for the inactive clusters by augmenting $A^0(\mathbf{c})$ as follows:

$$\tilde{A}^0(\mathbf{c}) = \begin{bmatrix} A^0(\mathbf{c}) & \mathbf{0} \\ \mathbf{0} & \alpha_0 \mathbf{I} \end{bmatrix}. \quad (7)$$

Here, we have sorted the links so that affinities among the active clusters are listed in the upper-left quadrant of $\tilde{A}^0(\mathbf{c})$. As indicated by the identity matrix \mathbf{I} , inactive clusters have zero affinity with all other clusters, and link to themselves with probability one. Under this augmented model, the joint probability factorizes as follows:

$$\begin{aligned} p(\mathbf{x}, \mathbf{k}, \tilde{\mathbf{k}}, \mathbf{c}) &= p(\mathbf{c})p(\mathbf{k} \mid \mathbf{c})p(\tilde{\mathbf{k}} \mid \mathbf{c})p(\mathbf{x} \mid \mathbf{c}, \mathbf{k}, \tilde{\mathbf{k}}) = \\ &= p(\mathbf{c})p(\mathbf{k} \mid \mathbf{c})p(\tilde{\mathbf{k}} \mid \mathbf{c})p(\mathbf{x} \mid \mathbf{c}, \mathbf{k}) = p(\mathbf{x}, \mathbf{k}, \mathbf{c})p(\tilde{\mathbf{k}} \mid \mathbf{c}). \end{aligned} \quad (8)$$

Here, we have recovered the joint distribution of Eq. (4) because given \mathbf{c} , the observations \mathbf{x} are conditionally independent of the inactive links $\tilde{\mathbf{k}}$. Crucially, because inactive cluster links have no uncertainty, we must only explicitly represent the active clusters at each MCMC iteration.

As the Markov chain evolves, clusters are swapped in and out of the active set. Although the number of active clusters varies with the state of the chain, the dimensionality of the augmented state space $(\mathbf{c}, \mathbf{k}, \tilde{\mathbf{k}})$ remains constant, allowing us to ignore complications that arise when dealing with chains whose state spaces have varying dimensionality. In particular, we employ standard *Metropolis-Hastings* (MH) proposals to change data and cluster links, and need not resort to reversible jump MCMC (Green, 1995).

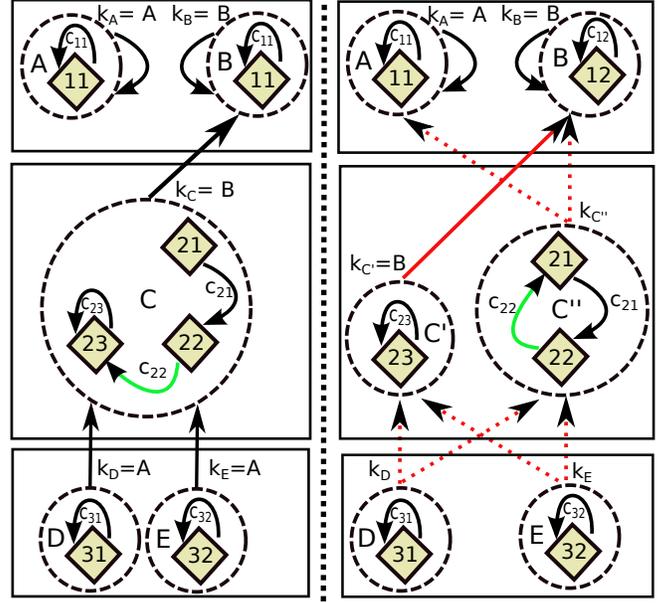

Figure 2: Illustration of changes induced by a data link proposal. Changing c_{22} (in the left configuration) splits cluster C into two clusters C' and C'' . The cluster links associated with C (shown in red) must also be resampled. The MH step of the sampler proposes a joint configuration of the links $\{c_{22}, k_{C'}, k_{C''}, k_D, k_E\}$. The dashed red arrows illustrate the possible values the resampled cluster links could take. A single data link can create large changes to the partition structure, with local clusters splitting or merging, and groups of clusters shifting between components.

3.2 LINK PROPOSAL DISTRIBUTIONS

In samplers previously developed for the hCRP (Teh et al., 2006) and the naive-hddCRP (Ghosh et al., 2011), local clusters directly sample their global component memberships. However for the hddCRP, cluster links indirectly determine global component memberships. This complicates inference, as any change to the cluster structure necessitates coordinated changes to the cluster links. As illustrated in Figure 2, consider the case where a data link proposal causes a cluster to break into two components. The new cluster must sample a cluster (outgoing) link, and cluster links pointing to the old cluster (incoming links) must be divided among the newly split clusters. Thus, we use a MH proposal to jointly resample data and affected cluster links.

To simplify the exposition, we focus on a particular group g and denote c_{gi} as c_i . Let the current state of the sampler be $\mathbf{k}(\mathbf{c})$ and $\mathbf{c} = \{c_{-i}, c_i = j\}$, so that i and j are members of the same cluster t_{ij} . Let $\mathcal{K}_{t_{ij}} = \{k_s \mid k_s = t_{ij}, s \neq t_{ij}\}$ denote the set of other clusters linking to t_{ij} .

Split? To construct our link proposal, we first set $c_i = i$. This may split current cluster t_{ij} into two new clusters, in which case we let t_i denote the cluster containing data i , and t_j the cluster containing formerly linked data j . Or, the partition structure may be unchanged so that $t_i = t_{ij}$.

Incoming links $k_s \in \mathcal{K}_{t_{ij}}$ to a split cluster are independently assigned to the new clusters with equal probability:

$$q_{\text{in}}(\mathcal{K}_{t_{ij}}) = \prod_{k_s \in \mathcal{K}_{t_{ij}}} \left(\frac{1}{2}\right)^{\delta(k_s, t_i)} \left(\frac{1}{2}\right)^{\delta(k_s, t_j)}. \quad (9)$$

The current outgoing link is retained by one of the split clusters, $k_{t_j} = k_{t_{ij}}$. To allow likelihood-based link proposals, we temporarily fix the other cluster link as $k_{t_i} = t_i$.

Propose Link We compare two proposals for c_i , the ddCRP prior distribution $q(c_i) = p(c_i | \alpha, A)$, and a data-dependent ‘‘pseudo-Gibbs’’ proposal distribution:

$$q(c_i) \propto p(c_i | \alpha, A) \Gamma(\mathbf{x}, \mathbf{z}(c_i, \mathbf{c}_{-i}, \mathbf{k})), \quad (10)$$

$$\Gamma(\mathbf{x}, \mathbf{z}(c_i, \mathbf{c}_{-i}, \mathbf{k})) = \begin{cases} \frac{p(\mathbf{x}_{\mathbf{z}=m_a} \cup \mathbf{x}_{\mathbf{z}=m_b} | \lambda)}{p(\mathbf{x}_{\mathbf{z}=m_a} | \lambda)p(\mathbf{x}_{\mathbf{z}=m_b} | \lambda)} & \text{if } c_i \text{ merges } m_a, m_b, \\ 1 & \text{otherwise.} \end{cases}$$

The prior proposal, although naïve, can perform reasonably when A is sparse. The pseudo-Gibbs proposal is more sophisticated, as data links are proposed conditioned on both the observations \mathbf{x} and the current state of the sampler. Our experiments in Sec. 4 show it is much more effective.

Merge? Let $c_i = j^*$ denote the new data link sampled according to either the ddCRP prior or Eq. (10). Relative to the reference configuration in which $c_i = i$, this link may either leave the partition structure unchanged, or cause clusters t_i and t_{j^*} to merge into t_{ij^*} . In case of a merge, the new cluster retains the current outgoing link $k_{t_{ij^*}} = k_{t_{j^*}}$, and inherits the incoming links $\mathcal{K}_{t_{ij^*}} = \mathcal{K}_{t_i} \cup \mathcal{K}_{t_{j^*}}$.

If a merge does not occur, but t_{ij} was previously split into t_i and t_j , the outgoing link $k_{t_j} = k_{t_{ij}}$ is kept fixed. For newly created cluster t_i , we then propose a corresponding cluster link k_{t_i} from its full conditional distribution:

$$q_{\text{out}}(k_{t_i}) = p(k_{t_i} | \alpha_0, A^0(\mathbf{c}), \mathbf{x}, \mathbf{k}_{-t_i}, \mathbf{c}). \quad (11)$$

Note that the proposal $c_i = j^*$ may leave the original partition unchanged if $c_i = i$ does not cause t_{ij} to split, and $c_i = j^*$ does not result in a merge. In this case, the corresponding cluster links are also left unchanged.

Accept or Reject Combining the two pairs of cases above, our overall proposal distribution equals

$$q(\mathbf{c}^*, \mathbf{k}^* | \mathbf{c}, \mathbf{k}, \mathbf{x}) = \begin{cases} q(c_i^*) q_{\text{in}}(\mathcal{K}_{t_{ij}^*}^*) & \text{split, merge,} \\ q(c_i^*) & \text{no split, merge,} \\ q(c_i^*) q_{\text{out}}(k_{t_i}^*) q_{\text{in}}(\mathcal{K}_{t_{ij}^*}^*) & \text{split, no merge,} \\ p(c_i^* | \alpha, A) & \text{otherwise.} \end{cases}$$

Here, \mathbf{c}^* and \mathbf{k}^* denote the proposed values, which are then accepted or rejected according to the MH rule. For acceptance ratio derivations and further details, please see the supplemental material. After cycling through all data links \mathbf{c} , we use the Gibbs update of Eq. (11) to resample the cluster links \mathbf{k} , analogously to a standard ddCRP.

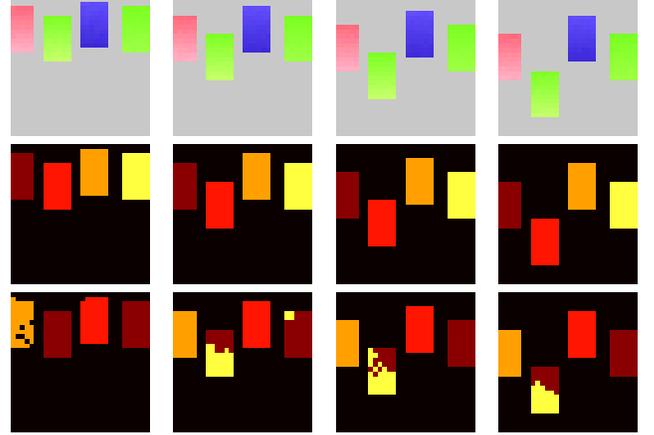

Figure 3: Experiments on synthetic data. *Top*: Ground truth partitions of a toy dataset containing four groups. Each group contains four objects exhibiting motion and color gradients. *Middle*: MAP partitions inferred by an hddCRP using size and optical flow-based cluster affinities. *Bottom*: MAP partitions discovered by a baseline hCRP using only color-based likelihoods.

4 EXPERIMENTS

In this section we present a series of experiments investigating the properties of the hddCRP model and our proposed MCMC inference algorithms. We examine a pair of challenging real-world tasks, video and discourse segmentation. We quantify performance by measuring agreement with held-out human annotations via the Rand index (Rand, 1971) and the WindowDiff metric (Pevzner & Hearst, 2002), demonstrating competitive performance.

To provide intuition, we first compare the hddCRP with the hCRP on a synthetic dataset (Figure 3) with four 30×30 frames (groups). Each frame contains four objects moving from top to bottom at different rates, and object appearances exhibit small color gradients. The hddCRP utilizes data link affinities that allow pixels (data instances) to connect to one of their eight spatial neighbors with equal probability. To exploit the differing motions of the objects, we define optical flow-based cluster affinities (Sun et al., 2010). Letting $w(t)$ denote the spatial positions occupied by cluster t after being warped by optical flow, and $w(s)$ the corresponding support of cluster s , the affinity is defined as $A_{ts}^0(\mathbf{c}) = (w(t) \cap w(s)) / (w(t) \cup w(s))$, $t \neq s$, encouraging clusters to link to other clusters with similar spatial support. Given this affinity function, hddCRP was able to robustly disambiguate the four uniquely moving objects, while the hCRP produced noisy segmentations and consistently confused objects with local similarity but distinct motion.

4.1 VIDEO SEGMENTATION

Likelihood As a preprocessing step, we divide each frame into approximately 1200 superpixels using the

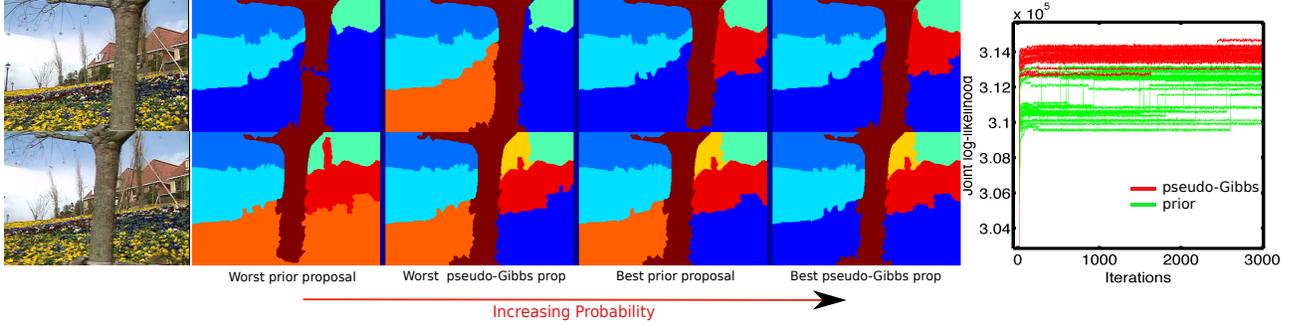

Figure 4: Data link proposal comparisons. *Left*: Two frames from the “garden” sequence, and partitions corresponding to the best and worst MAP samples using prior or pseudo-Gibbs proposals. *Right*: Joint log-likelihood trace plots for 25 trials of each proposal.

method proposed by Chang et al. (2013).¹ Each super-pixel is described by L_2 unit-normalized 120-bin HSV color and 128-bin local texton histograms. Unit normalization projects raw histograms to the surface of a hypersphere, where we use *von-Mises Fisher* (vMF) distributions (Mardia & Jupp, 2009) shared across all clusters of a global component. In preliminary experiments, we found that the vMF produced more accurate segmentations than multinomial models of raw histograms; similar L_2 normalizations are useful for image retrieval (Arandjelović & Zisserman, 2012). We also extracted optical flow using the “Classic+NL” algorithm (Sun et al., 2010), and associated a two-dimensional flow vector to each super-pixel, the median flow of its constituent pixels.

The color, texture, and flow features for super-pixel i in video frame g are denoted by $x_{gi} = \{x_{gi}^c, x_{gi}^t, x_{gi}^f\}$, where

$$x_{gi}^c \sim \text{vMF}(\mu_{z_{gi}}^c, \kappa^c), \mu_{z_{gi}}^c \sim \text{vMF}(\mu_0^c, \kappa_0^c), \quad (12)$$

where κ^c , μ_0^c , and κ_0^c are hyper-parameters controlling the concentration of color features around the direction $\mu_{z_{gi}}^c$, the mean color direction μ_0^c , and the concentration of $\mu_{z_{gi}}^c$ around μ_0^c . Texture features are generated similarly. Flow features are modeled via Gaussian distributions with conjugate, normal-inverse-Wishart priors:

$$\begin{aligned} x_{gi}^f &\sim \mathcal{N}(\mu_{z_{gi}}^f, \Sigma_{z_{gi}}^f), \Sigma_{z_{gi}}^f \sim \mathcal{IW}(n_0, S_0), \\ \mu_{z_{gi}}^f &| \Sigma_{z_{gi}}^f \sim \mathcal{N}(\mu_0, \tau_0 \Sigma_{z_{gi}}^f). \end{aligned} \quad (13)$$

Requiring all clusters in a global component, which may span several video frames, to share a single flow model is too restrictive. Instead we model the flow for each frame independently, requiring only that clusters in frame g assigned to the same component share a common flow model. Our model requires motion of a component to be locally (within a frame) coherent, but allows for large deviations between frames.² This assumption more closely reflects the motion statistics of objects in real videos.

Prior We used data affinities that encourage spatial neighbors not separated by strong intervening contours to

¹Chang et al. (2013) also estimate temporal correspondences between superpixels, but we do not utilize this information.

²See the supplement for specific hyper-parameter settings.

connect to one another. We computed them by independently running the Pb edge detector (Martin et al., 2004) on each video frame and computing $A_{ij} = (1 - b_{ij})^3 \times \mathbf{1}[i, j]$ for each superpixel pair. Here, $0 \leq b_{ij} \leq 1$ is the maximum edge response along a straight line segment connecting the centers of superpixels i, j , and $\mathbf{1}[i, j]$ takes a value of 1 if i and j are spatial neighbors, and 0 otherwise.

Flow-based affinities, as in the earlier toy example, were used to specify the cluster affinity functions. All $\alpha_{1:G}$ and α_0 were set to 10^{-8} . The naive-hddCRP used identical data affinities and hyper-parameters, but used sequential distances between clusters (see Sec. 2.2). The hCRP used sequential affinities to govern both the data and cluster links. For a CRP, the expected number of clusters given N data points is roughly $\alpha \log(N)$. We set $\alpha_{1:G}$ such that the expected number of clusters in a video frame matches the number of observed ground truth clusters, and $\alpha_0 = 1$.

Data link proposals We compare the two data link proposals on 10 frames from the classic “garden” sequence. For each proposal, we ran 3000 iterations of 25 MCMC chains. The results, including MAP samples from the highest and lowest probability chains and log-likelihood trace plots, are summarized in Figure 4. The visualized MAP partitions demonstrate that all chains eventually reach reasonable configurations, but segmentations nevertheless improve qualitatively with increasing model likelihood. This suggests a correspondence between the biases captured by the hddCRP and the statistics of video partitions.

We find that pseudo-Gibbs proposals reach higher probability states more rapidly than prior proposals, and have much lower sensitivity to initialization. Overall, 24 of the 25 pseudo-Gibbs chains reach states that are more probable than the best prior proposal trial. Subsequent experiments thus focus solely on the superior pseudo-Gibbs proposal.

Empirical evaluation We compare our performance against a popular non-probabilistic *hierarchical graph-based video segmentation* (HGVS) algorithm (Grundmann et al., 2010), against the naive-hddCRP variant that was recently used for video co-segmentation (Chiu & Fritz,

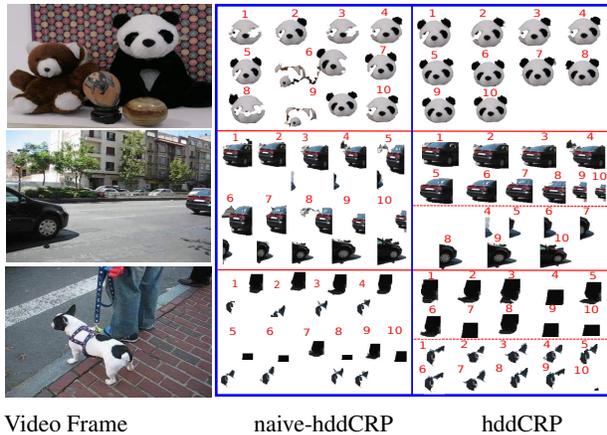

Figure 5: Video segments discovered by the naive-hddCRP and hddCRP. *Left to right*: A representative video frame, segments discovered by the naive-hddCRP and the corresponding segments discovered by hddCRP. Dashed red horizontal lines indicate different segments, and numbers indicate video frame numbers.

2013), and against the hCRP (Teh et al., 2006). For a controlled comparison, all three CRP models use identical likelihoods and hyperparameters. We use the MIT human annotated video dataset (Liu et al., 2008), which contains 9 human annotated videos, to quantitatively measure segmentation performance. We benchmark performance using the first 10 frames of each sequence.

Figure 6 summarizes this experiment. For HGVS the displayed segmentations were produced at 90 percent of the highest hierarchy level, which appears to produce the best visual and quantitative results. For the hddCRP variants, the segmentations correspond to the MAP sample of five MCMC chains, each run for 400 iterations³. We decided to run the samplers for 400 iterations based on the results shown in Figure 4, where a large majority of the pseudo-Gibbs chains converged within the first 300 iterations.

The Rand index was computed by treating the entire video sequence as one spatio-temporal block. This penalizes spatially coherent, but temporally inaccurate, segmentations that exhibit frequent “label switching” between frames. HGVS operates on pixels rather than superpixels and consequently produces finer-scale segmentations. However, these segmentations exhibit large segmentation errors (for instance, the neck and face regions get merged with the background in the second sequence). The hddCRP produces more coherent segmentations and in terms of Rand index, outperforms HGVS on all but one video sequence. The hddCRP also performs substantially better than the hCRP which ignores both superpixel and segment-level correlations; “bag of feature” assumptions are insufficient for this task. The gains over the naive-hddCRP appear to be more modest. However, a closer inspection (Figure 5)

³Roughly 6 hours on a 2.3 GHz intel core i7.

reveals that the hddCRP segments are visually cleaner and more coherent. Additionally, naive-hddCRP often falsely merges visually similar but distinctly moving objects together, while the hddCRP recognizes them as distinct segments. The videos in our dataset have large background regions with no significant motion. Both the hddCRP and the naive-hddCRP models tend to agree on such regions, while disagreeing on smaller foreground objects with distinct motions. Large regions dominate the Rand index, which explains the similar global performance by that metric.

4.2 DISCOURSE SEGMENTATION

Next we consider the problem of discourse segmentation. Given a collection of documents, the goal is to partition each document into a sequence of topically coherent non-overlapping discourse fragments. Previous work by Riedl & Biemann (2012) found that sharing information across documents tends to produce better segmentations, motivating the development of several text segmentation algorithms that exploit document relationships.

We conducted experiments on the *wikielements* dataset (Chen et al., 2009), which consists of 118 Wikipedia articles (at paragraph resolution) describing chemical elements. Although not explicitly made available in the dataset, each article corresponds to a chemical element that is characterized by its chemical properties and has a unique location in the periodic table. Our distance-dependent models are capable of exploiting this additional information to produce better discourse segmentations. As an illustration, consider the alternative problem of clustering articles. Figure 7 illustrates such a clustering where we leverage element properties by defining distances between documents as the Manhattan distance between corresponding element locations in the periodic table. The discovered clustering corresponds well with known element groupings. Discourse segmentation requires clustering the paragraphs describing documents, instead of the documents themselves. Nonetheless, we find that exploiting the periodic table location of each document’s element leads to noticeable performance gains.

We compare two versions of the hddCRP to the naive-hddCRP and hCRP. To encourage topic contiguity, naive-hddCRP and hddCRP allowed paragraphs to either link to themselves or to other paragraphs immediately preceding or succeeding them. We experimented with two affinity functions to capture the intuitions that similar documents tend to present similar topics in similar orders, and that clusters are more likely to be shared among articles about similar elements. The first function (hddCRP1) biased clusters of paragraphs to connect to those that occur at similar locations within other documents. Further, clusters were constrained to connect to only those that were contained in documents with lower atomic numbers. A second variant (hddCRP2) modeled distances between articles using the

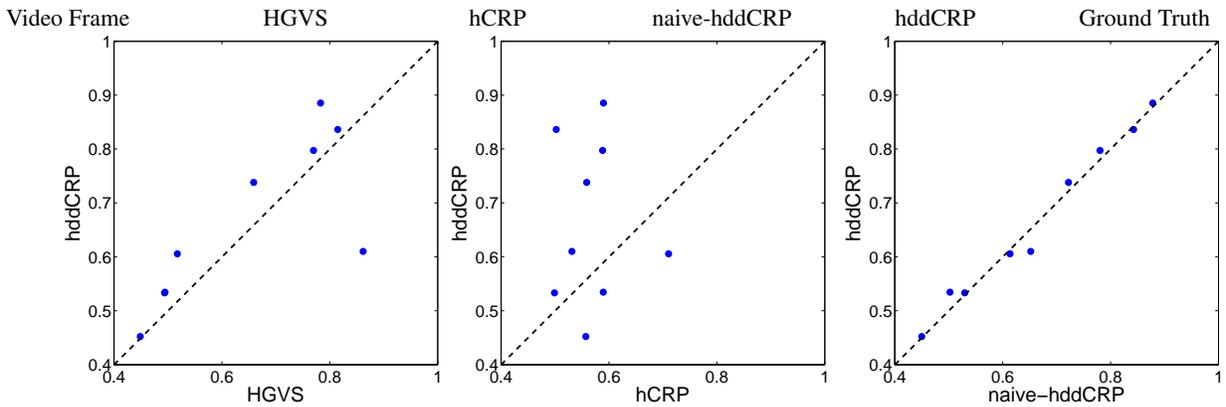

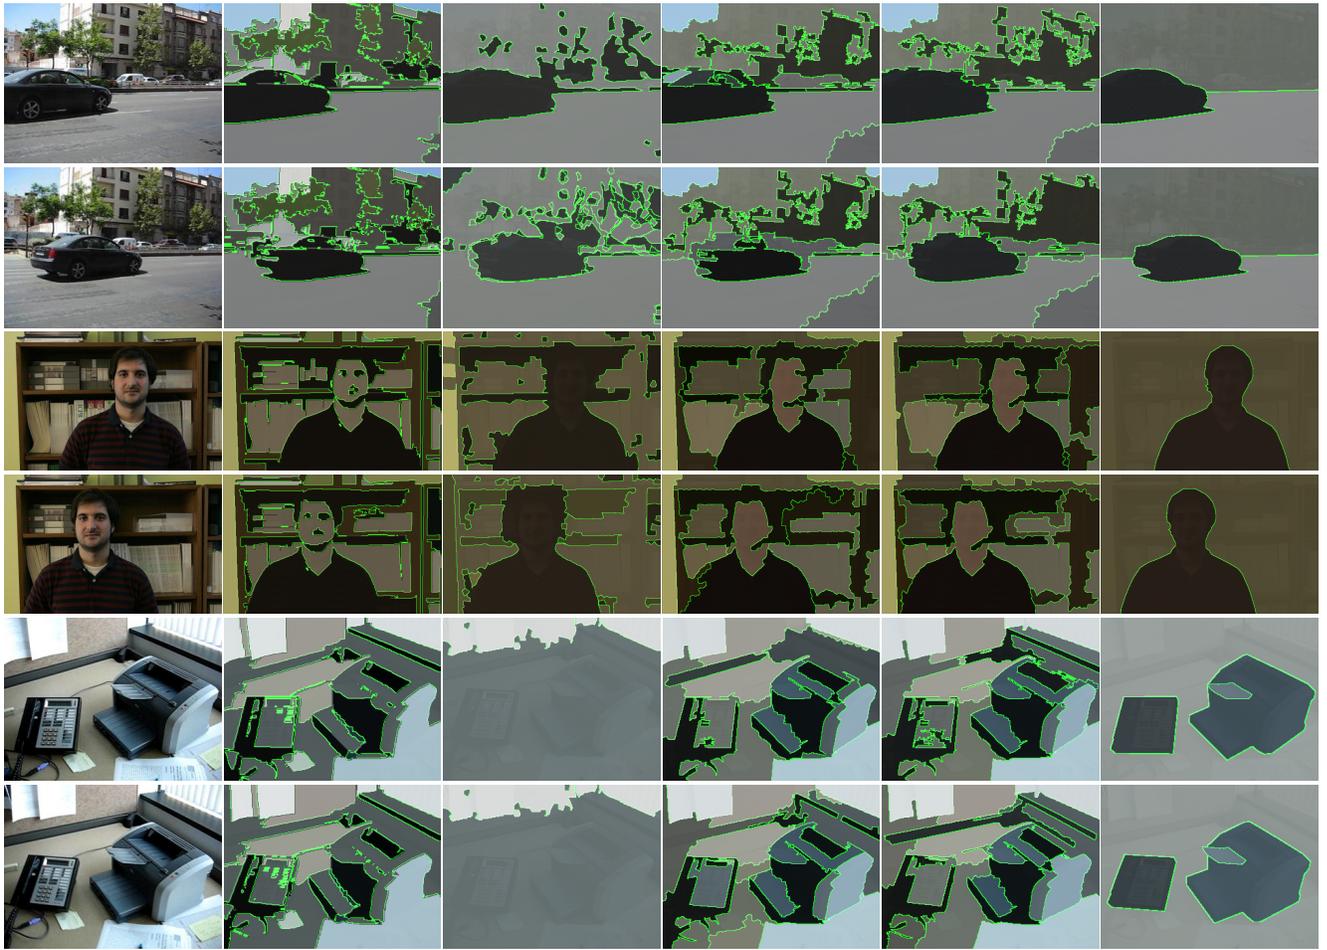

Figure 6: Video segmentation results. The top eight rows show the first and tenth frames of four videos from the MIT human annotated video dataset. *Left to right*: original video frames, segmentations produced by HGVS, hCRP, naive-hddCRP, and hddCRP, and the ground truth segmentations. *Bottom row*: Scatter plots comparing hddCRP, HGVS, naive-hddCRP, and hCRP in terms of Rand index achieved on all nine human annotated videos. Higher scores are better, and more points above the diagonal indicate favorable performance of hddCRP over competitors.

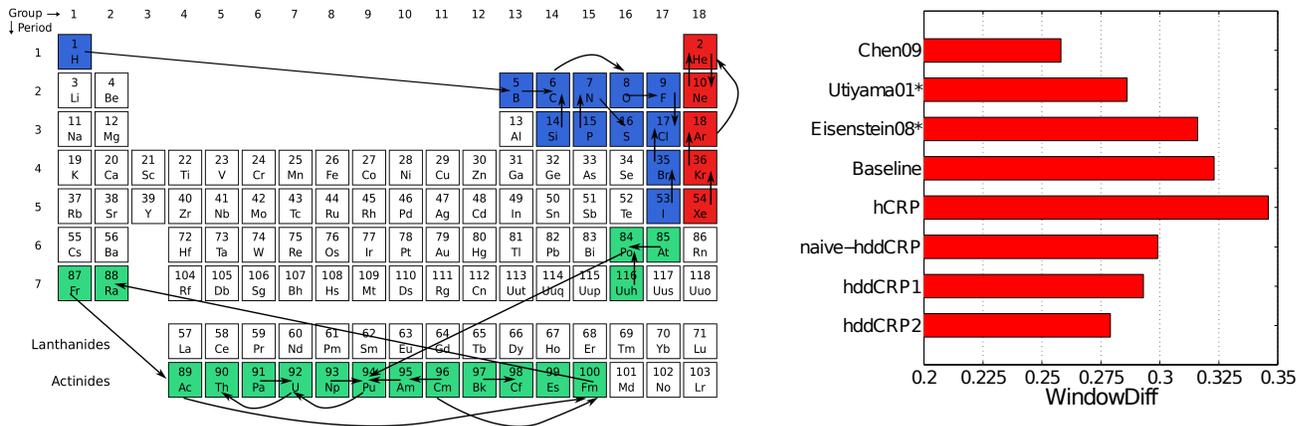

Figure 7: Discourse segmentation results on the *wikielements* dataset. *Left*: A partial visualization of the inferred customer links when clustering Wikipedia articles describing 118 chemical elements. The distance between articles equals the Manhattan distance between their locations in the periodic table. Only three of the nine discovered clusters have been visualized. *Right*: windowDiff scores achieved by competing methods, where lower scores indicate better performance. Asterisks indicate numbers reproduced from Chen et al. (2009).

Manhattan distance between the corresponding element locations in the periodic table, and defined cluster affinities as the logistic decay $f(d) = (1 + \exp(d))^{-1}$ of distances between their corresponding documents. In all cases, we model observed word counts using cluster-specific multinomial distributions with Dirichlet priors. The reported results correspond to the MAP sample of 5 MCMC chains, each run for 400 iterations.

We also compared against established text segmentation methods (Chen et al., 2009; Eisenstein & Barzilay, 2008; Utiyama & Isahara, 2001), and a naïve baseline that groups the entire dataset into one segment. We quantified performance using the windowDiff metric, which slides a window through the text incurring a penalty on discrepancies between the number of segmentation boundaries in the inferred segmentation and a gold standard segmentation. Figure 7 summarizes the performance of the competing models. Both hddCRP1 and hddCRP2 outperform naive-hddCRP and hCRP, showing that our cluster-level affinities capture important additional dataset structure. The hddCRP2 model was superior to all other hddCRP variants, as well as to the specialized text segmentation algorithms of Eisenstein & Barzilay (2008) and Utiyama & Isahara (2001). However, the generalized Mallows model (Chen et al., 2009) achieved the best performance; it is able to both globally bias segment orderings to be similar across related documents, while guaranteeing spatially connected topics. In contrast, the hddCRP weakly constrains segment order through local cluster affinities and while it encourages contiguity, the likelihood may prefer disconnected segments, resulting in a poorer match with the reference segmentation. We nevertheless find it encouraging that the general hddCRP framework, with appropriate affinities, is competitive with specialized text segmentation methods.

5 DISCUSSION AND FUTURE WORK

We have developed a versatile probabilistic model for clustering groups of data with complex structure. Applying it to diverse domains is straightforward: one need only specify appropriate distance functions. Our hierarchical ddCRP defines a valid joint probability distribution for any choice of “distances”, which need not be metrics or have any special properties. Using distances based on pixel locations and optical flow estimates, the hddCRP compares favorably to contemporary video segmentation methods. Using distances based on paragraph order and element positions in the periodic table, it outperforms several established textual discourse segmentation techniques.

While our MCMC inference methods are highly effective for moderate-sized datasets, further innovations will be needed for computational scaling to very large datasets. In cases where training examples of appropriate clusterings are available, we would also like to automatically learn effective hddCRP distance functions.

Transformation-based Probabilistic Clustering with Supervision

Siddharth Gopal

Abstract

One of the common problems with clustering is that the generated clusters often do not match user expectations. This paper proposes a novel probabilistic framework that exploits supervised information in a discriminative and transferable manner to generate better clustering of unlabeled data. The supervision is provided by revealing the cluster assignments for *some subset* of the ground truth clusters and is used to learn a transformation of the data such that labeled instances form well-separated clusters with respect to the given clustering objective. This estimated transformation function enables us to fold the remaining unlabeled data into a space where new clusters hopefully match user expectations. While our framework is general, in this paper, we focus on its application to Gaussian and von Mises-Fisher mixture models. Extensive testing on 23 data sets across several application domains revealed substantial improvement in performance over competing methods.

1 INTRODUCTION

Presenting structured and organized views of data to users is crucial for efficient browsing and locating relevant information. Unsupervised clustering techniques have been widely used for discovering latent structures in unlabeled data. Generative clustering models based on Gaussian, von-Mises and Multinomial distributions have emerged as the defacto methods for performing probabilistic clustering.

However, such clustering methods have a fundamental limitation that they do not take into account the user expectations or preferences over different views of data. For example, given a collection of news-stories, one user might prefer to organize them by subject topics such as *Politics*, *Sports*, *Business*, *etc.*, while another user might prefer to see the news-stories grouped by regions such as *U.S.*, *India*, *China*, *etc.* As another example, in a collection of speech

recordings, it is perfectly reasonable to cluster the recordings either by the content of the recording or by the speaker. In both cases, clustering algorithms cannot tell which type of clustering is preferable unless the user's expectation is effectively communicated to the system. This leads to two challenging problems in clustering:

1. How can we effectively inject supervised information to steer the clustering process towards user expectations?
2. If only **some clusters** identified by the user are available as supervision, can the learned user expectations be effectively transferred from the observed clusters to aid in the discovery of **unobserved** (new) clusters in data?

The first problem has been partially addressed by some work in constrained clustering and distance metric learning, although not in sufficient depth (see Section 2). The second problem, to our knowledge, has not been addressed by any work so far. The second problem is particularly important from a practical point of view because realistically users can only label a small set of clusters, whereas the data keeps growing and new clusters are bound to show up. Using a collection of news-stories as a concrete example, if the user identifies three clusters *U.S.*, *India*, and *China* as the supervision, the system should learn that the user is interested in region-based clustering and partition the incoming unlabeled data by regions and discover other new clusters such as *Iraq*, *Japan*, *etc.* In other words, we want the system to generalize the learned user expectation by modeling shared properties between the observed and unobserved clusters.

This paper addresses both challenges by proposing a novel probabilistic framework that assumes the existence of an underlying transformation of data (that is common to the observed and unobserved clusters) which reveals the true user expectations on clustering. Using the supervision in the form of labeled instances and true cluster labels for some subset of groundtruth clusters, we estimate such a transformation. Specifically, we define the transformation function \mathbf{G} in a discriminative manner that maximizes the conditional probability of the cluster label given the transformed instance. Once \mathbf{G} is learned, we apply it to un-

labeled data for clustering in the next step. Because the supervised information is propagated by means of a data transformation we call our framework Transformation-based Clustering with Supervision (TCS).

Our framework is flexible and can be applied to any probabilistic clustering model as long as an appropriate transformation function \mathbf{G} can be defined. In this paper, we explore our framework with two widely used probabilistic clustering models which have different clustering objectives, the Gaussian Mixture model (GM) (Bishop, 2006) and the von Mises-Fisher Mixture model (VM) (Banerjee et al., 2006). For GM, we define \mathbf{G} to be a linear transformation whereas for VM, \mathbf{G} is a linear transformation followed by unit normalization. For both the models we develop efficient optimization algorithms to estimate \mathbf{G} and related parameters.

We conducted thorough evaluations and tested our framework on 23 data sets from different application domains such as time-series, text, handwriting recognition, face recognition, etc. We have observed substantial and consistent improvement in performance (in five clustering metrics) over other competing methods.

2 RELATED WORK

There are two primary areas of related work that use supervision to improve clustering of unlabeled data - Probabilistic Constrained Clustering (PCC) and Distance Metric Learning (DML).

PCC methods (Wagstaff et al., 2001; Basu et al., 2002) try to inject supervision using a probabilistic generative model for the instances. The instances \mathbf{X} consists of both the labeled part \mathbf{X}_L , the unlabeled part \mathbf{X}_U and the cluster assignments $\mathbf{Z} = \{\mathbf{Z}_U \cup \mathbf{Z}_L\}$. The observed cluster assignments $\mathbf{Z}_L \subset \mathbf{Z}$ is used as supervision, i.e., the constraints. The model parameters θ and the latent cluster assignments \mathbf{Z}_U are estimated by maximizing the likelihood under the constraints as:

$$\max_{\theta, \mathbf{Z}_U} \log P(\mathbf{X}|\mathbf{Z}_L, \mathbf{Z}_U, \theta) \quad (1)$$

However, when the task is to detect previously unobserved cluster, this optimization reduces to plain clustering. This can be seen by rewriting the objective as a sum of the labeled objective (which is constant) and the unlabeled objective (which is just standard clustering) as:

$$\max_{\theta_L} \log P(\mathbf{X}_L|\mathbf{Z}_L, \theta_L) + \max_{\theta_U, \mathbf{Z}_U} \log P(\mathbf{X}_U|\mathbf{Z}_U, \theta_U)$$

Clearly, there is no *learning* nor transfer of information from the observed clusters to the unobserved clusters. There are other works in PCC where supervision is represented in the form of pairwise constraints instead of cluster labels, i.e. the constraints are defined as whether two instances should be put in the same cluster or not. These methods optimize eq (1) with an additional penalty term if the constraints are not obeyed. The penalty is introduced in the form of priors (Lu and Leen, 2005), (Basu

et al., 2006) or explicitly modeled using some loss function (Basu et al., 2004), (Bilenko et al., 2004). Despite the different variations in formulating the constraints, PCC methods (Wagstaff et al., 2001; Basu et al., 2002, 2004, 2006; Lu and Leen, 2005) have the same fundamental limitation, i.e., the supervised information from the *observed* clusters is not used to reshape the discovery of *unobserved* clusters. The clustering of the unlabeled part of the data reduces to standard unsupervised clustering.

A natural extension of PCC that addresses some of its limitations is to use a more *Bayesian* approach of sharing parameters across clusters. For example, one could use a Gaussian mixture model where each cluster k has its own mean parameter θ_k , but all clusters share a common covariance matrix Σ . Here the covariance matrix serves as the bridge to transfer information from the observed clusters to the unobserved clusters. One can envision more sophisticated models with common hyperpriors, e.g. a Gaussian hyperprior for the means and an Inverse Wishart hyperprior for the covariances. To our knowledge, such Bayesian revisions of PCC have not been studied in the context of discovering new clusters in unlabeled data (which is the focus of this paper). As we will show in our experiments (where we implemented such a Bayesian PCC model as a baseline), this way of sharing information is not as effective as directly fitting for the cluster labels in the transformed space, which we propose in the TCS framework.

In DML (Blitzer et al., 2005; Xing et al., 2002; Goldberger et al., 2004) the objective is to learn a distance metric that respects the supervision which is provided in the form pairwise constraints. More specifically, given a set of labeled clusters, the distance metric is estimated such that it pulls the within-cluster pairs towards each other and pushes the cross-cluster pairs away from each other. DML methods differ from each other in how the loss functions are defined over the pairwise constraints, such as the hinge loss (Blitzer et al., 2005), Euclidean-distance loss (Xing et al., 2002), log loss (Goldberger et al., 2004), etc. DML has been typically used in the context of nearest-neighbor classification but not in the context of discovering *unobserved* clusters. We argue that existing DML methods have two problems w.r.t to discovering unobserved clusters: Firstly, DML optimizes for pairwise distances and is therefore ‘unaware’ of the clustering criterion (the objective function for clustering) used. This can lead to overfitting, for example, even if the data is optimally clustered, DML would still try to increase inter-cluster distances and decrease intra-cluster distances. Secondly, optimizing for different loss functions (e.g., hinge loss or Euclidean loss) do not necessarily yield a metric that is also optimal for clustering. Explicitly fitting for the cluster-labels that also achieves the optimal clustering objective without resorting to surrogate measures like pairwise constraints is the fundamental difference between our TCS models and other DML methods.

Indirectly related to this paper are a few works in discrim-

Table 1: Likelihood at Local optimum reached by EM vs Likelihood of ground-truth. The Local optimum is better !

Algorithm →	GM	VM
Local optimum	-18115	4.09965e+09
Groundtruth	-18168	4.09906e+09

inative clustering (Krause et al., 2010), (Xu et al., 2004) and constrained spectral clustering (Rangapuram and Hein, 2012), (Wang and Davidson, 2010), (Lu and Carreira-Perpinán, 2008). These former methods use a discriminative objective like that of SVM for clustering, however, cannot handle supervision. The latter methods incorporate supervision in a spectral clustering framework, but however, cannot scale beyond a few thousands of instances, cannot produce probabilistic cluster memberships and do not *directly* optimize for the class-labels. A thorough discussion of the drawbacks of spectral clustering framework is however beyond the scope of this paper (see (Nadler and Galun, 2007) and reference therein). It is also worth mentioning that some other work like (Joulin et al., 2010), (Finley and Joachims, 2005) reformulate the classification problem as a clustering one, but however cannot discover previously unobserved clusters in data.

3 PROPOSED MODEL (TCS)

Any typical clustering task involves making at the least two assumptions - number of clusters (or the prior parameters if using Bayesian non-parameterics) and the distance measure, both of which determine the type of clusters generated. The distance measure in a probabilistic clustering framework is determined by the choice of the distribution for e.g. Euclidean corresponds to Gaussian, cosine-similarity corresponds to von Mises-Fisher etc. Typically, the user’s subjective choice of the probability distribution does not match the ground-truth and the generated clusters do not match user expectations.

To demonstrate this, we ran two popular clustering algorithms - the Gaussian Mixture model (GM) and the von Mises-Fisher mixture model (VM), which use different probability distributions and optimize different likelihoods, on the 20newsgroups dataset ¹ with 20 clusters using the EM algorithm. We compared the likelihoods (the clustering objective) of the algorithms under two settings,

1. The likelihood at a local optimum reached by EM ².
2. The likelihood when the true labels are given, i.e. cluster assignments fixed to the ground-truth.

As table 1 shows, the likelihood obtained at a local optimum is better than groundtruth - the groundtruth is suboptimal ! The clustering algorithm is optimizing for something else other than groundtruth. This means that the user

¹qwone.com/ jason/20NewsGroups/

²The EM algorithm was initialized with the ground-truth cluster assignments

expected clusters can never be recovered. This is a clear case of mismatch between what the user expects and the user specified probability distribution.

To address this issue, we propose to transform the data into another space where the instances are indeed distributed according to user expectations. We use the supervised information to estimate such a transformation i.e. we estimate a transformation function G in a discriminative manner that maximizes the likelihood of observing the given labels (not the data) in the transformed space.

More formally, we are provided supervised training data from K clusters, $\mathcal{S} = \{x_i, t_i\}_{i=1}^N$ where $x_i \in \mathcal{X}$, $t_i \in \{1, 2, \dots, K\}$ and unlabeled examples \mathcal{U} . For convenience define $y_{ik} = I(t_i = k)$. Given a probabilistic generative model using a mixture of K distributions $\{f(x|C_k)\}_{k=1}^K$ where C_k denotes the parameters of cluster K , we estimate G as,

$$\arg \max_G \log P(\mathbf{Y}|\mathbf{C}^{mle}(G), G(\mathbf{X}))$$

where $\mathbf{C}^{mle}(G) = \arg \max_{\mathbf{C}} P(G(\mathbf{X})|\mathbf{C}, \mathbf{Y})$,

$$P(\mathbf{Y}|G(\mathbf{X}), \mathbf{C}^{mle}(G)) = \prod_{i=1}^N \prod_{k=1}^K \left[\frac{f(G(x_i)|C_k^{mle}(G))}{\sum_{k'=1}^K f(G(x_i)|C_{k'}^{mle}(G))} \right]^{y_{ik}}$$

Here \mathbf{C}^{mle} denotes the maximum likelihood estimates of the cluster parameters in the transformed space i.e the cluster parameters that best explain the transformed data. G on the other hand is estimated by maximizing the conditional likelihood of the cluster-labels given \mathbf{C}^{mle} i.e. the transformation that best explains the cluster-labels. Together this ensures that we learn G such that the optimal cluster parameters \mathbf{C}^{mle} also optimally fit the cluster-labels \mathbf{Y} . The transformation G is then applied to \mathcal{U} thereby folding it into a space where hopefully the user specified distribution $f(x|C)$ matches user expectations.

Unlike typical clustering algorithms, our TCS framework has a *learning* component as well i.e. we learn how to discover unobserved clusters from supervision. Since any learning algorithm has chances of overfitting, we add an additional regularization term. Together,

$$\begin{aligned} [\text{OPT1}] \quad & \max_{G, \mathbf{C}} \log P(\mathbf{Y}|\mathbf{C}(G), G(\mathbf{X})) - \gamma \lambda(G) \\ & \text{s.t.} \quad \frac{\partial \log P(G(\mathbf{X})|\mathbf{C}, \mathbf{Y})}{\partial \mathbf{C}} = 0 \end{aligned}$$

where γ is the regularization parameter and λ is the regularization function. Note that the second constraint is another way to say \mathbf{C} is the MLE estimate of $G(\mathbf{X})$. In the following subsections, we discuss how to estimate G with two choices for $f(x|C_k)$ - Gaussian and von Mises-Fisher ³.

³The supplementary material also discusses the extension to Gamma distributions

3.1 TCS WITH GAUSSIAN MIXTURES

We define a simple mixture of K Gaussians with unit variance and cluster means $\{\theta_k\}_{k=1}^K$ over \mathcal{R}^P where

$$f(x|\theta_k) = \frac{1}{\sqrt{2\pi}} \exp(-\|x - \theta_k\|^2)$$

The transformation function is defined as $G(x) = Lx$, a linear transformation using matrix $L \in \mathcal{R}^{P \times P}$. The parameters $\{\theta_k\}_{k=1}^K$ and transformation L is estimated by solving OPT1. Note that the constraint in OPT1 can be written in closed form,

$$\begin{aligned} \text{[OPT1]} \quad & \max_{G,C} \log P(\mathbf{Y}|\boldsymbol{\theta}, L\mathbf{X}) - \gamma\lambda(G) \\ \text{s.t} \quad & \theta_k = \frac{1}{n_k} \sum_{i=1}^N y_{ik} Lx_i \quad \forall k \end{aligned}$$

where n_k denotes the number of instances assigned to cluster k . If m_k denotes the mean of instances assigned to cluster k , then OPT1 can be rewritten as,

$$\begin{aligned} \text{[OPT1]} \quad & \max_{G,C} \log P(\mathbf{Y}|\boldsymbol{\theta}, L\mathbf{X}) - \gamma\lambda(G) \\ \text{s.t} \quad & \theta_k = Lm_k \quad \forall k \end{aligned}$$

The conditional probability of y_{ik} given the transformed instance Lx_i is,

$$P(y_{ik} = 1|\theta_k, Lx_i) = \frac{e^{-\frac{1}{2}(Lx_i - \theta_k)^\top (Lx_i - \theta_k)}}{\sum_{k'=1}^K e^{-\frac{1}{2}(Lx_i - L\theta_{k'})^\top (Lx_i - L\theta_{k'})}}$$

Letting $\theta_k = Lm_k$ and defining $d_{ik} = x_i - m_k$,

$$P(y_{ik} = 1|\theta_k, Lx_i) = \frac{e^{-\frac{1}{2}d_{ik}L^\top Ld_{ik}}}{\sum_{k'=1}^K e^{-d_{ik'}L^\top Ld_{ik'}}}$$

By reformulating OPT1⁴ as an optimization problem in terms of $A = L^\top L$, we have a convex semidefinite program,

$$\begin{aligned} \min_A \quad & F(A) = \gamma\lambda(A) + \\ & \sum_{i=1}^N \sum_{k=1}^K \frac{y_{ik}}{2} d_{ik}^\top A d_{ik} + \sum_{i=1}^N \log \left(\sum_{k'} e^{-\frac{1}{2}d_{ik'}^\top A d_{ik'}} \right) \\ \text{s.t} \quad & A \succeq 0 \quad \text{where } d_{ik} = (x_i - m_k) \end{aligned}$$

We tried different choices for $\lambda(A)$,

1. $\|A - I\|^2$ (Frobenius Norm from Identity)
2. $\|A\|_2^2$ (Frobenius Norm from zero)
3. $\|A\|_*$ (Nuclear Norm)
4. $\text{trace}(A) - \log(\det(A))$ (Log-det divergence)
5. $\|A - I\|_1$ (Entrywise-L1 Norm)

⁴Due to the lack of space, we defer the detailed derivations to the supplementary material.

Algorithm 1 Accelerated gradient descent for TCS-GM.

- 1: **Input:** $\{\mathbf{X}, \mathbf{Y}\}$, step-length sequence S_t
 - 2: **Initialize:** Define $H_t = I, \beta_t = 1$
 - 3: **while** not converged **do**
 - 4: $A_t = \mathcal{PSD}(H_t - s_t \nabla F(H_t))$
 - 5: $\beta_{t+1} = \frac{1 + \sqrt{1 + 4\beta_t^2}}{2}$
 - 6: $H_{t+1} = A_t + \frac{\beta_t - 1}{\beta_t} (A_t - A_{t-1})$
 - 7: **end while**
 - 8: **Output:** A_t
 - 9: \mathcal{PSD} denotes projection to the positive semidefinite cone
-

Different regularizers favor different kinds of linear transformations, for e.g., Nuclear norm (Ma et al., 2011) favours lower rank solutions, Entrywise-L1 norm favours sparser transformations, the log-det regularizer also prefers lower rank solutions but penalizes sum of log of eigenvalues instead (Davis et al., 2007) etc.

For differentiable regularizers, the optimization can be solved using projected gradient descent where we take a step along the direction of the negative gradient (with the stepsize determined by backtracking line search) and then project the update back into the positive semidefinite cone. We observed that we could significantly improve the speed by using accelerated gradient descent (Beck and Teboulle, 2009) instead (Algorithm 1). For the non-differentiable regularizers we can use projected subgradient instead. These algorithms provably converge to the optimal solution if the step size is appropriately set (Boyd and Vandenberghe, 2004). The gradient of the objective can be succinctly written as,

$$\begin{aligned} \nabla F(A) = \gamma\lambda'(A) + \sum_{i=1}^N \sum_{k=1}^K (y_{ik} - p_{ik}(A)) d_{ik} d_{ik}^\top \\ \text{where } p_{ik}(A) = P(y_{ik}|Lx_i, \theta_k) \end{aligned}$$

We found that our customized parallel solver using accelerated projected gradient descent worked much faster than existing SDP solvers. The solution in A recovers L upto any rotation matrix. This is because $A = L^\top L$ can always be rewritten using $A = L^\top (Q^\top Q)L$, for any rotation matrix $Q^{-1} = Q^\top$. However rotating the data corresponds to changing the basis and does not affect the clustering algorithm.

Note that A is very different from the seemingly similar covariance matrix of a Gaussian distribution. Firstly, unlike the covariance matrix, A is not parameter of the distribution and does not make the distribution sum to 1. Secondly, covariance matrices are typically estimated by maximizing $P(\mathbf{X}|\mathbf{Y})$, this includes supervised versions such as linear discriminant analysis (LDA) and Fisher LDA (Hastie et al., 2009). The transformation matrix A on the other hand, is optimized to fit the labels $P(\mathbf{Y}|L\mathbf{X}, \theta)$. Unlike LDA, A does not have a closed form solution.

Algorithm 2 Optimizing $L, \{\mu_k\}_{k=1}^K$ for TCS-VM.

- 1: **Input:** $\{\mathbf{X}, \mathbf{Y}\}, T$ iterations
 - 2: **Initialize:** L
 - 3: **for** $t = 1, \dots, T$ **do**
 - 4: **update** $\mu_k = \frac{\sum_{i=1}^N y_{ik} n_i}{\sum_{i=1}^N y_{ik} n_i}$ where $n_i = \frac{Lx_i}{\|Lx_i\|}$
 - 5: **update** $L = \arg \min_L \gamma \lambda(L) + \sum_{i=1}^N \sum_k y_{ik} \left[\frac{x_i^\top L^\top \mu_k}{\|Lx_i\|} - \log \left(\sum_{j=1}^K \exp \left(\frac{x_i^\top L^\top \mu_j}{\|L^\top x_i\|} \right) \right) \right]$
 - 6: **end for**
-

3.2 TCS WITH VON-MISES FISHER MIXTURES

The von Mises-Fisher (vMF) distribution defines a probability density over points on a unit-sphere. It is parameterized by mean parameter μ and concentration parameter κ , the former defines the direction of the mean and the latter determines the spread of the probability mass around the mean. The density function over $\mathcal{X} \equiv \{x : \|x\| = 1, x \in \mathcal{R}^P\}$, is given by

$$f(x|\mu, \kappa) = \frac{\kappa^{(5P-1)}}{(2\pi)^{.5P} I_{.5P-1}(\kappa)} \exp(\kappa \mu^\top x)$$

where $I_\nu(a)$ is the modified bessel function of first kind with order ν and argument a .

As in the Gaussian mixtures case, we consider a mixture of K vMF distributions with mean parameters $\{\mu_k\}_{k=1}^K$ and a single concentration parameter κ . Since the support of vMF is only over the unit-sphere, any transformation function should ensure the transformed space still lies on the unit-sphere. Therefore we define the transformation function G as a linear transformation with matrix $L \in \mathcal{R}^{P \times P}$ with normalization,

$$G(x) = \frac{Lx}{\|Lx\|}$$

With this transformation function, the optimization problem OPT1 is a non-convex function in L . Note that the cluster mean parameters $\{\mu_k\}_{k=1}^K$ have a closed form expression for the MLE estimate in terms of L and \mathbf{X} . However unlike the GM case, we do not recommend substituting it into the objective of OPT1 as it leads to computationally intensive expressions. We instead resort to an alternating optimization between μ_k 's and L as shown in Algorithm 2. The optimization step in line 5 is nonconvex in L and can be solved using gradient descent to converge to a locally optimal solution. We found that in practice it worked fine.

4 EXPERIMENTS

4.1 METHODS FOR COMPARISON

We conducted an extensive empirical study of our proposed framework against several competing methods. We tested,

1. **GM** The simple Gaussian Mixture where the data is assumed to be generated from a mixture of K Gaussians with individual means and a single common variance parameter. All parameters are estimated using EM algorithm. Note that this model is unsupervised and cannot use supervision.
2. **TCS-GM** Our proposed TCS using Gaussian mixture model (section 3.1) and $\|A - I\|^2$ regularization, followed by GM on the linearly transformed unlabeled data.
3. **TCS-GM-L2** Our proposed TCS using Gaussian mixture model and plain $\|A\|^2$ regularization, followed by GM on the linearly transformed unlabeled data.
4. **LMNN (Weinberger and Saul, 2009)** One of the most popular local distance metric learning methods that uses hingeloss to push and pull target neighbors. To ensure competitive performance, the number of target neighbors was set to high value - 50. This is followed by GM on the linearly transformed unlabeled data. Note that LMNN is a stronger baseline than other DML methods like Relevant Component Analysis (Shental et al., 2006), Neighborhood Component Analysis (Goldberger et al., 2004), Linear Discriminant Analysis (Fisher, 1936), etc.
5. **PCC (Bilenko et al., 2004)** A popular probabilistic constrained clustering framework. We used a common covariance matrix for all clusters to ensure transfer of information from known to unknown clusters.
6. **Bayesian** We implemented a Bayesian Gaussian mixture model as an additional baseline, where all the cluster means are drawn from a Normal hyperprior and all clusters share a single covariance matrix. We also tried other variants such as cluster-specific covariance matrices with a shared Inverse Wishart hyperprior, but it did not yield any appreciable improvements. We used the familiar constrained EM algorithm (Basu et al., 2002) to derive point estimates for the unknown parameters.
7. **CSP (Wang and Davidson, 2010)** A representative spectral clustering method that can handle supervision in the form of constraints. We use the author recommended method of representing the unlabeled instances with top k (where k is the number of clusters) dimensions generated by the algorithm followed by GM.

We also tested the vMF-based models but due to lack of space we discuss only a part of the results in Section 5.2.1. We defer the complete set of vMF-based results to the supplementary material.

4.2 DATASETS

We tested our framework on 23 datasets (Table 2) from various application domains including timeseries, text, speech, images, etc. A thorough description of the datasets and the details of the feature extraction process is given in the supplementary material.

Table 2: A list of datasets used along with their characteristics.

As in any matrix learning method, for high dimensional datasets, learning (or even storing) a full matrix L is computationally intensive. Previous literature have identified three ways to tackle this issue,

1. Learn a diagonal L instead of full matrix L . This drastically improves the scalability, but at the cost of flexibility in the set of transformations (Weinberger and Saul, 2009).
2. Directly learn a low rank transformation, i.e. $L \in \mathcal{R}^{r \times P}$ where $r \ll P$ instead of a full rank matrix. However, the optimization problem now becomes nonconvex in terms of this low rank L (see (Journée et al., 2010)).
3. Reduce the dimension of the data using Singular Value Decomposition (SVD), followed by learning a full rank matrix on the low dimensional data.

In our experiments, we found that solution (3) worked best. Specifically, dimension reduction using SVD actually **improved** the clustering performance on multiple datasets since it removes the intrinsic noise in the data. This is agreement with several observations in practice (Zha et al., 2001), (Drineas et al., 2004) and in theory (Ding and He, 2004), (Kannan et al., 2004). Therefore, on datasets with more than 200 dimensions, we used SVD to fold the data into a 30 dimensional space. Refer supplementary material (sec 9.1) for detailed experiments on how SVD improves clustering.

4.3 EXPERIMENTAL SETTINGS

For all the experiments, we consider the class-labels associated with the data to be the user expected groundtruth clusters. We randomly partitioned the classes into three sets - training, validation and testing. The methods TCS-GM, TCS-GM-L2 and LMNN use the validation set for tuning the regularization parameter. Note that CSP could not scale on datasets with more than 5000 instances. All the results are reported only on the test-set.

We assume the number of clusters in the unlabeled data is always known, if not, well established techniques like AIC or BIC can be used (finding the right number of clusters is a separate problem that we will not focus on).

We used five clustering metrics for evaluations - Normalized Mutual Information (NMI), Mutual Information (MI), Rand Index (RI), Adjusted Rand Index (ARI) and Purity (refer supplementary material for definitions). All results are averaged over 50 different restarts with Kmeans++ initialization (Arthur and Vassilvitskii, 2007).

5 RESULTS

We present three sets of results that answer the following questions,

1. Does supervision help in clustering better ?
2. By how much do the different methods exploit this supervision ?
3. How does the amount of supervision affect the quality

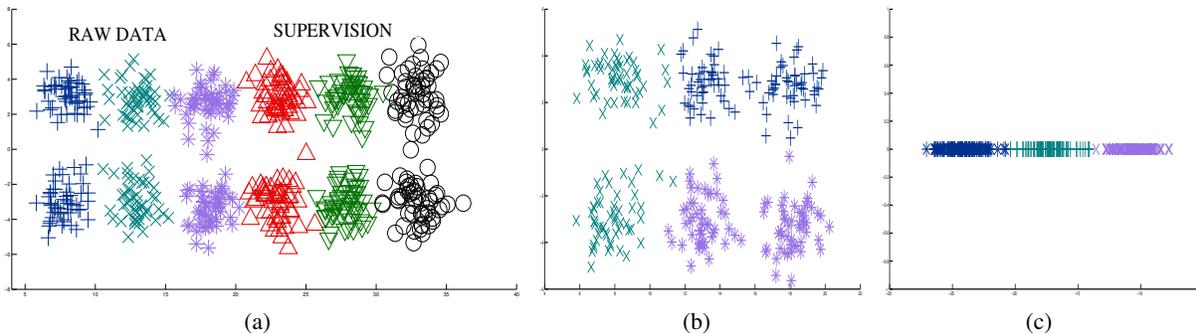

Figure 1: (a) Data from of a mixture of six bimodal Gaussians, (b) Clusters generated by GM on raw data. The generated clusters do not match ground-truth. (c) Clusters generated by TCS-GM. The generated clusters match ground-truth

of clusters generated ?

5.1 ANALYSIS ON SYNTHETIC DATA

First, we show how supervision can be helpful using a small synthetic dataset. We generated data from a mixture of six clusters, where each cluster is a bimodal Gaussian distribution. The clusters lie along the x-axis, where as the modes of the Gaussians are stretched out on the Y-axis (Figure 1a). These are the clusters the user expects to see in the data.

Consider the task of clustering the raw data from first 3 clusters - the darkblue, cyan and purple clusters. Without any supervision, using unsupervised GM results in a clustering show in Figure 1b. Clearly there is confusion between clusters 2 and 3 and the user expectations are not met. On the other hand, if we use TCS-GM with clusters 4, 5, 6 as supervision, we learn a transformation that successfully captures user expectations i.e. the transformation simply collapses all points to the X-axis. When we apply this learnt transformation to the raw data and cluster using GM, we can accurately recover the ground-truth (Fig 1c)

5.2 PERFORMANCE ON REAL-WORLD DATA

Due to lack of space, we report the results only using the NMI metric (the supplementary material contains detailed results using all metrics). Table 3 reports the results of the all supervised and unsupervised models. We defer the results of the vMF-based methods to Section 5.2.1. The results show that our proposed TCS-GM and TCS-GM-L2 achieve the best performance in 19 out of the 23 datasets. We now discuss the results from each domain.

In the time-series domain, *Aussign* and *Libras* are sign-language datasets where each instance represents hand-movement over time, *DSPA* is a human activity recognition dataset where each instance is a human performing one of many predefined actions such as walking, running, etc, *Char* is a handwriting recognition dataset where the instances are (x, y) co-ordinates of pen-tip velocity over time. For all these datasets, the instances are represented as a sequence of vectors (sensor measurements) over time

and the goal is to cluster the instances by the associated classes i.e. handsign (*Aussign*, *Libras*) or activity (*DSPA*) or character (*Char*). To represent each instance as a fixed dimensional vector, we used fast fourier transform to extract the first several high-frequency components of each feature and concatenated them. In this domain TCS-GM-L2 performs the best by showing a 14.2% average improvement over unsupervised GM, followed by TCS-GM with a 9.6% average improvement.

CNAE, *K9*, *TDT4*, *TDT5* are popular text datasets for classification and clustering (Banerjee et al., 2006). We used the standard bag-of-words with ‘lrc’ term-weighting⁵. On all datasets, only TCS-GM and CSP show any improvement at all. The rest are mostly negatively impacted by supervision. The improvement of TCS-GM is higher than that of CSP.

In the handwritten characters domain (*Penbased*, *Letter*, *USPS*, *Binalpha*, *Optrec* and *MNIST*) each instance is an image-representation of a single character and the task is to cluster the instances characterwise. For feature representation, on the latter four datasets, we used histogram of oriented gradients (HOG) (Srikantan et al., 1996) representation with a patchsize of 2 across 9 different orientations. *Penbased* and *Letter* datasets have predefined set of features such as mean pixel value, edgewise mean, etc. Performance wise, TCS-GM and TCS-GM-L2 achieve the best performance, TCS-GM seems to be more suited to HOG-based features whereas TCS-GM-L2 works better with pixel-based statistical features.

In the face clustering tasks (*AT & T*, *Umist*, *Faces96* and *LFW*) each instance is an image of a single person’s face and the task is to cluster the instances by faces. We represented each instance using HOG features extracted from the image in 9 orientations and varying patchsizes. Both TCS-GM-L2 and LMNN show competitive performance in this task. However, we believe that all datasets except LFW are highly contrived - the images on these other datasets were taken in ideal lighting and posing conditions. The

LFW dataset, on the other hand, represents a more *realistic* distribution of images as found on the web. On this dataset, TCS-GM-L2 works best with a 45.6% improvement.

In the speech domain, we tested on two datasets *Isolet*, *WSJ*. In *Isolet* the task is to cluster the instances by the content of the speech (more specifically the letter uttered) and in *WSJ* the task is to cluster by the speaker. The instances are represented using well known audio features such as MFCC's. On both datasets TCS-GM achieves the best performance. The results on *WSJ* particularly highlight the importance of having supervision with a 46% improvement over unsupervised GM.

Image, *Vowel* and *Leaves* are other popularly used classi-

fication datasets. The instances in *Image* and *Leaves* are pictures of outdoor scenes and leaves, whereas in *Vowel* the instances are various utterances of different vowels. On two out of the three datasets, TCS-GM achieves the best results.

To further validate our results, we conducted two-sided significance tests using paired t-test between the best-performing method against the rest of the methods on each dataset. The NMI on the 50 different restarts are considered as observed samples. The null hypothesis is that there is no significance difference between the methods. The results of the testing (Table 3) show that almost all the results are significant.

Table 4: The NMI of TCS-VM with other supervised and unsupervised methods on normalized data. The results of the significance tests between the best method against the other methods on each dataset is denoted by a † for significance at 1% level.

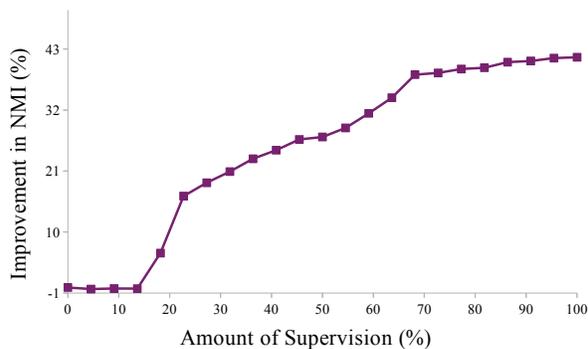

Figure 2: Effect of amount of supervision on the quality of clusters. We plot the improvement in NMI achieved by TSC-GM over baseline GM as we increase the number of training clusters.

5.2.1 PERFORMANCE OF vMF-BASED METHODS

Due to lack of space we present the results of vMF-based models only in the text domain. Normalization to a unit sphere has often shown to work very well for text data, especially vMF-based models have been particularly effective in generating good clusters (Banerjee et al., 2006). We compare the following vMF-based methods on text data,

1. **VM** A mixture of K vMF distributions with individual means and a single common concentration parameter. All parameters are estimated using EM algorithm. Note that this model like GM is unsupervised and cannot use supervision.
2. **TCS-VM** Our proposed TCS using vMF mixture model (section 3.2) and $\|A - I\|^2$ regularization, followed by VM on the transformed unlabeled data.

For data representation, we used the bag-of-words with ‘ltc’ term-weighting and svd-based dimension reduction to 30 dimensions, followed by a normalization to unit-sphere. The results are shown in Table 4. For an informative comparison we also included the results of the other methods - TCS-GM, TCS-GM-L2, LMNN, PCC, BP, CSP and GM. On all text datasets the proposed TCS-VM model performs best. In the complete set of results for all domains for normalized data (presented in the supplementary material), our

proposed TCS models achieve the best performance in 20 out of the 23 datasets.

5.3 EFFECT OF AMOUNT OF SUPERVISION

We analyze how the quality of clusters generated depend on the amount of supervision provided. We used a subset of the WSJ dataset with 25 training and 25 testing clusters for this task.

Figure 2 plots the improvement in NMI achieved by TCS-GM over baseline GM as we increase the number of training clusters. Initially there is no improvement in performance, but as training clusters increase, there is a gradual improvement in performance, until it reaches a saturation level. This shows that (a) there is some minimum amount of supervision needed to see any improvement (b) providing more supervision does not increase performance indefinitely but saturates at certain level. This kind of curve is typical of most machine learning algorithms.

6 CONCLUSION

In this paper we proposed a novel framework that can exploit supervision to generate *better* clustering of unlabeled data. By learning a common underlying transformation function, our framework is able to successfully generalize the observed clusters to discover new clusters that match user expectations. We explored two instantiations of our framework with Gaussian and von Mises-Fisher mixture models. For both the models we developed fast optimization algorithms to estimate the model parameters. Our extensive testing on 23 datasets provide strong empirical support in favour of our proposed framework. In future, we would like to adapt our framework to spectral clustering based methods.

Abstract

In this paper we study lifted inference for the Weighted First-Order Model Counting problem (WFOMC), which counts the assignments that satisfy a given sentence in first-order logic (FOL); it has applications in Statistical Relational Learning (SRL) and Probabilistic Databases (PDB). We present several results. First, we describe a lifted inference algorithm that generalizes prior approaches in SRL and PDB. Second, we provide a novel dichotomy result for a non-trivial fragment of FO CNF sentences, showing that for each sentence the WFOMC problem is either in PTIME or #P-hard in the size of the input domain; we prove that, in the first case our algorithm solves the WFOMC problem in PTIME, and in the second case it fails. Third, we present several properties of the algorithm. Finally, we discuss limitations of lifted inference for symmetric probabilistic databases (where the weights of ground literals depend only on the relation name, and not on the constants of the domain), and prove the impossibility of a dichotomy result for the complexity of probabilistic inference for the entire language FOL.

1 INTRODUCTION

Weighted model counting (WMC) is a problem at the core of many reasoning tasks. It is based on the model counting or #SAT task (Gomes et al., 2009), where the goal is to count assignments that satisfy a given logical sentence. WMC generalizes model counting by assigning a weight to each assignment, and computing the *sum of their weights*. WMC has many applications in AI and its importance is increasing. Most notably, it underlies state-of-the-art probabilistic inference algorithms for Bayesian networks (Darwiche, 2002; Sang et al., 2005; Chavira and Darwiche,

2008), relational Bayesian networks (Chavira et al., 2006) and probabilistic programs (Fierens et al., 2011).

This paper is concerned with weighted *first-order* model counting (WFOMC), where we sum the weights of assignments that satisfy a sentence in finite-domain first-order logic. Again, this reasoning task underlies efficient algorithms for probabilistic reasoning, this time for popular representations in statistical relational learning (SRL) (Getoor and Taskar, 2007), such as Markov logic networks (Van den Broeck et al., 2011; Gogate and Domingos, 2011) and probabilistic logic programs (Van den Broeck et al., 2014). Moreover, WFOMC uncovers a deep connection between AI and database research, where query evaluation in *probabilistic databases* (PDBs) (Suciu et al., 2011) essentially considers the same task. A PDB defines a probability, or weight, for every possible world, and each database query is a sentence encoding a set of worlds, whose combined probability we want to compute.

Early on, the disconnect between compact relational representations of uncertainty, and the intractability of inference at the ground, propositional level was noted, and efforts were made to exploit the relational structure for inference, using so-called *lifted inference* algorithms (Poole, 2003; Kersting, 2012). SRL and PDB algorithms for WFOMC all fall into this category. Despite these commonalities, there are also important differences. SRL has so far considered *symmetric* WFOMC problems, where relations of the same type are assumed to contribute equally to the probability of a world. This assumption holds for certain queries on SRL models, such as single marginals and partition functions, but fails for more complex conditional probability queries. These break lifted algorithms based on symmetric WFOMC (Van den Broeck and Darwiche, 2013). PDBs, on the other hand, have considered the *asymmetric* WFOMC setting from the start. While there are many semantics for PDBs, the most common models are tuple-independent PDBs, which assign each tuple a distinct probability, many tuples have probability zero, and no symmetries can be expected. However, current asymmetric WFOMC algorithms (Dalvi and Suciu, 2012) suffer from a major limitation of

their own, in that they can only count models of sentences in monotone disjunctive normal form (MDNF) (i.e., DNF without negation). Such sentences represent unions of conjunctive database queries (UCQ). WFOMC encodings of SRL models almost always fall outside this class.

The present work seeks to upgrade a well-known PDB algorithm for asymmetric WFOMC (Dalvi and Suciu, 2012) to the SRL setting, by enabling it to count models of arbitrary sentences in conjunctive normal form (CNF). This permits its use for lifted SRL inference with arbitrary soft or hard evidence, or equivalently, probabilistic database queries with negation. Our first contribution is this algorithm, which we call **Lift^R**, and is presented in Section 3.

Although **Lift^R** has clear practical merits, we are in fact motivated by fundamental theoretical questions. In the PDB setting, our algorithm is known to come with a sharp complexity guarantee, called the *dichotomy theorem* (Dalvi and Suciu, 2012). By only looking at the structure of the first-order sentence (i.e., the database query), the algorithm reports failure when the problem is #P-hard (in terms of data complexity), and otherwise guarantees to solve it in time polynomial in the domain (i.e., database) size. It can thus precisely classify MDNF sentences as being tractable or intractable for asymmetric WFOMC. Whereas several complexity results for symmetric WFOMC exist (Van den Broeck, 2011; Jaeger and Van den Broeck, 2012), the complexity of asymmetric WFOMC for SRL queries with evidence is still poorly understood. Our second and main contribution, presented in Section 4, is a *novel dichotomy result* over a small but non-trivial fragment of CNFs. We completely classify this class of problems as either computable in polynomial time or #P-hard. This represents a first step towards proving the following conjecture: **Lift^R** provides a dichotomy for asymmetric WFOMC on arbitrary CNF sentences, and therefore perfectly classifies all related SRL models as tractable or intractable for conditional queries.

As our third contribution, presented in Section 5, we illustrate the algorithm with examples that show its application to common probabilistic models. We discuss the capabilities of **Lift^R** that are not present in other lifted inference techniques.

As our fourth and final contribution, in Section 6, we discuss extensions of our algorithm to symmetric WFOMC, but also show the impossibility of a dichotomy result for arbitrary first-order logic sentences.

2 BACKGROUND

We begin by introducing the necessary background on relational logic and weighted model counting.

2.1 RELATIONAL LOGIC

Throughout this paper, we will work with the relational fragment of first-order logic (FOL), which we now briefly review. An *atom* $P(t_1, \dots, t_n)$ consists of predicate P/n of arity n followed by n arguments, which are either *constants* or *logical variables* $\{x, y, \dots\}$. A *literal* is an atom or its negation. A *formula* combines atoms with logical connectives and quantifiers \exists and \forall . A *substitution* $[a/x]$ replaces all occurrences of x by a . Its application to formula F is denoted $F[a/x]$. A formula is a sentence if each logical variable x is enclosed by a $\forall x$ or $\exists x$. A formula is *ground* if it contains no logical variables. A *clause* is a universally quantified disjunction of literals. A *term* is an existentially quantified conjunction of literals. A *CNF* is a conjunction of clauses, and a *DNF* is a disjunction of terms. A *monotone* CNF or DNF contains no negation symbols. As usual, we drop the universal quantifiers from the CNF syntax.

The semantics of sentences are defined in the usual way (Hinrichs and Genesereth, 2006). An interpretation, or world, I that satisfies sentence Δ is denoted by $I \models \Delta$, and represented as a set of literals. Our algorithm checks properties of sentences that are undecidable in general FOL, but decidable, with the following complexity, in the CNF fragment we investigate.

Theorem 2.1. (Sagiv and Yannakakis, 1980) (Farré et al., 2006) *Checking whether logical implication $Q \Rightarrow Q'$ or equivalence $Q \equiv Q'$ holds between two CNF sentences is Π_2^P -complete.*

2.2 WEIGHTED MODEL COUNTING

Weighted model counting was introduced as a propositional reasoning problem.

Definition 2.2 (WMC). *Given a propositional sentence Δ over literals \mathcal{L} , and a weight function $w : \mathcal{L} \rightarrow \mathbb{R}^{\geq 0}$, the weighted model count (WMC) is*

$$\text{WMC}(\Delta, w) = \sum_{I \models \Delta} \prod_{\ell \in I} w(\ell).$$

We will consider its generalization to *weighted first-order model counting* (WFOMC), where Δ is now a sentence in relational logic, and \mathcal{L} consists of all ground first-order literals for a given domain of constants.

The WFOMC task captures query answering in probabilistic database. Take for example the database

Prof(Arne) : 0.9 Prof(Charlie) : 0.1
 Student(Bob) : 0.5 Student(Charlie) : 0.8
 Advises(Arne, Bob) : 0.7 Advises(Bob, Charlie) : 0.1

and the UCQ (monotone DNF) query

$$Q = \exists x, \exists y, \text{Prof}(x) \wedge \text{Advises}(x, y) \wedge \text{Student}(y).$$

If we set $\Delta = Q$ and w to map each literal to its probability in the database, then our query answer is

$$\Pr(Q) = \text{WFOMC}(\Delta, w) = 0.9 \cdot 0.7 \cdot 0.5 = 0.315.$$

We refer to the general case above as *asymmetric* WFOMC, because it allows $w(\text{Prof}(\text{Anne}))$ to be different from $w(\text{Prof}(\text{Charlie}))$. We use *symmetric* WFOMC to refer to the special case where w simplifies into two weight functions w^*, \bar{w}^* that map *predicates* to weights, instead of literals, that is

$$w(\ell) = \begin{cases} w^*(P) & \text{when } \ell \text{ is of the form } P(c) \\ \bar{w}^*(P) & \text{when } \ell \text{ is of the form } \neg P(c) \end{cases}$$

Symmetric WFOMC no longer directly captures PDBs. Yet it can still encode many SRL models, including parfactor graphs (Poole, 2003), Markov logic networks (MLNs) (Richardson and Domingos, 2006) and probabilistic logic programs (De Raedt et al., 2008). We refer to (Van den Broeck et al., 2014) for the details, and show here the following example MLN.

$$2 \quad \text{Prof}(x) \wedge \text{Advises}(x, y) \Rightarrow \text{Student}(y)$$

It states that the probability of a world increases by a factor e^2 with every pair of people x, y for which the formula holds. Its WFOMC encoding has Δ equal to

$$\forall x, \forall y, \text{F}(x, y) \Leftrightarrow [\text{Prof}(x) \wedge \text{Advises}(x, y) \Rightarrow \text{Student}(y)]$$

and weight functions w^*, \bar{w}^* such that $w^*(\text{F}) = e^2$ and all other predicates map to 1.

Answering an SRL query Q given evidence E , that is, $\Pr(Q|E)$, using a symmetric WFOMC encoding, generally requires solving two WFOMC tasks:

$$\Pr(Q|E) = \frac{\text{WFOMC}(Q \wedge E \wedge \Delta, w)}{\text{WFOMC}(E \wedge \Delta, w)}$$

Symmetric WFOMC problems are strictly more tractable than asymmetric ones. We postpone the discussion of this observation to Section 5, but already note that all theories Δ with up to two logical variables per formula support *domain-lifted* inference (Van den Broeck, 2011), which means that any WFOMC query runs in time polynomial in the domain size (i.e, number of constants). For conditional probability queries, even though fixed-parameter complexity bounds exist that use symmetric WFOMC (Van den Broeck and Darwiche, 2013), the actual underlying reasoning task is asymmetric WFOMC, whose complexity we investigate for the first time.

Finally, we make three simplifying observations. First, SRL query Q and evidence E typically assign values to random variables. This means that the query and evidence can be absorbed into the asymmetric weight function, by setting the weight of literals disagreeing with Q or E to

zero. We hence compute:

$$\Pr(Q|E) = \frac{\text{WFOMC}(\Delta, w_{Q \wedge E})}{\text{WFOMC}(\Delta, w_E)}$$

This means that our complexity analysis for a given encoding Δ applies to both numerator and denominator for arbitrary Q and E , and that polytime WFOMC for Δ implies polytime $\Pr(Q|E)$ computation. The converse is not true, since it is possible that both WFOMC calls are #P-hard, but their ratio is in PTIME. Second, we will from now on assume that Δ is in CNF. The WFOMC encoding of many SRL formalisms is already in CNF, or can be reduced to it (Van den Broeck et al., 2014). For PDB queries that are in monotone DNF, we can simply compute $\Pr(Q) = 1 - \Pr(\neg Q)$, which reduces to WFOMC on a CNF. Moreover, by adjusting the probabilities in the PDB, this CNF can also be made monotone. Third, we will assume that $w(\ell) = 1 - w(\neg\ell)$, which can always be achieved by normalizing the weights.

Under these assumptions, we can simply refer to $\text{WFOMC}(Q, w)$ as $\Pr(Q)$, to Q as the CNF query, to $w(\ell)$ as the probability $\Pr(\ell)$, and to the entire weight function w as the PDB. This is in agreement with notation in the PDB literature.

3 ALGORITHM Lift^R

We present here the lifted algorithm Lift^R (pronounced *lift-ER*), which, given a CNF formula Q computes $\Pr(Q)$ in polynomial time in the size of the PDB, or fails. In the next section we provide some evidence for its completeness: under certain assumptions, if Lift^R fails on formula Q , then computing $\Pr(Q)$ is #P-hard in the PDB size.

3.1 DEFINITIONS

An *implicate* of Q is some clause C s.t. the logical implication $Q \Rightarrow C$ holds. C is a *prime implicate* if there is no other implicate C' s.t. $C' \Rightarrow C$.

A *connected component* of a clause C is a minimal subset of its atoms that have no logical variables in common with the rest of the clause. If some prime implicate C has more than one connected component, then we can write it as:

$$C = D_1 \vee D_2 \vee \dots \vee D_m$$

where each D_i is a clause with distinct variables. Applying distributivity, we write Q in *union-CNF* form:

$$Q = Q_1 \vee Q_2 \vee \dots \vee Q_m$$

where each Q_i is a CNF with distinct variables.

We check for disconnected prime implicates $D_1 \vee D_2$ where both D_1 and D_2 subsume some clause of Q . Intuitively, this means that when we apply inclusion/exclusion to the union-CNF, the resulting queries are simpler. The search

for D_1, D_2 can proceed using some standard inference algorithm, e.g. resolution. By Theorem 2.1, this problem is Π_2^p -complete in the size of the query Q , but independent of the PDB size.

A set of *separator variables* for a query $Q = \bigwedge_{i=1}^k C_i$ is a set of variables $x_i, i = 1, k$ such that, (a) for each clause C_i, x_i occurs in all atoms of C_i , and (b) any two atoms (not necessarily in the same clause) referring to the same relation R have their separator variable on the same position.

3.2 PREPROCESSING

We start by transforming Q (and PDB) such that:

1. No constants occur in Q .
2. If all the variables in Q are x_1, x_2, \dots, x_k , then every relational atom in Q (positive or negated) is of the form $R(x_{i_1}, x_{i_2}, \dots)$ such that $i_1 < i_2 < \dots$

Condition (1) can be enforced by *shattering* Q w.r.t. its variables. Condition (2) can be enforced by modifying both the query Q and the database, in a process called *ranking* and described in the appendix. Here, we illustrate ranking on an example. Consider the query:

$$Q = (R(x, y) \vee S(x, y)) \wedge (\neg R(x, y) \vee \neg S(y, x))$$

Define $R_1(x, y) \equiv R(x, y) \wedge (x < y)$; $R_2(x) \equiv R(x, x)$; $R_3(y, x) \equiv R(x, y) \wedge (x > y)$. Define similarly S_1, S_2, S_3 . Given a PDB with relations R, S , we define a new PDB' over the six relations by setting $\Pr(R_1(a, b)) = \Pr(R(a, b))$ when $a < b$, $\Pr(R_1(a, b)) = 0$ when $a > b$, $\Pr(R_2(a)) = \Pr(R(a, a))$, etc. Then, the query Q over PDB is equivalent to the following query over PDB':

$$\begin{aligned} & (R_1(x, y) \vee S_1(x, y)) \wedge (\neg R_1(x, y) \vee \neg S_3(x, y)) \wedge \\ & (R_2(x) \vee S_2(x)) \wedge (\neg R_2(x) \vee \neg S_2(x)) \wedge \\ & (R_3(x, y) \vee S_3(x, y)) \wedge (\neg R_3(x, y) \vee \neg S_1(x, y)) \end{aligned}$$

3.3 ALGORITHM DESCRIPTION

Algorithm **Lift^R**, given in Figure 1, proceeds recursively on the structure of the CNF query Q . When it reaches ground atoms, it simply looks up their probabilities in the PDB. Otherwise, it performs the following sequence of steps.

First, it tries to express Q as a union-CNF. If it succeeds, and if the union can be partitioned into two sets that do not share any relational symbols, $Q = Q_1 \vee Q_2$, then it applies a *Decomposable Disjunction*:

$$\Pr(Q) = 1 - (1 - \Pr(Q_1))(1 - \Pr(Q_2))$$

Otherwise, it applies the *Inclusion/Exclusion* formula:

$$\Pr(Q) = - \sum_{s \subseteq [m]} (-1)^{|s|} \Pr(\bigwedge_{i \in s} Q_i)$$

However, before computing the recursive probabilities, our algorithm first checks for equivalent expressions, i.e. it

Algorithm **Lift^R**

Input: Ranked and shattered query Q
 Probabilistic DB with domain D

Output: $\Pr(Q)$

- 1 Step 0: If Q is a single ground literal ℓ , return its probability $\Pr(\ell)$ in PDB
 - 2 Step 1: Write Q as a union-CNF: $Q = Q_1 \vee Q_2 \vee \dots \vee Q_m$
 - 3 Step 2: If $m > 1$ and Q can be partitioned into two sets $Q = Q' \vee Q''$ with disjoint relation symbols, return $1 - (1 - \Pr(Q_1)) \cdot (1 - \Pr(Q_2))$
 - 4 */* Decomposable Disjunction */*
 - 5 Step 3: If Q cannot be partitioned, return $\sum_{s \subseteq [m]} (-1)^{|s|} \Pr(\bigwedge_{i \in s} Q_i)$
 - 6 */* Inclusion/Exclusion - perform cancellations before recursion */*
 - 7 Step 4: Write Q in CNF: $Q = C_1 \wedge C_2 \wedge \dots \wedge C_k$
 - 8 Step 5: If $k > 1$, and Q can be partitioned into two sets $Q = Q' \wedge Q''$ with disjoint relation symbols, return $\Pr(Q_1) \cdot \Pr(Q_2)$
 - 9 */* Decomposable Conjunction */*
 - 10 Step 6: If Q has a separator variable, return $\prod_{a \in D} \Pr(C_1[a/x_1] \wedge \dots \wedge C_k[a/x_k])$
 - 11 */* Decomposable Universal Quantifier */*
 - 12 Otherwise **FAIL**
-

Figure 1: Algorithm for Computing $\Pr(Q)$

checks for terms s_1, s_2 in the inclusion/exclusion formula such that $\bigwedge_{i \in s_1} Q_i \equiv \bigwedge_{i \in s_2} Q_i$: in that case, these terms either cancel out, or add up (and need be computed only once). We show in Section 5.4 the critical role that the cancellation step plays for the completeness of the algorithm. To check cancellations, the algorithm needs to check for equivalent CNF expressions. This can be done using some standard inference algorithm (recall from Theorem 2.1 that this problem is Π_2^p -complete in the size of the CNF expression).

If neither of the above steps apply, then the algorithm checks if Q can be partitioned into two sets of clauses that do not share any common relation symbols. In that case, $Q = Q' \wedge Q''$, and its probability is computed using a *Decomposable Conjunction*:

$$\Pr(Q) = \Pr(Q') \cdot \Pr(Q'')$$

Finally, if none of the above cases apply to the CNF query $Q = C_1 \wedge C_2 \wedge \dots \wedge C_k$, then the algorithm tries to find a set of separator variables x_1, \dots, x_k (one for each clause). If it finds them, then the probability is given by a *Decomposable Universal Quantifier*:

$$\Pr(Q) = \prod_{a \in \text{Domain}} \Pr(C_1[a/x_1] \wedge \dots \wedge C_k[a/x_k])$$

We prove our first main result:

Theorem 3.1. *One of the following holds: (1) either **Lift^R** fails on Q , or (2) for any domain size n and a PDB consisting of probabilities for the ground tuples, **Lift^R** computes*

$\Pr(Q)$ in polynomial time in n .

Proof. (Sketch) The only step of the algorithm that depends on the domain size n is the decomposable universal quantifier step; this also reduces by 1 the arity of every relation symbol, since it substitutes it by the same constant a . Therefore, the algorithm runs in time $O(n^k)$, where k is the largest arity of any relation symbol. We note that the constant behind $O(\dots)$ may be exponential in the size of the query Q . \square

4 MAIN COMPLEXITY RESULT

In this section we describe our main technical result of the paper: that the algorithm is complete when restricted to a certain class of CNF queries.

We first review a prior result, to put ours in perspective. (Dalvi and Suciu, 2012) define an algorithm for Monotone DNF (called Unions Of Conjunctive Queries), which can be adapted to Monotone CNF; that adaptation is equivalent to **Lift^R** restricted to Monotone CNF queries. (Dalvi and Suciu, 2012) prove:

Theorem 4.1. *If algorithm **Lift^R** FAILS on a Monotone CNF query Q , then computing $\Pr(Q)$ is #P-hard.*

However, the inclusion of negations in our query language increases significantly the difficulty of analyzing query complexities. Our major technical result of the paper extends Theorem 4.1 to a class of CNF queries with negation.

Define a *Type-1* query to be a CNF formula where each clause has at most two variables denoted x, y , and each atom is of one of the following three kinds:

- Unary symbols $R_1(x), R_2(x), R_3(x), \dots$
- Binary symbols $S_1(x, y), S_2(x, y), \dots$
- Unary symbols $T_1(y), T_2(y), \dots$

or the negation of these symbols.

Our main result is:

Theorem 4.2. *For every Type-1 query Q , if algorithm **Lift^R** FAILS then computing $\Pr(Q)$ is #P-hard.*

The proof is a significant extension of the techniques used by (Dalvi and Suciu, 2012) to prove Theorem 4.1; we give a proof sketch in Section 7 and include the full proof in the appendix.

5 PROPERTIES OF **Lift^R**

We now describe several properties of **Lift^R**, and the relationship to other lifted inference formalisms.

5.1 NEGATIONS CAN LOWER THE COMPLEXITY

The presence of negations can lower a query’s complexity, and our algorithm exploits this. To see this, consider the following query

$$Q = (\text{Tweets}(x) \vee \neg \text{Follows}(x, y)) \\ \wedge (\text{Follows}(x, y) \vee \neg \text{Leader}(y))$$

The query says that if x follows anyone then x tweets, and that everybody follows the leader¹.

Our goal is to compute the probability $\Pr(Q)$, knowing the probabilities of all atoms in the domain. We note that the two clauses are dependent (since both refer to the relation `Follow`), hence we cannot simply multiply their probabilities; in fact, we will see that if we remove all negations, then the resulting query is #P-hard; the algorithm described by (Dalvi and Suciu, 2012) would immediately get stuck on this query. Instead, **Lift^R** takes advantage of the negation, by first computing the prime implicate:

$$\text{Tweets}(x) \vee \neg \text{Leader}(y)$$

which is a disconnected clause (the two literals use disjoint logical variables, x and y respectively). After applying distributivity we obtain:

$$Q \equiv (Q \wedge (\text{Tweets}(x))) \vee (Q \wedge (\neg \text{Leader}(y))) \\ \equiv Q_1 \vee Q_2$$

and **Lift^R** applies the inclusion-exclusion formula:

$$\Pr(Q) = \Pr(Q_1) + \Pr(Q_2) - \Pr(Q_1 \wedge Q_2)$$

After simplifying the three queries, they become:

$$Q_1 = (\text{Follows}(x, y) \vee \neg \text{Leader}(y)) \\ \wedge (\text{Tweets}(x))$$

$$Q_2 = (\text{Tweets}(x) \vee \neg \text{Follows}(x, y)) \\ \wedge (\neg \text{Leader}(y))$$

$$Q_1 \wedge Q_2 = (\text{Tweets}(x)) \wedge (\neg \text{Leader}(y))$$

The probability of Q_1 can now be obtained by multiplying the probabilities of its two clauses; same for the other two queries. As a consequence, our algorithm computes the probability $\Pr(Q)$ in polynomial time in the size of the domain and the PDB.

If we remove all negations from Q and rename the predicates we get the following query:

$$h_1 = (R(x) \vee S(x, y)) \wedge (S(x, y) \vee T(y))$$

(Dalvi and Suciu, 2012) proved that computing the probability of h_1 is #P-hard in the size of the PDB. Thus, the query Q with negation is *easy*, while h_1 is *hard*, and our algorithm takes advantage of this by applying resolution.

¹To see this, rewrite the query as $(\text{Follows}(x, y) \Rightarrow \text{Tweets}(x)) \wedge (\text{Leader}(y) \Rightarrow \text{Follows}(x, y))$.

5.2 ASYMMETRIC WEIGHTS CAN INCREASE THE COMPLEXITY

(Van den Broeck, 2011) has proven that any query with at most two logical variables per clause is domain-liftable. Recall that this means that one can compute its probability in PTIME in the size of the domain, in the symmetric case, when all tuples in a relation have the same probability. However, queries with at most two logical variables per clause can become #P-hard when computed over asymmetric probabilities, as witnessed by the query h_1 above.

5.3 COMPARISON WITH PRIOR LIFTED FO-CIRCUITS

(Van den Broeck et al., 2011; Van den Broeck, 2013) introduce FO d-DNNF circuits, to compute symmetric WFOMC problems. An FO d-DNNF is a circuit whose nodes are one of the following: decomposable conjunction ($Q_1 \wedge Q_2$ where Q_1, Q_2 do not share any common predicate symbols), deterministic-disjunction ($Q_1 \vee Q_2$ where $Q_1 \wedge Q_2 \equiv \text{false}$), inclusion-exclusion, decomposable universal quantifier (a type of $\forall x, Q(x)$), and deterministic automorphic existential quantifier. The latter is an operation that is specific only to structures with symmetric weights, and therefore does not apply to our setting. We prove that our algorithm can compute all formulas that admit an FO d-DNNF circuit.

Fact 5.1. *If Q admits an FO d-DNNF without a deterministic automorphic existential quantifier, then Lift^R computes $\Pr(Q)$ in PTIME in the size of the PDB.*

The proof is immediate by noting that all other node types in the FO d-DNNF have a corresponding step in Lift^R , except for deterministic disjunction, which our algorithm computes using inclusion-exclusion: $\Pr(Q_1 \vee Q_2) = \Pr(Q_1) + \Pr(Q_2) - \Pr(Q_1 \wedge Q_2) = \Pr(Q_1) + \Pr(Q_2)$ because $Q_1 \wedge Q_2 \equiv \text{false}$.

5.4 CANCELLATIONS IN INCLUSION/EXCLUSION

We now look at a more complex query. First, let us denote four simple queries:

$$\begin{aligned} q_0 &= (R(x_0) \vee S_1(x_0, y_0)) \\ q_1 &= (S_1(x_1, y_1) \vee S_2(x_1, y_1)) \\ q_2 &= (S_2(x_2, y_2) \vee S_3(x_2, y_2)) \\ q_3 &= (S_3(x_3, y_3) \vee T(y_3)) \end{aligned}$$

(Dalvi and Suciu, 2012) proved that their conjunction, i.e. the query $h_3 = q_0 \wedge q_1 \wedge q_2 \wedge q_3$, is #P-hard in data complexity. Instead of h_3 , consider:

$$Q_W = (q_0 \vee q_1) \wedge (q_0 \vee q_3) \wedge (q_2 \vee q_3)$$

There are three clauses sharing relation symbols, hence we cannot apply a decomposable conjunction. However, each

clause is disconnected, for example q_0 and q_1 do not share logical variables, and we can thus write Q_W as a disjunction. After removing redundant terms:

$$Q_W = (q_0 \wedge q_2) \vee (q_0 \wedge q_3) \vee (q_1 \wedge q_3)$$

Our algorithm applies the inclusion/exclusion formula:

$$\begin{aligned} \Pr(Q_W) &= \Pr(q_0 \wedge q_2) + \Pr(q_0 \wedge q_3) + \Pr(q_1 \wedge q_3) \\ &\quad - \Pr(q_0 \wedge q_2 \wedge q_3) - \Pr(q_0 \wedge q_1 \wedge q_3) - \Pr(q_0 \wedge \dots \wedge q_3) \\ &\quad + \Pr(q_0 \wedge \dots \wedge q_3) \end{aligned}$$

At this point our algorithm performs an important step: it cancels out the last two terms of the inclusion/exclusion formula. Without this key step, no algorithm could compute the query in PTIME, because the last two terms are precisely h_3 , which is #P-hard. To perform the cancellation the algorithm needs to first check which FOL formulas are equivalent, which, as we have seen, is decidable for our language (Theorem 2.1). Once the equivalent formulas are detected, the resulting expressions can be organized in a lattice, as shown in Figure 2, and the coefficient of each term in the inclusion-exclusion formula is precisely the lattice's Möbius function (Stanley, 1997).

6 EXTENSIONS AND LIMITATIONS

We describe here an extension of Lift^R to symmetric WFOMC, and also prove that a complete characterization of the complexity of all FOL queries is impossible.

6.1 SYMMETRIC WFOMC

Many applications of SRL require weighted model counting for FOL formulas over PDBs where the probabilities are associated to relations rather than individual tuples. That is, $\text{Friend}(a, b)$ has the same probability, independently of the constants a, b in the domain. In that symmetric WFOMC case, the model has a large number of symmetries (since the probabilities are invariant under permutations of constants), and lifted inference algorithms may further exploit these symmetries. (Van den Broeck, 2013) employ one operator that is specific to symmetric probabilities, called *atom counting*, which is applied to a unary predicate $R(x)$ and iterates over all possible worlds of that predicate. Although there are 2^n possible worlds for R , by conditioning on any world, the probability will depend only on the cardinality k of R , because of the symmetries. Therefore, the system iterates over $k = 0, n$, and adds the conditional probabilities multiplied by $\binom{n}{k}$. For example, consider the following query:

$$H = (\neg R(x) \vee S(x, y) \vee \neg T(y)) \quad (1)$$

Computing the probabilities of this query is #P-hard (Theorem 4.2). However, if all tuples $R(a)$ have the same probability $r \in [0, 1]$, and similarly tuples in S, T have proba-

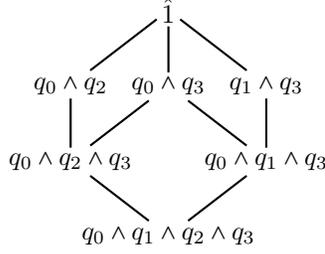

Figure 2: Lattice for Q_w . The bottom query is #P-hard, yet all terms in the inclusion/exclusion formula that contain this term cancel out, and $\Pr(Q_w)$ is computable in PTIME.

bilities s, t , then one can check that²

$$\Pr(H) = \sum_{k,l=0,n} r^k \cdot (1-r)^{n-k} \cdot t^l \cdot (1-t)^{n-l} \cdot (1-s^{kl})$$

Denote **Sym-Lift^R** the extension of **Lift^R** with a deterministic automorphic existential quantifier operator. The question is whether this algorithm is complete for computing the probabilities of queries over PDBs with symmetric probabilities. Folklore belief was that this existential quantifier operator was the only operator required to exploit the extra symmetries available in PDBs with symmetric probabilities. For example, all queries in (Van den Broeck et al., 2011) that can be computed in PTIME over symmetric PDBs have the property that, if one removes all unary predicates from the query, then the residual query can be computed in PTIME over asymmetric PDBs.

We answer this question in the negative. Consider the following query:

$$Q = (S(x_1, y_1) \vee \neg S(x_1, y_2) \vee \neg S(x_2, y_1) \vee S(x_2, y_2))$$

Here, we interpret $S(x, y)$ as a *typed relation*, where the values x and y are from two disjoint domains, of sizes n_1, n_2 respectively, in other words, $S \subseteq [n_1] \times [n_2]$.

Theorem 6.1. *We have that*

- $\Pr(Q)$ can be computed in time polynomial in the size of a symmetric PDB with probability p as $\Pr(Q) = f(n_1, n_2) + g(n_1, n_2)$ where:

$$f(0, n_2) = 1 \quad f(n_1, n_2) = \sum_{k=1}^{n_1} p^{kn_2} g(n_1 - k, n_2)$$

$$g(n_1, 0) = 1 \quad g(n_1, n_2) = \sum_{\ell=1}^{n_2} (1-p)^{n_1\ell} f(n_1, n_2 - \ell)$$

- **Sym-Lift^R** fails to compute Q .

The theorem shows that new operators will be required for symmetric WFOMC. We note that it is currently open whether computing $\Pr(Q)$ is #P-hard in the case of asymmetric WFOMC.

²Conditioned on $|R| = k$ and $|T| = l$, the query is true if S contains at least one pair $(a, b) \in R \times T$.

Proof. Denote D_x, D_y the domains of the variables x and y . Fix a relation $S \subseteq D_1 \times D_2$. We will denote $a_1, a_2, \dots \in D_1$ elements from the domain of the variable x , and $b_1, b_2, \dots \in D_2$ elements from the domain of the variable y . For any a, b , define $a < b$ if $(a, b) \in S$, and $a > b$ if $(a, b) \notin S$; in the latter case we also write $b < a$. Then, (1) for any a, b , either $a < b$ or $b < a$, (2) $<$ is a partial order on the disjoint union of the domains D_1 and D_2 iff S satisfies the query Q . The first property is immediate. To prove the second property, notice that Q states that there is no cycle of length 4: $x_1 < y_2 < x_2 < y_1 < x_1$. By repeatedly applying resolution between Q with itself, we derive that there are no cycles of length 6, 8, 10, etc. Therefore, $<$ is transitive, hence a partial order. Any finite, partially ordered set has a minimal element, i.e. there exists z s.t. $\forall x, x \not< z$. Let Z be the set of all minimal elements, and denote $X = D_1 \cap Z$ and $Y = D_2 \cap Z$. Then exactly one of X or Y is non-empty, because if both were non-empty then, for $a \in X$ and $b \in Y$ we have either $a < b$ or $a > b$ contradicting their minimality. Assuming $X \neq \emptyset$, we have (a) for all $a \in X$ and $b \in D_2$, $(a, b) \in S$, and (b) Q is true on the relation $S' = (D_1 - X) \times D_2$. This justifies the recurrence formula for $\Pr(Q)$. \square

6.2 THE COMPLEXITY OF ARBITRARY FOL QUERIES

We conjecture that, over asymmetric probabilities (asymmetric WFOMC), our algorithm is complete, in the sense that whenever it fails on a query, then the query is provably #P-hard. Notice that **Lift^R** applies only to a fragment of FOL, namely to CNF formulas without function symbols, and where all variables are universally quantified. We present here an impossibility result showing that a complete algorithm cannot exist for general FOL queries. We use for that a classic result by Trakhtenbrot (Libkin, 2004):

Theorem 6.2 (Finite satisfiability). *The problem: “given a FOL sentence Φ , check whether there exists a finite model for Φ ” is undecidable.*

From here we obtain:

Theorem 6.3. *There exists no algorithm that, given any FOL sentence Q checks whether $\Pr(Q)$ can be computed*

in PTIME in the asymmetric PDB size.

Proof. By reduction from the finite satisfiability problem. Fix the hard query H in Eq.(1), for which the counting problem is #P-hard. Recall that H uses the symbols R, S, T . Let Φ be any formula over a disjoint relational vocabulary (i.e. it doesn't use R, S, T). We will construct a formula Q , such that computing $\Pr(Q)$ is in PTIME iff Φ is unsatisfiable in the finite: this proves the theorem. To construct Q , first we modify Φ as follows. Let $P(x)$ be another fresh, unary relational symbol. Rewrite Φ into Φ' as follows: replacing every $(\exists x.\Gamma)$ with $(\exists x.P(x) \wedge \Gamma)$ and every $(\forall x.\Gamma)$ with $(\forall x.P(x) \Rightarrow \Gamma)$ (this is not equivalent to the guarded fragment of FOL); leave the rest of the formula unchanged. Intuitively, Φ' checks if Φ is true on the substructure defined by the domain elements that satisfy P . More precisely: for any database instance I , Φ' is true on I iff Φ is true on the substructure of I defined by the domain elements that satisfy $P(x)$. Define the query $Q = (H \wedge \Phi')$. We now prove the claim.

If Φ is unsatisfiable then so is Φ' , and therefore $\Pr(Q) = 0$ is trivially computable in PTIME.

If Φ is satisfiable, then fix any deterministic database instance I that satisfies Φ ; notice that I is deterministic, and $I \models \Phi$. Let J be any probabilistic instance over the vocabulary for H over a domain disjoint from I . Define $P(x)$ as follows: $P(a)$ is true for all domain elements $a \in I$, and $P(b)$ is false for all domain elements $b \in J$. Consider now the probabilistic database $I \cup J$. (Thus, $P(x)$ is also deterministic, and selects the substructure I from $I \cup J$; therefore, Φ' is true in $I \cup J$.) We have $\Pr(Q) = \Pr(H \wedge \Phi') = \Pr(H)$, because Φ' is true on $I \cup J$. Therefore, computing $\Pr(Q)$ is #P-hard. Notice the role of P : while I satisfies Φ , it is not necessarily the case that $I \cup J$ satisfies Φ . However, by our construction we have ensured that $I \cup J$ satisfies Φ' . \square

7 PROOF OF THEOREM 4.2

The proof of Theorem 4.2 is based on a reduction from the #PP2-CNF problem, which is defined as follows. Given two disjoint sets of Boolean variables X_1, \dots, X_n and Y_1, \dots, Y_n and a bipartite graph $E \subseteq [n] \times [n]$, count the number of satisfying truth assignments $\#\Phi$ to the formula: $\Phi = \bigwedge_{(i,j) \in E} (X_i \vee Y_j)$. (Provan and Ball, 1983) have shown that this problem is #P-hard.

More precisely, we prove the following: given any Type-1 query Q on which the algorithm **Lift^R** fails, we can reduce the #PP2-CNF problem to computing $\Pr(Q)$ on a PDB with domain size n . The reduction consists of a combinatorial part (the construction of certain gadgets), and an algebraic part, which makes novel use of the concepts of algebraic independence (Yu, 1995) and annihilating polynomials (Kayal, 2009). We include the latter in the appendix,

and only illustrate here the former on a particular query of Type-1.

We illustrate the combinatorial part of the proof on the following query Q :

$$(R(x) \vee \neg S(x, y) \vee T(y)) \wedge (\neg R(x) \vee S(x, y) \vee \neg T(y))$$

To reduce Φ to the problem of computing $\Pr(Q)$, we construct a structure with unary predicates R and T and binary predicate S , with active domain $[n]$.

We define the tuple probabilities as follows. Letting $x, y, a, b \in (0, 1)$ be four numbers that will be specified later, we define:

$$\begin{aligned} \Pr(R(i)) &= x \\ \Pr(T(j)) &= y \\ \Pr(S(i, j)) &= \begin{cases} a & \text{if } (i, j) \in E \\ b & \text{if } (i, j) \notin E \end{cases} \end{aligned}$$

Note this PDB does not have symmetric probabilities: in fact, over structures with symmetric probabilities one can compute $\Pr(Q)$ in PTIME.

Let θ denote a valuation of the variables in Φ . Let E_θ denote the event $\forall i.(R(i) = \text{true} \iff \theta(X_i) = \text{true}) \wedge \forall j.(T(j) = \text{true} \iff \theta(Y_j) = \text{true})$.

E_θ completely fixes the unary predicates R and T and leaves S unspecified. Given E_θ , each Boolean variable corresponding to some $S(x, y)$ is now independent of every other $S(x', y')$. In general, given an assignment of $R(i)$ and $T(j)$, we examine the four formulas that define the probability that the query is true on (i, j) : $F_1 = Q[R(i) = 0, T(j) = 0]$, $F_2 = Q[R(i) = 0, T(j) = 1]$, $F_3 = Q[R(i) = 1, T(j) = 0]$, $F_4 = Q[R(i) = 1, T(j) = 1]$.

For Q , F_1, F_2, F_3, F_4 are as follows:

$$F_1 = \neg S(i, j) \quad F_2 = F_3 = \text{true} \quad F_4 = S(i, j)$$

Denote f_1, f_2, f_3, f_4 the arithmetization of these Boolean formulas:

$$\begin{aligned} f_1 &= \begin{cases} 1 - a & \text{if } (i, j) \in E \\ 1 - b & \text{if } (i, j) \notin E \end{cases} \\ f_4 &= \begin{cases} a & \text{if } (i, j) \in E \\ b & \text{if } (i, j) \notin E \end{cases} \end{aligned}$$

Note that $f_2 = f_3 = 1$ and do not change $\Pr(Q)$.

Define the parameters k, l, p, q of E_θ as k = number of i 's s.t. $R(i) = \text{true}$, l = number of j 's s.t. $T(j) = \text{true}$, p = number of $(i, j) \in E$ s.t. $R(i) = T(j) = \text{true}$, q = number of $(i, j) \in E$ s.t. $R(i) = T(j) = \text{false}$.

Let $N(k, l, p, q)$ = the number of θ 's that have parameters k, l, p, q . If we knew all $(n+1)^2(m+1)^2$ values of $N(k, l, p, q)$, we could recover $\#\Phi$ by summing over $N(k, l, p, q)$ where $q = 0$. That is, $\#\Phi = \sum_{k, l, p} N(k, l, p, 0)$.

We now describe how to solve for $N(k, l, p, q)$, completing the hardness proof for $\Pr(Q)$.

We have $\Pr(E_\theta) = x^k(1-x)^{n-k}y^l(1-y)^{n-l}$ and $\Pr(Q|E_\theta) = a^p(1-a)^q b^{kl-p}(1-b)^{(n-k)(n-l)-q}$. Combined, these give the following expression for $\Pr(Q)$:

$$\begin{aligned} \Pr(Q) &= \sum_{\theta} \Pr(Q|E_\theta) \Pr(E_\theta) \\ &= (1-b)^{n^2} (1-x)^n (1-y)^n \sum_{k,l,p,q} T \end{aligned} \quad (1)$$

where:

$$\begin{aligned} T &= N(k, l, p, q) * (a/b)^p [(1-a)/(1-b)]^q \\ &\quad [x/(1-b)^n (1-x)]^k [y/(1-b)^n \\ &\quad (1-y)]^l [b(1-b)]^{kl} \\ &= N(k, l, p, q) * A^p B^q X^k Y^l C^{kl} \end{aligned} \quad (2)$$

Equations (1) and (2) express $\Pr(Q)$ as a polynomial in X, Y, A, B, C with unknown coefficients $N(k, l, p, q)$. Our reduction is the following: we choose $(n+1)^2(m+1)^2$ values for the four parameters $x, y, a, b \in (0, 1)$, consult an oracle for $\Pr(Q)$ for these settings of the parameters, then solve a linear system of $(n+1)^2(m+1)^2$ equations in the unknowns $N(k, l, p, q)$. The crux of the proof consists of showing that the matrix of the system is non-singular: this is far from trivial, in fact had we started from a PTIME query Q then the system *would* be singular. Our proof consists of two steps (1) prove that we can choose X, Y, A, B independently, in other words that the mapping $(x, y, a, b) \mapsto (X, Y, A, B)$ is locally invertible (has a non-zero Jacobian), and (2) prove that there exists a choice of $(n+1)^2(m+1)^2$ values for (X, Y, A, B) such that the matrix of the system is non-singular: then, by (1) it follows that we can find $(n+1)^2(m+1)^2$ values for (x, y, a, b) that make the matrix non-singular, completing the proof. For our particular example, Part (1) can be verified by direct computations (see Section A.3); for general queries this requires Section A.12. Part (2) for this query is almost as general as for any query and we show it in Section A.2.

8 RELATED WORK

The algorithm and complexity results of (Dalvi and Suciu, 2012), which apply to positive queries, served as the starting point for our investigation of asymmetric WFOMC with negation. See (Suciu et al., 2011) for more background on their work. The tuple-independence assumption of PDBs presents a natural method for modeling asymmetric WFOMC. Existing approaches for PDBs can express complicated correlations (Jha et al., 2010; Jha and Suciu, 2012) but only consider queries without negation.

Close in spirit to the goals of our work are (Van den Broeck, 2011) and (Jaeger and Van den Broeck, 2012). They introduce a formal definition of lifted inference and describe a

powerful knowledge compilation technique for WFOMC. Their completeness results for first-order knowledge compilation on a variety of query classes motivate our exploration of the complexity of lifted inference. (Cozman and Polastro, 2009) analyze the complexity of probabilistic description logics.

Other investigations of evidence in lifted inference include (Van den Broeck and Davis, 2012), who allow arbitrary hard evidence on unary relations, (Bui et al., 2012), who allow asymmetric soft evidence on a single unary relation, and (Van den Broeck and Darwiche, 2013), who allow evidence of bounded Boolean rank. Our model allows entirely asymmetric probabilities and evidence.

9 CONCLUSION

Our first contribution is the algorithm **Lift^R** for counting models of arbitrary CNF sentences over asymmetric probabilistic structures. Second, we prove a novel dichotomy result that completely classifies a subclass of CNFs as either PTIME or #P-hard. Third, we describe capabilities of **Lift^R** not present in prior lifted inference techniques. Our final contribution is an extension of our algorithm to symmetric WFOMC and a discussion of the impossibility of establishing a dichotomy for all first-order logic sentences.

Abstract

Interactive learning deals with the problem of learning and solving tasks using human instructions. It is common in human-robot interaction, tutoring systems, and in human-computer interfaces such as brain-computer ones. In most cases, learning these tasks is possible because the signals are predefined or an ad-hoc calibration procedure allows to map signals to specific meanings. In this paper, we address the problem of simultaneously solving a task under human feedback and learning the associated meanings of the feedback signals. This has important practical application since the user can start controlling a device from scratch, without the need of an expert to define the meaning of signals or carrying out a calibration phase. The paper proposes an algorithm that simultaneously assign meanings to signals while solving a sequential task under the assumption that both, human and machine, share the same a priori on the possible instruction meanings and the possible tasks. Furthermore, we show using synthetic and real EEG data from a brain-computer interface that taking into account the uncertainty of the task and the signal is necessary for the machine to actively plan how to solve the task efficiently.

1 INTRODUCTION

Interactive learning [1, 2] aims at developing systems that can learn by practical interaction with the user and finds applications in a wide range of fields such as human-robot interaction, tutoring systems or human-machine interfaces. This type of learning combines ideas of learning from demonstration [3], learning by exploration [4] and tutor feedback [5]. Under this approach the human teacher interacts with the machine and provides extra feedback or guidance.

Approaches have considered: extra reinforcement signals [6], action requests [7], disambiguation among actions [8], preferences among states [9], iterations between practice and user feedback sessions [10], and choosing actions that maximize the user feedback [11].

A usual assumption in such systems is that the learner and the teacher share a mutual understanding of the meaning of each others' signals, and in particular the learning agent is usually assumed to know how to interpret teaching instructions from the human. In practice, this problem is solved due to two simplifications. On the one hand, the range of accepted instructions is limited to those predefined by the system developer. This approach, commonly used in human-robot interaction, lacks flexibility and adaptation to user specificities and, consequently, may not be well accepted by non-experts users with different preferences. On the other hand, sometimes it is not enough to predefine the instruction sets and it is necessary to perform a calibration phase to map raw signals such as speech or brain activity to their meanings. This is usually done using an ad-hoc protocol to collect labeled samples of the user instruction signals. This process must be well controlled to ensure signals are associated to the true intended meaning of the user.

The previous engineering solution is needed due to the chicken egg nature of the problem. In order to teach a system a new skill, it needs to understand the human instructions. And, in order to understand this feedback, the system must have some interaction with the human (e.g. through a controlled task as done in the calibration process) to learn what the instructions mean. Few works have studied and developed interactive learning systems that can learn both the meaning of signals and the task simultaneously. In human-robot interaction Griffiths et al. [12] conducted an experiment with humans learning the meaning of unknown symbolic teaching signals. Lopes et al. [13] presented sequential task experiments considering symbolic teaching signals and requiring a bootstrap with known signals. Grizou et al. [14] extended their system for non-symbolic teaching signals while removing the need for bootstrapping with known signals. Which they later extended to non-

invasive brain-computer interfaces (BCIs), proposed an uncertainty measure on both the task and the signal model for efficient planning, and performed online experiments [15]. Also, for P300 spellers, Kindermans et al. have shown that it is possible to exploit the repetition of signals [16] together with prior information (language models, information from other subjects) [17] to calibrate the EEG decoder while using the speller. They exploit the particular fact that only one event out of six encodes a P300 potential in the speller paradigm. BCIs usually require user-dependent calibration and have to deal with the EEG brain signals non-stationarities. These facts, together with the poor signal-to-noise ratio of the EEG, make the EEG self-calibration one of the most challenging ones.

This paper aims at solving the general problem of developing machines that can execute a task from human instructions and simultaneously learn the communicative signals. Our approach is based on a discretization of the possible tasks into a finite number. Each task assigns different expected meanings to the instruction provided by the user. The machine solves the most likely task according to a pseudo-likelihood function computed using the corresponding task labels. The experimental results, both synthetic and based on real EEG data, show that in order to simultaneously recover the meanings and solve the task it is of paramount importance to take into account the uncertainty on both task and signal space.

Compared to the work of Grizou et al. [14, 15], we improve the algorithm formalism for both learning and planning, the robustness to noisy high-dimensional signals (e.g. EEG), and allow to seamlessly transition from task to task without changing the algorithm paradigm. Grizou et al. methods in [14] and [15] required a different set of equations for the first task than for the further ones where only a fixed classifier, common for all hypothesis, was used. Compared to the work of Kindermans et al. [16, 17], our approach is more general and do not need to rely on specific patterns in the signal occurrences, i.e. they exploit the fact that only one event out of six encodes a P300 potential in the speller paradigm. The setup considered in this paper can not guarantee a specific ratio of meanings between received feedback signals.

In the following section, we present the set of assumptions and algorithmic details of our system. Then we introduce the specificity of the uncertainty inherent to our problem using an intuitive example and present the details of our action selection method. Finally we present a set of simulated experiment showing that a) our action selection method is reliable and improve over other methods, b) our algorithm scale to the use of high dimensional signals coming from previously recorded brain signals, and c) by being operational from the first step, as opposed to calibration procedure, we can estimate the correct task as soon as sufficient evidence has been collected.

2 ALGORITHM

2.1 Problem definition

We consider interaction sessions where a machine can perform discrete actions from a set of available actions $a \in \mathcal{A}$ in an either discrete or continuous state space $s \in \mathcal{S}$. The user, that wants to achieve a task $\hat{\xi}$, is providing feedback to the machine using some specific signal e , represented as a feature vector. The task is sequential meaning it is completed by performing a sequence of actions. The machine ignores the task the user has in mind, as well as the actual meaning of each user’s signal. Its objective is to simultaneously solve the task and learn a model for the user’s signals. To achieve this, it has access to a sequence of triplets in the form $D_M = \{(s_i, a_i, e_i), i = 1, \dots, M\}$, where s_i , a_i and e_i represent, respectively, the state, action and instruction signals at time step i . The behavior of the machine is determined by the actions $a \in \mathcal{A}$ and the corresponding transition model $p(s' | s, a)$.

We make the following assumptions under this general paradigm. First, the system has access to a set of tasks ξ_1, \dots, ξ_T which includes the task the user wants to solve. We assume the instruction signals e have a finite and discrete number of meanings $l \in \{l_1, l_2, \dots, l_L\}$ which we call labels and this is known by the user and the machine. In this work we will consider two possible meanings for the signals: correct or incorrect; but more complex meanings could be used, such as guidance instructions (go up, go left, ...). We assume that given these labels, it is possible to compute a model that generates or classifies signals e into meanings l . The parameters of such a model will be denoted by θ and we assume this mapping between signal e and their label l to be fixed. However this mapping is unknown to the agent at start.

2.2 Estimating Tasks Likelihoods

We start by assuming we are provided a signal decoder $\hat{\theta}$ and relax this assumption later on. As mentioned in the introduction, knowing $\hat{\theta}$, we can compute the probability of each task ξ_t after observation of a signal e when performing action a in state s :

$$p(\xi_t | e, s, a, \hat{\theta}) \propto p(e | s, a, \hat{\theta}, \xi_t) p(\xi_t) \quad (1)$$

where $p(e | s, a, \hat{\theta}, \xi_t)$ needs to take into account the probability of each possible meaning l given the target ξ_t , the current state s and the action a executed by the machine:

$$p(e | s, a, \hat{\theta}, \xi_t) = \sum_{k \in 1, \dots, L} p(e | l = l_k, \hat{\theta}) p(l = l_k | s, a, \xi_t) \quad (2)$$

This process can be repeated recursively for several inter-

action steps i :

$$\begin{aligned}\mathcal{L}_i^{\xi_t} &= p(\xi_t | D_i^{\xi_t}, \hat{\theta}) \\ &\propto p(e_i | s_i, a_i, \hat{\theta}, \xi_t) p(\xi_t | D_{i-1}^{\xi_t}, \hat{\theta})\end{aligned}\quad (3)$$

with $p(\xi_t | D_0^{\xi_t}, \hat{\theta})$ being the prior at time 0 (before the experiment starts) for the task ξ_t , usually uniform over the task distribution.

We now relax the assumption we are given a model $\hat{\theta}$. The natural extension from the previous models is to compute the posterior distribution over the task and the model, $p(\xi, \theta | e, s, a)$. However, the resulting distribution does not have a close form solution even when linear Gaussian likelihoods are used due to the combination of mixtures for each possible task. Another alternative is to compute the θ and ξ that maximize the data likelihood. This is prone to fail in certain scenarios due to two reasons. First, it is common that different tasks share many labels (e.g. the policies to reach neighboring cells on a grid world are almost identical and, therefore, share most of the labels l) and results on large uncertainties in the task space that require multiple actions to be disambiguated. Second, if the signals are not well separated the meaning parameters θ of different tasks will not differ much.

For instance, under Gaussian assumptions for $p(e|l = l_k, \theta)$ and deterministic task labels $p(l = l_k | s, a, \xi)$, it is possible to integrate out θ to compute the marginal likelihood $p(D_M | \xi)$. The resulting likelihood depends only on the traces of each $p(e|l = l_k, \theta)$. Empirical results with synthetic and EEG data for a reaching task on a grid revealed that, when the distributions over e overlap, the traces were not enough to recover the most likely task and the corresponding meaning parameters.

To cope with these problems, we define the following pseudo-likelihood function:

$$\begin{aligned}P(D_M | \xi, \theta) &\approx \prod_{i=1}^M p(e_i | s_i, a_i, \xi, \theta_{-i}) \\ &= \prod_{i=1}^M \sum_{l_c} \sum_l p(e_i | l_c, \theta_{-i}) p(l_c | l, \theta_{-i}) p(l | s_i, a_i, \xi)\end{aligned}\quad (4)$$

where l represents the meaning assigned by task ξ , action a_i and state s_i and l_c is the label corrected based on what we know about our classifier θ_{-i} for a given label l .

The pseudo-likelihood is built using a leave-one-out cross-validation strategy to evaluate the likelihood $p(e_i | s_i, a_i, \xi, \theta_{-i})$ of each signal based on the meaning parameters θ_{-i} learned for each task using all the other available signals. The use of θ_{-i} indicates we use a leave one out method. If we interpret $p(e_i | s_i, a_i, \xi, \theta_{-i})$ as a classifier, its predicted labels should match the ones provided by the task for different state-actions pairs. The rationale behind it is that for the correct task, the signals

and labels will be more coherent than for other tasks, which we measure as the predictive ability of a classifier trained on the signal-label pairs. Note that wrong tasks will assign wrong labels l to the signals e , therefore the learned models will have larger overlaps (see Figure 1c).

Each term of the pseudo-likelihood is computed from three terms. $p(l | s_i, a_i, \xi)$ represents the probability distributions of the meanings according to a task, the executed action and the current state. $p(l_c | l, \theta_{-i})$ encodes which label will be actually recovered by θ_{-i} . Intuitively, it models the quality of the model θ_{-i} . $p(e_i | l_c, \theta_{-i})$ is the likelihood of the signal given the meaning. The pseudo-likelihood is maximized in two steps. First, the maximum a posteriori estimate θ_{-i} of each task is computed. Then, the term $p(l_c | l, \theta_{-i})$ is approximated by the corresponding confusion matrix of the classifier based on θ_{-i} . It is the probability that the classifier itself is reliable in its prediction. Finally, the best task ξ should be the one that maximizes the pseudo-likelihood in Eq. 4.

2.3 Decision and Task Change

The machine must decide which task is the correct one. To do so, we define W^{ξ_t} the minimum of pairwise normalized likelihood between hypothesis ξ_t and each other hypothesis:

$$W^{\xi_t} = \min_{x \in 1, \dots, T \setminus \{t\}} \frac{P(D_M | \xi_t, \theta)}{P(D_M | \xi_t, \theta) + P(D_M | \xi_x, \theta)} \quad (6)$$

When it exists a t such that W^{ξ_t} exceeds a threshold $\beta \in [0.5, 1]$ we consider task ξ_t is the one taught by the user.

Once a task is identified with confidence, the robot executes it and prepares to receive instructions from the user to execute a new task. Assuming the user starts teaching a new task using the same kind of signals, we now have much more information about the signal model. Indeed, we are confident that the user was providing instructions related to the previously identified task; therefore we can infer the true labels of the past signals. We can now assign such labels to all hypothesis and by using the same algorithm we can start learning the new task faster as all hypothesis now share a common set of signal-label pairs. The meaning models for each hypothesis are still updated step after step until the new task is identified and labels reassigned.

3 PLANNING UNDER UNCERTAINTY

To solve our problem we need to identify simultaneously the task and how to interpret teaching signals. To do so the system has to explore regions that allow to disambiguate among hypothesis. There are several efficient model-based reinforcement learning exploration methods that add an exploration bonus for states that might provide more learn-

ing gains. Several theoretical results show that these approaches allow to learn tasks efficiently [18, 19]. We define an uncertainty measure and use model-based planning to select sequences of actions that guide the agent toward states that better identify the desired task.

In order to exemplify the specificity of our problem in terms of planning we present a simple experiment and compare the effect of different action selection strategies. In this scenario, the agent is in a T world with 7 states and can perform 4 actions (right, left, up, and down). The user wants the robot to reach the left edge (marked by G1) of the T, (see Figure 1 top). The agent knows the users wants it to go to one of the two edges (G1 or G2) but not which one. The agent will perform some actions, and the user will assess the correctness of each agent’s action by providing a two dimensional teaching signal. The agent does not know which signal means “correct” and which signal means “incorrect”. As there is two possible tasks, the agent will assign labels to every user’s signals according to each hypothesis. The result of the labeling process is displayed as colored dots (green for “correct” and red for “incorrect”) in Figure 1 (a, b, and c), where the left part corresponds to hypothesis 1 (G1) and the right part to hypothesis 2 (G2).

If the agent knew how to interpret the signal, i.e. which signal corresponds to correct or incorrect feedback, the optimal action to differentiate between the two hypothesis would be to perform right and left actions in the top part of the T. However in our problem the classifier is not given and the agent is building a different model for each hypothesis. As a results, we end up with two opposite interpretations of the user signal, which are both as valid (see Figure 1a) and do not allow to differentiate between hypothesis.

Considering that the agent does not know the signal to meaning classifier, a sensitive option is to select actions that allow to unequivocally identify the model. In our scenario taking only up and down actions in the trunk of the T leads to identical interpretation for each hypothesis (see Figure 1b). However this method do not allow to disambiguate between hypothesis and in most setting, such as the grid world we consider later, there is no state-action pair leading to unequivocal interpretations.

However performing all the four actions allow to disambiguate between hypothesis. As shown in Figure 1c, hypothesis 1 stands out by the nice coherence between the labels and the spacial organization of the data. This informs us that hypothesis 1 is the task the user has in mind and that feedback signals in the right and left part of the feature space means “correct” and “incorrect” respectively.

For our kind of problem the agent can not just try to differentiate hypothesis by finding state-action pair where expected feedback differs but should also collect data to build a good model or at least invalidate other models. Can we

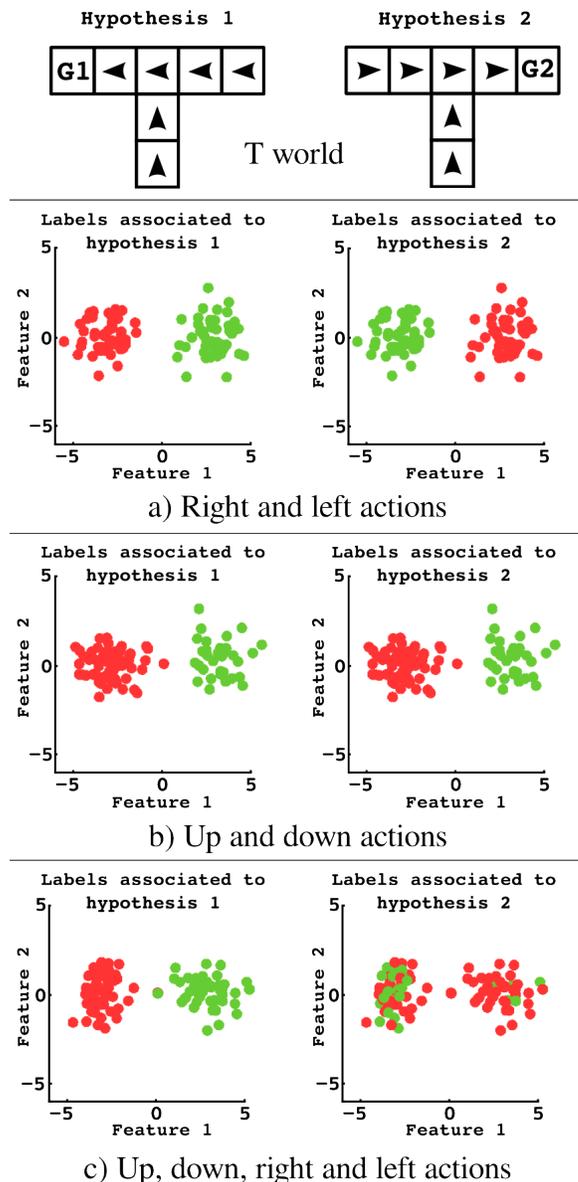

Figure 1: A “T world” scenario and the interpretation results for different planning strategies. The agent knows it should reach either of the two edges of the T world (marked with the letter G). The arrows represent the optimal policy. For each move the agent receives an unlabeled two dimensional teaching signal, corresponding to user’s assessments on the agent’s actions. The teacher’s goal is to have the agent reach G1. As the agent do not have access to this information, it interprets the signal according to each hypothesis (G1 and G2). a) shows the interpretation results if the agent only perform right and left actions in the top of the T world, b) shows the interpretation results when the agent only performs up and down actions in the trunk of the T, and c) shows the interpretation results for an agent performing all possible actions. Only the method c) allow to differentiate between hypothesis.

find a measure of uncertainty that account for both? Going back to Figure 1 (a and b), we understand that, to differentiate hypothesis in situation a) the best actions to perform are up and down in the T trunk while in situation b) the best actions to perform are right and left in the top part of the T. This corresponds to the uncertainty in the signal space. In the case of a) when going left both hypothesis agree that they will receive a signal in the right part of the feature space even if they disagree on its meaning. However for action down, both hypothesis agree they should receive a signal of meaning “incorrect” but disagree on the expected location of such signal in the feature space. In the case of b) when going up both hypothesis agree they will receive a signal in the right part of the feature space and agree on its meaning. However for action left, both hypothesis disagree about the meaning of the signal they should receive and as both share the same signal model they expect a signal in different locations of the feature space.

Estimating uncertainty in the signal space is in practice too costly as it requires to compute, for every state-action pair, the overlap between many continuous probability distributions weighted by their respective expected contribution. Following the discussion presented in previous section, we will rely on our pseudo-likelihood metric. As we cannot predict, neither control, the signal we will receive for a particular state-action, we will rely on our past history of signal and compute the expected joint probability based on previously experienced signals.

We note:

$$J^{\xi_t}(s, a, e) = \sum_{l_c} \sum_l p(e|l_c, \theta) p(l_c|l, \theta) p(l|s, a, \xi_t)$$

which is Eq. 5 for only one new expected observation e , so the product over iterations disappears. And $J^\xi(s, a, e)$ the vector $[J^{\xi_1}(s, a, e), \dots, J^{\xi_T}(s, a, e)]$.

The uncertainty of one state-action pair given a signal e is computed as the weighted variance of the joint probability predictions with weights $W^\xi = [W^{\xi_1}, \dots, W^{\xi_T}]$ (see Eq. 6):

$$U(s, a|e) = \text{weightedVariance}(J^\xi(s, a, e), W^\xi) \quad (7)$$

The uncertainty for a state-action pair is given by:

$$U(s, a) = \int_e U(s, a|e) p(e) de \quad (8)$$

which we approximate by summing values of $U(s, a|e)$ for different signals e :

$$U(s, a) \approx \sum_e U(s, a|e) p(e) \quad (9)$$

with $p(e)$ assumed uniform.

Our measure of global uncertainty $U(s, a)$ will be higher when, for a given state-action there is a high incongruity of expectation between each hypothesis and according to each hypothesis current probability.

This measure is then used as a classical exploration bonus method. We will switch to a pure exploitation of the task after reaching the desired confidence level.

Interestingly this approach generalizes over other active sampling method [7], if the classifier is known, equation 7 reduces to the one presented in [13] and is no longer dependent on signal e . As our uncertainty function combines uncertainty on both signal and task space, when the former is known, the latter becomes the sole source of ambiguity.

4 METHOD

In the subsequent analysis, we assume that a trainer provides feedback for the actions taken by a learner. Specifically, we consider the user is delivering signals that can be mapped into binary feedback: correct c and incorrect w .

4.1 World and Task

We consider a 5x5 grid world, where an agent can perform five different discrete actions: move up, down, left, right, or a “no move” action. The user goal is to teach the agent to reach one (unknown to the agent) of the 25 discrete positions which represent the set of possible tasks. We thus consider that the agent has access to 25 different task hypothesis (one with goal location at each of the cells). We use *Markov Decision Processes* (MDP) to represent the problem [4]. From a given task ξ , represented as a reward function, we can compute the corresponding policy π^ξ using, for instance, Value Iteration [4]. The policies allow us to interpret the teaching signals with respect to the interaction protocol defined. For the current work we will consider the user is providing feedback on the agent action. We define $p(l|s, a, \xi)$ as:

$$p(l|s, a, \xi) = \begin{cases} 1 - \alpha & \text{if } a = \text{argmax}_a \pi^\xi(s, a) \\ \alpha & \text{otherwise} \end{cases}$$

with α modeling the expected error rate of the user.

4.2 Signal properties and classifier

We aim at applying this algorithm to error-related potentials (ErrPs) for EEG-based BCI applications. These signals are generated in the user’s brain after s/he assesses actions performed by an external agent [20], where correct and erroneous assessments will elicit different brain signals. Past approaches have already demonstrated that these signals can be classified online with accuracies of around 80% and translated into binary feedback, thanks to a prior calibration session that lasts for 30-40 minutes [20, 21].

Following the literature [22], we will model the signals using independent multivariate normal distributions for each class, $\mathcal{N}(\mu_c, \Sigma_c), \mathcal{N}(\mu_w, \Sigma_w)$. With θ the set of parameters $\{\mu_c, \Sigma_c, \mu_w, \Sigma_w\}$. Given the high dimensionality of the problem we will also need to regularize. For this we apply shrinkage to the covariance matrix ($\lambda = 0.5$) and compute the value of the marginal pdf function using a non-informative (Jeffreys) prior [[23], p88]:

$$p(e|l, \theta) = t_{n-d}(e|\mu_l, \frac{\Sigma_l(n+1)}{n(n-d)}) \quad (10)$$

where θ represents the ML estimates (mean μ_l and covariance Σ_l for each class l) required to estimate the marginal under the Jeffreys prior, n is the number of signals, and d is the dimensionality of a signal feature vector.

4.3 Task Achievement

A task is considered completed when the confidence level β as been reached for this task and the agent is located at the task associated goal state. If the state is the one intended by the user it is a success. Whatever the success or failure of the first task, the user selects a new goal state randomly, the agent resets task likelihoods, propagates the believed labels, and teaching starts again. At no point the agent has access to a measure of its performance, it can only refer to the unlabeled feedback signals from the user.

4.4 Evaluation scenarios

Two different evaluation scenarios were tested with two different types of signals: artificial datasets, and real ErrP datasets recorded from previous experiments [21].

Artificial datasets The goal of this evaluation was to analyze the feasibility of learning a task from scratch in a 5x5 grid world. The artificial dataset was composed of two classes, with 1000 examples per class. Each example was generated by sampling from a normal distribution with a covariance matrix of diagonal 1 and mean selected randomly. The datasets were generated while varying two factors: (i) the dimensionality of the data, where 2, 5, 10 and 30 features were tested; and (ii) the quality of the dataset, measured in terms of the ten-fold accuracy the classifier would obtain.

Once the datasets were generated, two different evaluations were performed: (i) the goodness of our proposed planning strategy versus a) random action selection, b) greedy action selection, and c) a task-only uncertainty based method; (ii) the time required by the agent to learn the first task (i.e. to reach the first target), and (iii) the number of tasks that can be learned in 500 iterations.

EEG datasets Once the algorithm was evaluated with artificial datasets, we tested the feasibility of the proposed

self-calibration approach using real ErrP datasets. The objective of this analysis is to study the scalability of our method to EEG data, which may have different properties than our artificial dataset.

The EEG data were recorded in a previous study [21] where participants monitored on a screen the execution of a task where a virtual device had to reach a given goal. The motion of the device could be correct (towards the goal) or erroneous (away from the goal). The subjects were asked to mentally assess the device movements as erroneous or non-erroneous. The EEG signals were recorded with a gTec system with 32 electrodes distributed according to an extended 10/20 international system with the ground on FPz and the reference on the left earlobe. The ErrP features were extracted from two fronto-central channels (FCz and Cz) within a time window of [200, 700] ms (being 0 ms the action onset of the agent) and downsampled to 32 Hz. This led to a vector of 34 features.

Comparison with calibration methods In order to show the benefit of learning without explicit calibration, we compare our method with the standard supervised BCI calibration procedure. In this calibration procedure, which can last for up to 40 minutes, the experimenter needs to record enough data from the user from several offline runs, where the user is not controlling the agent but just passively assessing its actions. Following the literature on ErrPs [20, 21] our training data will consist of 80 percent of positive examples (associated to a correct feedback) and 20 percent of negative examples (associated to an incorrect feedback). Our proposed algorithm is compared with different (but standard) sizes of calibration datasets: 200, 300 and 400 examples.

4.5 Settings

We used $\alpha = 0.1$, $\beta = 0.9$. For dataset of dimension d , we started computing likelihoods after $d+10$ steps as equation 10 requires at least $d+1$ samples and to allow for cross validation. For the planning (Eq. 9) we selected randomly 20 signals from D_M .

5 RESULTS

We present most of the results in terms of the quality of the dataset, measured as the ten-fold classification accuracy that a calibrated signal classifier would obtain. Each simulation was run 100 times using different sampled datasets, and their associated box plots were computed. For each boxplot, colored bars show the interquartile range (between 25th and 75th percentile), and the median and the mean are marked as a horizontal line and a colored dot respectively. Additionally, the two “whiskers” show the 5th and 95th percentiles, black crosses are outliers.

5.1 Artificial Datasets

The first objective is to study the impact of the exploration approach proposed in Section 3. The second is to evaluate performances and robustness with respect to the dimension and the quality of each dataset.

Planning Methods Figure 2 compares the number of steps (with maximum values of 500 steps) needed to identify the first task when learning from scratch with different planning methods. Following the most probable task (i.e. going greedy) does not allow the system to explore sufficiently. On the contrary, our proposed planning method leads the system towards regions that maximize disambiguation among hypotheses. Furthermore, it also performs better than assessing uncertainty on the task space only. Given these results, the remainder of this section will only consider our planning method.

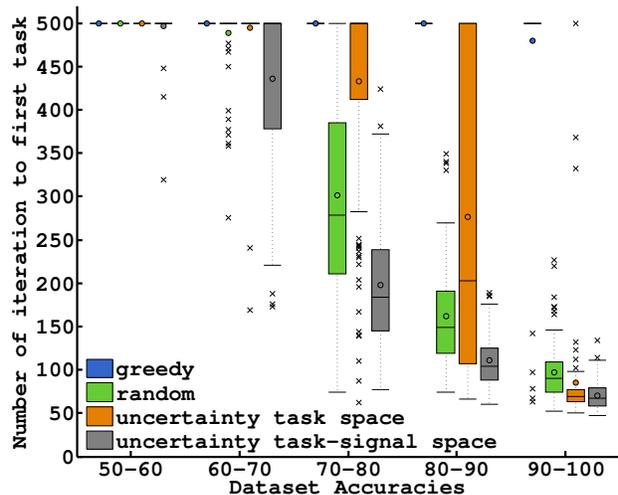

Figure 2: Number of steps to complete first task, comparison of different exploration methods with 30 dimensional artificial data. When learning from scratch, planning upon uncertainty in both task and signal space performs better than relying only on task uncertainty. Greedy action selection rarely disambiguates between hypothesis.

As depicted in Figure 1, the system needs to collect two types of information, some about the true underlying model (Fig. 1b) and some to differentiate between hypotheses (Fig. 1a). The properties of the grid world make the random strategy quite efficient at collecting those two types of information. The differences between planning methods should be more evident when navigating a complex maze since our method allows to plan in order to collect the type of information we need. Studying how different world properties affect the learning efficiency is part of our future work. Also, we note that all planning methods were switched to pure exploitation (greedy) once the confidence level was reached. Therefore the performance in Figure 2

compares the ability of the different methods to discriminate between different task hypotheses, not their ability to solve the task itself.

Dimensionality Figure 3 compares the number of steps (with maximum values of 500 steps) needed to identify the first task when learning from scratch with different dimensionality of datasets. The convergence speed is only slightly affected by the features dimensionality. On the other hand, the dataset quality (measured in terms of its associated ten-fold accuracy) is the main cause of performances decay. Furthermore, for those datasets with accuracies between 50% and 60%, the system is not able to identify a task with confidence after 500 steps.

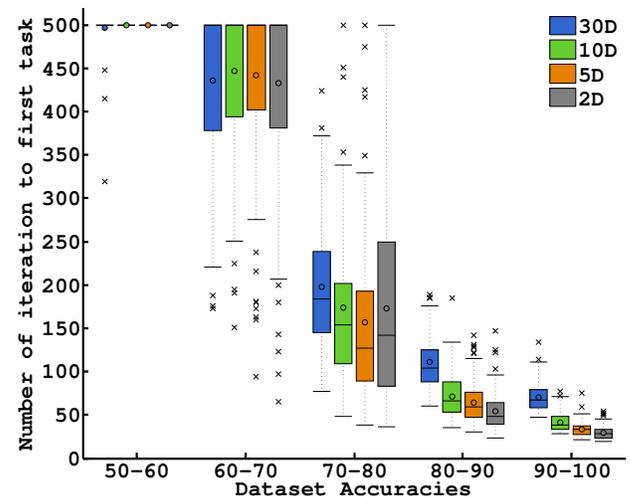

Figure 3: Number of steps to complete first task using artificial data. Under 60 percent accuracy, the confidence threshold cannot be reached in 500 steps. The dataset qualities, more than their dimensionality, impact the learning time.

Once one task is completed, a new one is selected randomly. Figure 4 compares the number of tasks that can be achieved in 500 steps. As expected, the lower the quality of the data, the less number of task can be completed. With dataset accuracies higher than 90% we can achieve more than 30 tasks on average.

An important aspect of the proposed learning approach was that the first task learned was always the correct one. We reported only 9 erroneous estimations across all simulated experiments (5 in the 70-80 group and 4 in the 80-90 group).

5.2 EEG datasets and comparison with calibration method

Example Figure 5 shows one particular run of 500 steps comparing our self-calibration method with a calibration

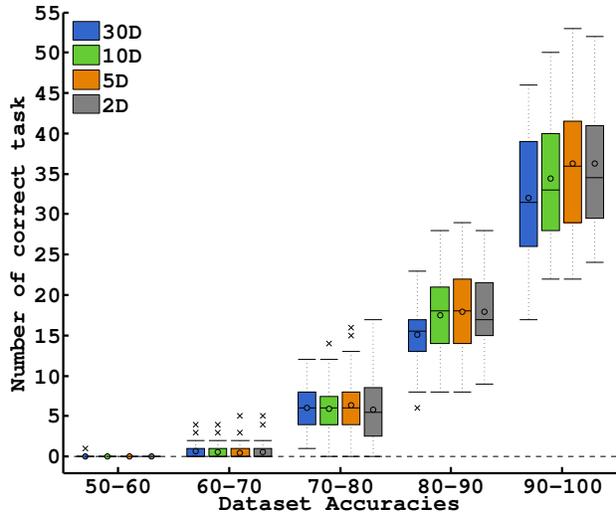

Figure 4: Number of tasks correctly achieved in 500 steps, artificial data. Quality of dataset impacts the number of task identified in 500 steps as more evidence should be collected to reach the confidence threshold.

procedure of 400 steps. The two independent runs use as real EEG dataset with 80% ten-fold classification accuracy. As our algorithm is operational from the first step, it can estimate the real task when sufficient evidence has been collected. On the other hand, a calibration approach collects signal-label pairs for a fixed number of steps and use the resulting classifier without updating it. This provokes that, during the calibration phase, no tasks can be learned, substantially delaying the user’s online operation.

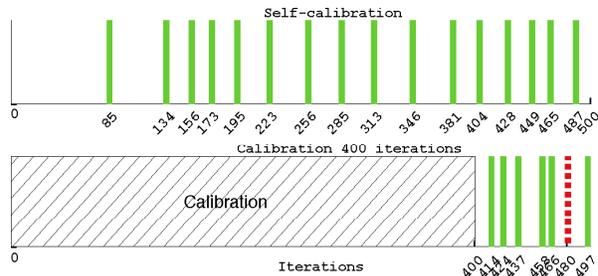

Figure 5: Time-line of one run from EEG dataset of 80 percent ten-fold classification accuracy, self-calibration (top) versus 400 steps calibration (bottom). Green (filled) and red (dashed) bars represents respectively correct and incorrect task achievement. The proposed self-calibration method allow to reach a first task faster than would take a calibration procedure.

Figure 6 shows the evolution of classification rate between our self-calibration method with a calibration procedure of 400 steps. As our method assigns different labels to each new teaching signal, the resulting classifiers have different performances, which help identifying the correct task.

Once a task is identified (e.g. step 85 and 134), the corresponding labels are taken as ground truth, and all classifiers will have the same accuracies. As the agent starts exploring again to estimate the new tasks, all the classifiers except the true one will start to have worse accuracies again.

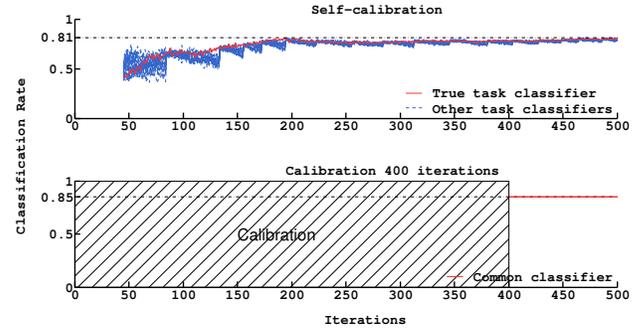

Figure 6: Evolution of classification rate of one run from EEG data, self-calibration (top) versus 400 steps calibration (bottom). On top, the red line represents the classifier corresponding to the successive tasks taught by the user, the dashed blue lines represent all other tasks. Our method updates classifiers every steps.

Time to first task Figure 7 shows the results per group of dataset. Our algorithm allows to complete the first task without errors and in a fair amount of iteration. For our method, the learning time is strongly correlated with the dataset quality. However calibration methods, which do not update their classifier once calibrated, identify more tasks incorrectly.

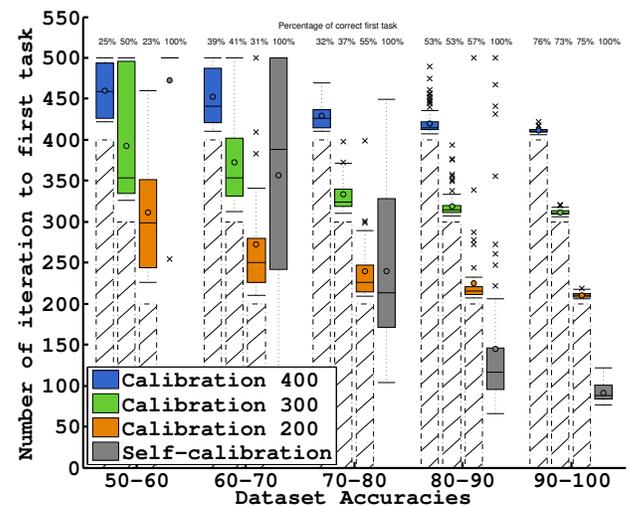

Figure 7: Number of steps to complete first task with EEG data. The method scale well to EEG data. Contrary to the standard calibration approaches, we do not make mistakes with low quality datasets.

Cumulative performances Figure 8 compares the number of tasks that can be achieved in 500 steps. With 90% and more dataset quality we can achieve about 20 tasks on average. The results are consistent with artificial dataset analysis.

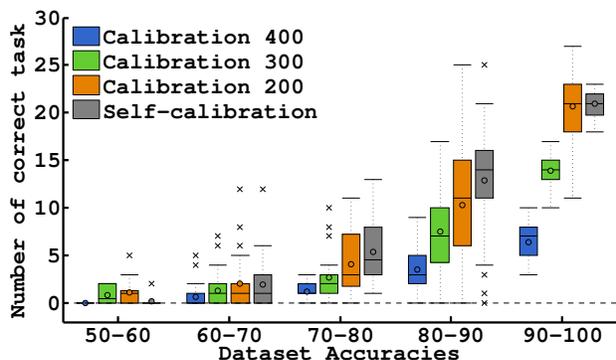

Figure 8: Number of task correctly achieved in 500 steps with EEG data. Calibration methods can not complete a significant number of task as most of the time is spent on calibration.

The calibration methods can not complete many task as a significant amount of iteration was used for calibrating the system. A calibration of 200 steps makes as many good estimation than our method, but it also makes many wrong estimation, see Figure 9. For calibration methods, the less time spent on calibration, the poorer the classifier which implies more mistakes.

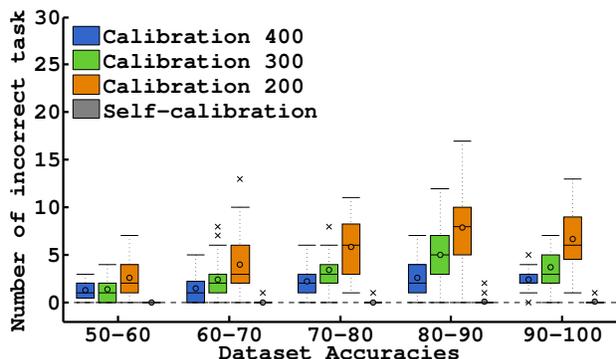

Figure 9: Number of task incorrectly achieved in 500 steps with EEG data. Calibration methods, which do not update their models once calibrated, make more errors.

6 CONCLUSION

In this paper we have shown that, given a limited number of possible tasks, it is possible to solve sequential tasks using human feedback without defining a map between feedback signals and their meaning beforehand. The proposed algorithm optimizes a pseudo-likelihood function and performs active planing according to the uncertainty in the task

and meaning spaces. Indeed, taking into account this uncertainty is crucial to solve the task efficiently and to recover the actual meanings. This combination allows: a) a human to start interacting with a system without calibration; b) to automatically adapt calibration time to the user needs which can even outperform fixed calibration procedures; c) to adapt to the uncertainty of the information source from scratch. We showed the applicability of the approach to brain-machine interfaces based on error potentials which could work out of the box without calibration, a long-desired property of this type of systems.

A number of open questions remain to be addressed:

- How the task properties (symmetries, size, ...) affect the learning properties?
- How to leverage from the finite set of hypothesis constraint? A potential avenue is to use a combination of particle filter and regularization on the task space.
- In real-world applications, users are usually told how to interact with machines. Do people want to have an open-ended choice about what signal to use? Would they be more efficient? When is it better to use a calibration procedure?
- Only prerecorded datasets have been used. However, signals may change during the learning. For instance, people can try to adapt themselves to a robot if they believe the latter is not understanding properly. Or, brain signals are sensitive to the protocol, the duration of the experiment or even the percentage of errors made by the agent [20]. To which extend the behavior of our agent changes the properties of the teaching signal? Can we adapt to such changes online?

Finally, while we only considered correct/incorrect labels, in other works we have considered the use of guidance instructions (go up, go left, ...) in human-robot interaction scenario [14]. But increasing the set of possible labels logically requires collecting more examples to obtain a good enough representation of the different signals. Hence, for BCI domains, it is reasonable to keep a limited number of labels.

Abstract

Active learning has been proven to be quite effective in reducing the human labeling efforts by actively selecting the most informative examples to label. In this paper, we present a batch-mode active learning method based on logistic regression. Our key motivation is an out-of-sample bound on the estimation error of class distribution in logistic regression conditioned on any fixed training sample. It is different from a typical PAC-style passive learning error bound, that relies on the i.i.d. assumption of example-label pairs. In addition, it does not contain the class labels of the training sample. Therefore, it can be immediately used to design an active learning algorithm by minimizing this bound iteratively. We also discuss the connections between the proposed method and some existing active learning approaches. Experiments on benchmark UCI datasets and text datasets demonstrate that the proposed method outperforms the state-of-the-art active learning methods significantly.

1 INTRODUCTION

In a typical supervised learning problem, one often requires sufficient labeled data to train an accurate classifier, whereas the labeling process may be expensive and time consuming. This motivates *Active Learning* [11], which has been proven to be effective in reducing the human labeling efforts by actively selecting the most informative examples for labeling. The goal of active learning is to learn a classifier which accurately predicts the labels of new examples, while requesting as few labels as possible.

In the past decades, many active learning methods have been proposed. Depending on the label query strategy, active learning can be roughly categorized into fully sequential active learning [13, 27, 30, 5, 24, 7, 22], batch-

mode active learning [20, 17, 21] and one-shot active learning [29, 15, 16, 14]. Fully sequential active learning algorithms select only one example to query its label at one time, and update the classifier. In contrast, batch-mode active learning algorithms select multiple examples at one time. It is more efficient since the classifier is trained fewer times. More importantly, it is able to take into account the information overlap among the multiple examples. Both fully sequential and batch-mode active learning are adaptive, as in the query process, the newly labeled data in an earlier iteration can be used to guide the selection of unlabeled data in a latter iteration (e.g., by updating the classifier). In contrast, one-shot active learning is non-adaptive. In this paper, we consider batch-mode active learning, because it is more general than the other two query strategies both in theory and practice. It can be directly adapted to fully sequential and one-shot active learning, by simply setting the batch-size to one or to a sufficient large number.

On the other hand, the most widely used criteria for active learning include but not limited to uncertainty sampling [27, 21], query by committee [13], mutual information [24, 16], experimental design [29, 3], and expected error minimization [15, 14]. Besides these practical algorithms mentioned above, there are also several theoretical studies [5, 12, 7, 18, 1], which provide bounds on the label complexity. The method we are going to propose belongs to the family of expected error minimization. The main advantage of the methods in this family is that the criteria are minimizing certain kind of error bounds, which directly relate the label selection procedure with the prediction error. As a result, we are particularly interested in designing such kind of active learning algorithm.

With the above motivation, we present a batch-mode active learning method, which is based on the well-known statistical model of logistic regression [19]. One advantage of logistic regression is that it has an inherent model assumption and thus it is amenable to theoretical analysis. Furthermore, it is in nature a classification model and consequently more suitable for active learning towards classification. We perform a finite sample analysis on the logistic regression

and derive an error bound on the class distribution conditioned on any fixed training sample. This bound is essential because it is different from a typical PAC-style error bound for model-free passive learning [8], that relies on the i.i.d. assumption of the example-class pairs. In contrast, our derived bound allows the training examples to be dependent, which meets the scenario of active learning. Furthermore, the derived error bound does not contain the class labels of the training sample, which allows us to do minimization by choosing training examples without knowing their labels. We propose an active learning criterion to select the examples by minimizing this upper bound iteratively. The resulting method is a combinatorial optimization problem, which is relaxed and solved approximately by projected gradient descent. It is worth noting that the derivation approach we proposed is quite general and is applicable to other generalized linear models beyond logistic regression.

As we mentioned before, although we mainly study batch-mode active learning in this paper, our proposed method supports fully sequential and one-short active learning as well. Furthermore, unlike many active learning methods [5, 12, 7], which rely on sampling the hypothesis space, our method is deterministic and easy to implement. Extensive experiments on UCI datasets and text datasets show that the proposed method significantly outperforms the state-of-the-art active learning methods.

The remainder of this paper is organized as follows. In Section 2, we analyze the logistic regression, and derive a finite sample error bound on its response distribution. In Section 3, we present an active learning criterion based on minimizing the derived error bound, followed by its optimization algorithm. We discuss some related methods in Section 4. The experiments are demonstrated in Section 5. Finally, we draw conclusions and point out the future work in Section 6.

2 FINITE SAMPLE ANALYSIS OF LOGISTIC REGRESSION

In this section, to keep this paper self-contained, we first briefly review logistic regression [19]. Then we derive an estimation error bound for the conditional class distribution based on finite-sample analysis. It is among the main contributions of this paper, and is the theoretical underpinning of the active learning approach proposed in the next section.

2.1 NOTATION

Throughout this paper, we will use lower case letters to denote scalars, lower case bold letters to denote vectors, upper case letters to denote the elements of a matrix or a set, and bold-face upper case letters to denote matrices. \mathbf{I} is an identity matrix with an appropriate size. We

use superscript \top to denote the transpose of a vector or a matrix. The ℓ_2 -norm of a vector $\mathbf{x} \in \mathbb{R}^d$ is defined as $\|\mathbf{x}\|_2 = \sqrt{\sum_{i=1}^d x_i^2}$. The spectral norm of a matrix \mathbf{A} is defined as $\|\mathbf{A}\|_2 = \max_{\|\mathbf{x}\|_2=1} \|\mathbf{A}\mathbf{x}\|_2$. In particular, for a squared matrix $\mathbf{A} \in \mathbb{R}^{d \times d}$, we denote its maximum eigenvalue by $\lambda_{\max}(\mathbf{A})$, and its minimum eigenvalue by $\lambda_{\min}(\mathbf{A})$. We use $[n]$ to denote the index set $\{1, 2, \dots, n\}$. Given a matrix $\mathbf{X} \in \mathbb{R}^{d \times n}$, $\mathbf{X}_{\mathcal{L}}$ denotes a submatrix of \mathbf{X} , which consists of the columns of \mathbf{X} indexed by $\mathcal{L} \subset [n]$. \mathbf{x}_i denotes the i -th column of \mathbf{X} . And for a symmetric matrix $\mathbf{D} \in \mathbb{R}^{n \times n}$, $\mathbf{D}_{\mathcal{L}\mathcal{L}}$ denotes a submatrix of \mathbf{D} , which contains the rows and columns indexed by \mathcal{L} .

2.2 LOGISTIC REGRESSION

Let us consider the binary classification case for simplicity. Given a sample set $S = \{(\mathbf{x}_i, y_i)\}_{i=1}^n$ where $\mathbf{x}_i \in \mathbb{R}^d$ and $y_i \in \{\pm 1\}$, to have a simpler derivation without considering the bias term θ , one often augments each example with an additional dimension: $\mathbf{x}^\top \leftarrow [\mathbf{x}^\top; 1]$ and $\mathbf{w}^\top \leftarrow [\mathbf{w}^\top; \theta]$. In logistic regression [19], the conditional class probability $\Pr(y|\mathbf{x})$ is given by

$$\Pr(y|\mathbf{x}; \mathbf{w}) = \sigma(y\mathbf{w}^\top \mathbf{x}),$$

where $\sigma(a)$ is the logistic sigmoid function, i.e., $\sigma(a) = 1/(1 + \exp(-a))$. Note that $\sigma(a)$ is a concave function when $a > 0$.

To avoid over-fitting, we place a prior on \mathbf{w} in the form of a zero-mean Gaussian distribution with isotropic covariance, i.e., $\mathcal{N}(\mathbf{0}, 1/\lambda \mathbf{I})$, and seek a \mathbf{w} which maximizes the log-likelihood of the posterior distribution given the training data S , which is equivalent to

$$\hat{\mathbf{w}} = \arg \min_{\mathbf{w}} \lambda \|\mathbf{w}\|_2^2 - \frac{1}{n} \sum_{i=1}^n \log \sigma(y_i \mathbf{w}^\top \mathbf{x}_i), \quad (1)$$

where λ is a positive regularization parameter. Eq. (1) is also known as penalized logistic regression, or more precisely, ℓ_2 -regularized Logistic regression. It is worth noting that although logistic regression is called “regression”, it is in nature a classification model, because its response is binary and it directly estimates the conditional class probability given the data. This is also the reason that we deem that deriving an active learning algorithm based on logistic regression is more natural and effective for classification than inventing one from the real regression models [29, 14].

2.3 ERROR BOUNDS FOR LOGISTIC REGRESSION

In the following, we will analyze ℓ_2 -regularized logistic regression reviewed above. First of all, we assume that there exists an unknown true parameter $\mathbf{w}_* \in \mathbb{R}^d$, by which the class label of an example is generated as follows

$$\Pr(y|\mathbf{x}) = \sigma(y\mathbf{w}_*^\top \mathbf{x}). \quad (2)$$

where $\|\mathbf{w}_*\|_2 \leq R$ for some $R > 0$. This is our model assumption. All the theoretical results we are going to present are built up on this assumption.

Without loss of generality, we assume $\|\mathbf{x}_i\|_2 \leq 1$ for $\forall i$. Then it is easy to verify that

$$\left\| \frac{1}{n} \sum_{i=1}^n \mathbf{x}_i \mathbf{x}_i^\top \right\|_2 \leq 1.$$

The following theorem provides a bound on the estimation error of $\hat{\mathbf{w}}$, which is central in our theoretical results. The detailed proofs can be found in the supplementary material.

Theorem 1. *For any fixed sample $S = \{(\mathbf{x}_i, y_i)\}_{i=1}^n$, where y_i follows the conditional distribution as in Eq. (2), and $\|\mathbf{x}_i\|_2 \leq 1$ for $\forall i$. $\hat{\mathbf{w}}$ is the estimated weight vector by logistic regression on S , then the estimation error of $\hat{\mathbf{w}}$ is upper bounded as*

$$\begin{aligned} & \mathbb{E}_{Y|X} [\|\hat{\mathbf{w}} - \mathbf{w}_*\|_2] \\ & \leq C_1 \lambda_{\max} \left(\left(\lambda \mathbf{I} + \frac{1}{n} \mathbf{X} \mathbf{D} \mathbf{X}^\top \right)^{-1} \right), \end{aligned}$$

where $\mathbb{E}_{Y|X}$ is the shorthand for $\mathbb{E}_{y_1, \dots, y_n | \mathbf{x}_1, \dots, \mathbf{x}_n}$, $C_1 = 1 + 2\lambda R$, $\mathbf{X} = [\mathbf{x}_1, \dots, \mathbf{x}_n]$, \mathbf{D} is a diagonal matrix with diagonal elements defined as follows

$$D_{ii} = (1 - \sigma(\mathbf{w}_*^\top \mathbf{x}_i)) \sigma(\mathbf{w}_*^\top \mathbf{x}_i). \quad (3)$$

Proof. (Sketch of proof): We use a similar technique adopted in [25]. Define $f(\mathbf{w}) = \lambda \|\mathbf{w}\|_2^2 - 1/n \sum_{i=1}^n \log \sigma(y_i \mathbf{w}^\top \mathbf{x}_i)$. Let $\hat{\mathbf{w}} = \arg \min_{\mathbf{w}} f(\mathbf{w})$.

Define $g(\Delta)$ as follows

$$\begin{aligned} g(\Delta) = & \mathbb{E}_{Y|X} [\lambda \|\mathbf{w}_* + \Delta\|_2^2 - \frac{1}{n} \sum_{i=1}^n \log \sigma(y_i (\mathbf{w}_* + \Delta)^\top \mathbf{x}_i) \\ & - \lambda \|\mathbf{w}_*\|_2^2 + \frac{1}{n} \sum_{i=1}^n \log \sigma(y_i \mathbf{w}_*^\top \mathbf{x}_i)], \end{aligned}$$

where $\Delta = \mathbf{w} - \mathbf{w}_*$. It is easy to verify that $g(0) = 0$. Using the optimality of $\hat{\mathbf{w}}$, we have $f(\hat{\mathbf{w}}) \leq f(\mathbf{w}_*)$, yielding

$$\begin{aligned} & \lambda \|\hat{\mathbf{w}}\|_2^2 - \frac{1}{n} \sum_{i=1}^n \log \sigma(y_i \hat{\mathbf{w}}^\top \mathbf{x}_i) \\ & \leq \lambda \|\mathbf{w}_*\|_2^2 - \frac{1}{n} \sum_{i=1}^n \log \sigma(y_i \mathbf{w}_*^\top \mathbf{x}_i). \end{aligned}$$

Therefore, we have $g(\hat{\Delta}) \leq 0$ with $\hat{\Delta} = \hat{\mathbf{w}} - \mathbf{w}_*$. Suppose that we show for some radius $B > 0$, and for $\Delta \in \mathbb{R}^d$ with $\|\Delta\|_2 = B$, we have $g(\Delta) > 0$. We then can claim that $\|\hat{\Delta}\|_2 \leq B$. We prove it by contradiction: If $\hat{\Delta}$ lies outside the ball of radius B , then by convexity of $g(\cdot)$, we have

$$g(t\hat{\Delta} + (1-t)0) \leq tg(\hat{\Delta}) + (1-t)g(0) \leq 0,$$

for some appropriately chosen $t \in (0, 1)$ such that $t\hat{\Delta} + (1-t)0$ lies on the boundary of the ball. This is contradict with the fact that $g(t\hat{\Delta} + (1-t)0) > 0$.

By some calculations, we have

$$g(\Delta) \geq C_{\min} B^2 - B - 2\lambda R B + \lambda B^2,$$

where $C_{\min} = \lambda_{\min}(1/n \sum_{i=1}^n \sigma(\mathbf{w}_*^\top \mathbf{x}_i)(1 - \sigma(\mathbf{w}_*^\top \mathbf{x}_i)) \mathbf{x}_i \mathbf{x}_i^\top)$.

It is easy to show that $B = (1 + 2\lambda R)/(C_{\min} + \lambda)$ makes $g(\Delta) > 0$. Based on previous argument, since $g(\hat{\Delta}) \leq 0$, we have

$$\begin{aligned} \|\hat{\Delta}\|_2 & \leq \frac{1 + 2\lambda R}{C_{\min} + \lambda} \\ & = \frac{1 + 2\lambda R}{\lambda_{\min} \left(\lambda \mathbf{I} + \frac{1}{n} \sum_{i=1}^n \sigma(\mathbf{w}_*^\top \mathbf{x}_i)(1 - \sigma(\mathbf{w}_*^\top \mathbf{x}_i)) \mathbf{x}_i \mathbf{x}_i^\top \right)} \\ & = (1 + 2\lambda R) \lambda_{\max} \left(\left(\lambda \mathbf{I} + \frac{1}{n} \sum_{i=1}^n D_{ii} \mathbf{x}_i \mathbf{x}_i^\top \right)^{-1} \right). \end{aligned}$$

□

Remark 1: The above bound is derived by analyzing the second-order Taylor expansion of Eq. (1). If we simply use the strongly convex property of Eq. (1), we cannot get the desired bound, because the information of the second-order derivative will not be fully utilized. Consequently, the above bound is sharper than the bound derived by strong convexity.

In logistic regression, the classification of a new example is solely based on its estimated conditional class probability. Therefore, we aim to bound the estimation error of the conditional class probability rather than $(\hat{\mathbf{w}}^\top \mathbf{v} - \mathbf{w}_*^\top \mathbf{v})^2$ as in linear regression. Based on Theorem 1, we can prove the following theorem, which achieves our goal.

Theorem 2. *For any fixed sample $S = \{(\mathbf{x}_i, y_i)\}_{i=1}^n$ where y_i follows the conditional distribution as in Eq. (2), and $\|\mathbf{x}_i\|_2 \leq 1$ for $\forall i$. $\hat{\mathbf{w}}$ is the estimated weight vector by logistic regression on S . Then the estimated conditional class probability on a validation set $\{\mathbf{v}_j\}_{j=1}^m$ is upper bounded as*

$$\begin{aligned} & \mathbb{E}_{Y|X} \left[\sum_{j=1}^m (\Pr(y|\mathbf{v}_j; \hat{\mathbf{w}}) - \Pr(y|\mathbf{v}_j; \mathbf{w}_*))^2 \right] \\ & \leq C_2 \text{tr} \left(\left(\lambda \mathbf{I} + \frac{1}{n} \mathbf{X} \mathbf{D} \mathbf{X}^\top \right)^{-1} \mathbf{V} \mathbf{\Sigma} \mathbf{V}^\top \right), \end{aligned}$$

where $C_2 = (1 + \lambda R)^2 (\lambda + 1)^2 / \lambda^2$, $\mathbf{X} = [\mathbf{x}_1, \dots, \mathbf{x}_n]$ and $\mathbf{V} = [\mathbf{v}_1, \dots, \mathbf{v}_m]$, $\mathbf{\Sigma}$ is a diagonal matrix with diagonal elements defined as follows

$$\Sigma_{jj} = (1 - \sigma(\tilde{\mathbf{w}}^\top \mathbf{v}_i)) \sigma(\tilde{\mathbf{w}}^\top \mathbf{v}_i), \quad (4)$$

with $\tilde{\mathbf{w}} = \mathbf{w}_* + \alpha(\hat{\mathbf{w}} - \mathbf{w}_*)$ for some $\alpha \in [0, 1]$.

Proof. (Sketch of proof): Consider the second-order Taylor expansion of $\sigma(\widehat{\mathbf{w}}^\top \mathbf{v}_j)$, we have the following inequality,

$$\sigma(\widehat{\mathbf{w}}^\top \mathbf{v}_j) = \sigma(\mathbf{w}_*^\top \mathbf{v}_j) + \sigma(\tilde{\mathbf{w}}^\top \mathbf{v}_j) (1 - \sigma(\tilde{\mathbf{w}}^\top \mathbf{v}_j)) \mathbf{v}_j \cdot \widehat{\Delta},$$

where $\tilde{\mathbf{w}} = \mathbf{w}_* + \alpha(\widehat{\mathbf{w}} - \mathbf{w}_*) = \mathbf{w}_* + \alpha\widehat{\Delta}$ for some $\alpha \in [0, 1]$.

Then we have

$$\begin{aligned} & \mathbb{E}_{Y|X} \left[\sum_{j=1}^m (\Pr(y|\mathbf{v}_j, \widehat{\mathbf{w}}) - \Pr(y|\mathbf{v}_j, \mathbf{w}_*))^2 \right] \\ &= \sum_{j=1}^m (\sigma(\widehat{\mathbf{w}}^\top \mathbf{v}_j) - \sigma(\mathbf{w}_*^\top \mathbf{v}_j))^2 \\ &= \sum_{j=1}^m (\sigma(\tilde{\mathbf{w}}^\top \mathbf{v}_j) (1 - \sigma(\tilde{\mathbf{w}}^\top \mathbf{v}_j)) \mathbf{v}_j \cdot \widehat{\Delta})^2 \\ &= \sum_{j=1}^m (\Sigma_{jj} \mathbf{v}_j \cdot \widehat{\Delta})^2, \end{aligned}$$

which can be further bounded by Theorem 1. \square

Remark 2: All the above theoretical results hold under the conditional expectation with respect to the conditional class distribution $\Pr(Y|X)$, given any fixed design matrix \mathbf{X} . They do not require either $\{(\mathbf{x}_i, y_i)\}_{i=1}^n$ or $\{\mathbf{x}_i\}_{i=1}^n$ to be i.i.d., which is the common assumption in passive learning. In addition, the derived bounds do not depend on the class labels of the training sample explicitly.

It can be observed from Theorem 2 that, the expected estimation error of the conditional class probability $P(Y|X)$ on a validation set is upper bounded by a term which can be approximately computed based on the training set together with the validation set without their labels. Therefore, they can be used to guide the design of active learning algorithms, because the examples in the pool are not only dependent (starting from the second round of label query) in active learning, but also unlabeled. It also explains why we need to derive such a kind of bounds to design active learning algorithms rather than using existing PAC-style bounds for model-free learning [8]. In a nutshell, we can minimize this bound by choosing a subsample of the training set. We will discuss this in details in the next section.

3 ACTIVE LEARNING BASED ON ERROR BOUND MINIMIZATION

Before presenting the new active learning method, let us recall the basic setting of batch-mode active learning as follows. Given a training data matrix, i.e., $\mathbf{X} = [\mathbf{x}_1, \dots, \mathbf{x}_n] \in \mathbb{R}^{d \times n}$, and an initial labeled set \mathcal{L} , together with a set of unlabeled examples, i.e., \mathcal{U} . Batch-mode active learning operates in T iterations. In each iteration, the

learner will choose b examples (denoted by \mathcal{B}) from the unlabeled set \mathcal{U} to label, and add these labeled examples into the existing labeled set \mathcal{L} (also remove \mathcal{B} from the unlabeled set \mathcal{U}). The goal of batch-mode active learning is to find bT examples in total, which are the most informative examples, namely selected subsample set, to query their labels.

3.1 THE CRITERION

The proposed active learning method is motivated by Theorem 2. In Theorem 2, we can see that the estimation error of the conditional class probability is upper bounded by $\text{tr}(\Sigma^{\frac{1}{2}} \mathbf{V}^\top (\lambda \mathbf{I} + 1/n \mathbf{X} \mathbf{D} \mathbf{X}^\top)^{-1} \mathbf{V}^\top \Sigma^{\frac{1}{2}})$, where \mathbf{D} and Σ are depending on \mathbf{w}_* and $\tilde{\mathbf{w}}$. Since \mathbf{w}_* and $\tilde{\mathbf{w}}$ are unknown, we cannot calculate \mathbf{D} and Σ exactly. Instead, we use the current $\widehat{\mathbf{w}}$ to approximate \mathbf{w}_* and $\tilde{\mathbf{w}}$. Based on the approximate \mathbf{D} and Σ , we can choose b examples from \mathcal{U} which minimizes the upper bound. Then we will use these newly labeled b examples together with existing labeled examples to update the classifier. After that, we may get better approximations to \mathbf{D} and Σ . This process is repeated until the label budget is used out.

More specifically, in the t -th iteration, we have labeled set \mathcal{L} and unlabeled set \mathcal{U} . We also have the classifier $\widehat{\mathbf{w}}_t$, based on which we can get approximations of \mathbf{D} and Σ . Then we are going to choose the next b examples by minimizing the following criterion,

$$\arg \min_{\mathcal{B} \subset \mathcal{U}} \text{tr} \left(\Sigma^{\frac{1}{2}} \mathbf{V}^\top (\lambda \mathbf{I} + \mathbf{X}_{\mathcal{B}} \mathbf{D}_{\mathcal{B}} \mathbf{X}_{\mathcal{B}}^\top)^{-1} \mathbf{V} \Sigma^{\frac{1}{2}} \right),$$

where we absorb $1/n$ into λ . By introducing $\tilde{\mathbf{v}}_j = \sqrt{\Sigma_{jj}} \mathbf{v}_j$ and $\tilde{\mathbf{x}}_i = \sqrt{D_{ii}} \mathbf{x}_i$, the above optimization problem can be simplified as

$$\arg \min_{\mathcal{B} \subset \mathcal{U}} \text{tr} \left(\tilde{\mathbf{V}}^\top (\lambda \mathbf{I} + \tilde{\mathbf{X}}_{\mathcal{B}} \tilde{\mathbf{X}}_{\mathcal{B}}^\top)^{-1} \tilde{\mathbf{V}} \right). \quad (5)$$

It is a combinatorial optimization problem. Similar problems have been encountered in previous work [29]. One way to solve it is applying the sequential minimization algorithm derived in [29] b times, to get a batch \mathcal{B} . However, this sacrifices the advantage of batch-mode active learning, because it neglects the information overlap among examples. Another way is formulating it as a semi-definite programming [9], which is computationally very expensive. Here, we do some relaxation and use the projected gradient descent to solve it, following the idea adopted in [14].

3.2 OPTIMIZATION

We introduce a selection matrix $\mathbf{S} \in \mathbb{R}^{|\mathcal{U}| \times b}$, which is defined as

$$S_{ij} = \begin{cases} 1, & \text{if the } i\text{-th example in } \mathcal{U} \text{ is selected} \\ & \text{as the } j\text{-point in } \mathcal{B} \\ 0, & \text{otherwise.} \end{cases}$$

It is easy to check that each column of \mathbf{S} has one and only one 1, and each row has at most one 1. We denote the constraint set for \mathbf{S} by $\mathcal{S}_1 = \{\mathbf{S} | \mathbf{S} \in \{0, 1\}^{|\mathcal{U}| \times b}, \mathbf{S}^\top \mathbf{S} = \mathbf{I}\}$.

With \mathbf{S} , we have $\tilde{\mathbf{X}}_B = \tilde{\mathbf{X}}\mathbf{S}$. Then Eq. (5) can be simplified as

$$\arg \min_{\mathbf{S} \in \mathcal{S}_1} \text{tr} \left(\tilde{\mathbf{V}}^\top (\lambda \mathbf{I} + \tilde{\mathbf{X}}\mathbf{S}\mathbf{S}^\top \tilde{\mathbf{X}}^\top)^{-1} \tilde{\mathbf{V}} \right).$$

The above optimization problem is almost continuous, except the constraint set \mathcal{S}_1 . In order to apply continuous optimization algorithms, we relax it into the following continuous domain, i.e., $\mathcal{S}_2 = \{\mathbf{S} | \mathbf{S} \geq 0, \mathbf{S}^\top \mathbf{S} = \mathbf{I}\}$.

Since the projection onto $\{\mathbf{S} : \mathbf{S}^\top \mathbf{S} = \mathbf{I}\}$ is computationally expensive, we would like to design an algorithm in which the constraint $\mathbf{S}^\top \mathbf{S} = \mathbf{I}$ is automatically satisfied after each gradient descent. To cope with $\mathbf{S}^\top \mathbf{S} = \mathbf{I}$, we introduce a Lagrange multiplier $\mathbf{\Lambda} \in \mathbb{R}^{b \times b}$, and write down the Lagrangian function as

$$L(\mathbf{S}) = \text{tr} \left(\tilde{\mathbf{V}}^\top (\lambda \mathbf{I} + \tilde{\mathbf{X}}\mathbf{S}\mathbf{S}^\top \tilde{\mathbf{X}}^\top)^{-1} \tilde{\mathbf{V}} \right) + \text{tr} (\mathbf{\Lambda} (\mathbf{S}^\top \mathbf{S} - \mathbf{I})).$$

The derivative of $L(\mathbf{S})$ with respect to \mathbf{S} is

$$\frac{\partial L}{\partial \mathbf{S}} = -2\tilde{\mathbf{X}}^\top \mathbf{B} \tilde{\mathbf{X}} \mathbf{S} + 2\mathbf{S} \mathbf{\Lambda}, \quad (6)$$

where $\mathbf{B} = \mathbf{A}^{-1} (\tilde{\mathbf{V}} \tilde{\mathbf{V}}^\top) \mathbf{A}^{-1}$ and $\mathbf{A} = \lambda \mathbf{I} + \tilde{\mathbf{X}}\mathbf{S}\mathbf{S}^\top \tilde{\mathbf{X}}^\top$. Using the fact that $\mathbf{S}^\top \mathbf{S} = \mathbf{I}$ yields $\mathbf{\Lambda} = \mathbf{S}^\top \tilde{\mathbf{X}}^\top \mathbf{B} \tilde{\mathbf{X}} \mathbf{S}$. Substituting the Lagrange multiplier $\mathbf{\Lambda}$ back into Eq. (6), we obtain the derivative depending solely on \mathbf{S} . Then following [14], we can use projected gradient descent to find a local optimal solution for Eq. (6), where the projection is only onto $\{\mathbf{S} : \mathbf{S} \geq 0\}$. After the local optimal \mathbf{S}^* is obtained, we can discretize it to obtain the desired solution. The analysis of the gap between the local optima and the global optima is challenging and perhaps an open problem. It may be helpful to realize that \mathcal{S}_2 is a matching polytope [23] for such kind of analysis.

In summary, we present the whole algorithm for active learning based on error bound minimization in Algorithm 1. Since our algorithm is designed from logistic regression, we call it **Logistic Bound**. In the special case that $b = 1$, i.e., fully sequential active learning, we do not need to use projected gradient descent in each iteration. In that case, we can find the best single example by sorting.

We emphasize that α in Theorem 2 is some parameter within $[0, 1]$. This parameter comes from the mean value theorem in the derivation. It is not a parameter of our algorithm, because we use $\hat{\mathbf{w}}$ to approximate $\tilde{\mathbf{w}}$ in Algorithm 1. So we do not need to tune α at all.

Algorithm 1 Batch-Mode Active Learning Based on Error Bound Minimization (Logistic Bound)

Input: \mathbf{X}, \mathbf{V} , number of iterations T , batch size b , regularization parameter λ , initial labeled set \mathcal{L} and unlabeled set \mathcal{U} ;

for $t = 1 \rightarrow T$ **do**

 Compute $\hat{\mathbf{w}}_t$ based on \mathcal{L} ;

 Compute \mathbf{D} and $\mathbf{\Sigma}$ based on Eqs. (3) and (4);

 Compute $\mathcal{B} \subset \mathcal{U}$ based on Eq. (5);

 Update $\mathcal{L} = \mathcal{L} \cup \mathcal{B}$ and $\mathcal{U} = \mathcal{U} \setminus \mathcal{B}$;

end for

3.3 TIME COMPLEXITY

In this subsection, we analyze the time complexity of the proposed active learning algorithm. The computation of Eq. (6) involves \mathbf{A}^{-1} , which is the inverse of a $d \times d$ matrix. However, we do not need to compute it directly. Since $\mathbf{A}^{-1} = (\lambda \mathbf{I} + \mathbf{X}\mathbf{S}\mathbf{S}^\top \mathbf{X}^\top)^{-1}$, by applying the Woodbury matrix identity, we have $\mathbf{A}^{-1} = 1/\lambda \mathbf{I} - 1/\lambda \mathbf{X}\mathbf{S}(\lambda \mathbf{I} + \mathbf{S}^\top \mathbf{X}^\top \mathbf{X}\mathbf{S})^{-1} \mathbf{S}^\top \mathbf{X}^\top$. Thus we only need to calculate the inverse of $(\lambda \mathbf{I} + \mathbf{S}^\top \mathbf{X}^\top \mathbf{X}\mathbf{S})$, whose size is $b \times b$, where b is the batch size. So the time complexity of computing the gradient in Eq. (6) can be reduced to $O(ndb + db^2 + b^3)$, which is dominated by $O(ndb)$ because b is often set to 5 to 50. The total complexity of the projected gradient descent is $O(ndbt)$, where t is the iteration number. The time complexity is clearly linear to the sample size n , and the dimension of the input space d .

4 RELATED WORK

In this section, we show the connections of the proposed approach with some existing active learning methods.

One thread of related work is experimental design [2]. For instance, Yu et al. [29] proposed transductive experimental design (TED), whose intent is to select the examples to learn a least squares regression function which has minimum prediction variance on the validation data. As we mentioned before, it is a *non-adaptive* active learning method, because the label information of the selected examples cannot be utilized to select subsequent unlabeled examples. Intuitively, taking into account the labels of queried examples is beneficial for subsequent label query. Our method is able to utilize the labeled examples obtained up to now to choose the next batch of examples through \mathbf{D} and $\mathbf{\Sigma}$. Recall that in our method, each example in the pool is weighted by $D_{ii} = \sigma(\hat{\mathbf{w}}^\top \mathbf{x}_i)(1 - \sigma(\hat{\mathbf{w}}^\top \mathbf{x}_i))$. Apparently, the more uncertain an example is, the bigger its weight will be (because D_{ii} is maximized when $\sigma(\hat{\mathbf{w}}^\top \mathbf{x}_i) = 1/2$). In the special case, if $\sigma(\hat{\mathbf{w}}^\top \mathbf{x}_i) = 1/2$ for every example in the pool, then all the examples are equally weighted, and our method will degrade to TED. By applying the derivation technique to ridge regression, we

can obtain a very similar result to [29]. However, using the derivation technique from experimental design, we cannot get the results in this paper. So the derivation technique used in this paper is more general.

The second line of related work is active learning based on logistic regression [30, 26]. Based on the asymptotic analysis, Zhang and Oles [30] derived the inverse of the Fisher information matrix of the maximum likelihood estimation (MLE) of logistic regression, which measures the variance of model. Thus they proposed an active learning criterion by minimizing the variance. Our criterion derived in Theorem 2 is from finite sample analysis, which is non-asymptotic and different from the criterion derived in [30]. Since finite sample error bounds characterize the behavior of a classifier provided with a finite training sample, they provide more accurate guidance on algorithm design than asymptotic analysis. Following this seminal work, several incremental studies were presented, which solve the same criterion using different sophisticated optimization algorithms. For example, Hoi et al. [20] proposed to reformulate it as a submodular function maximization problem. On the other hand, Guo and Schuurmans [17] proposed a batch-mode active learning algorithm based on logistic regression, by maximizing the likelihood on the labeled training sample and minimizing the entropy on the selected unlabeled training sample. The main innovation lies in the optimization part rather than the theoretical results.

The last but not least related work is the family of expected error minimization-based approaches. Recently, Gu et al. [14] proposed an active learning method based on minimizing the out-of-sample error bound for Laplacian regularized least squares (LapRLS) [6], a semi-supervised version of least squares regression. It sheds light on designing active learning algorithms via deriving certain kind of error bounds, which do not rely on the i.i.d assumption of the training sample nor the class labels. The method is non-adaptive¹, raising a question that whether we can design an adaptive active learning algorithm along this line. Our result in this paper is in the affirmative. However, the linear regression model as well as the derivation technique used there are not capable to achieve this goal. So we study logistic regression with a new analyzing technique instead. Note also that in the supervised case, the methods proposed in [14] and [29] are identical in terms of the criterion.

¹It is nonadaptive, in the sense that when the model (\hat{w}) is updated using the newly labeled examples, the algorithm is not able to use the information from the updated model (\hat{w}) to choose next batch of examples to label. In fact, the active learning algorithm in [14] does not use any information from \hat{w} in the process of active learning, because its criterion does not depend on \hat{w} .

5 EXPERIMENTS

In this section, we evaluate the proposed method on both UCI datasets [3] (wdbc, wpbc, sonar, heart, australian, diabetes, splice) and two text datasets (Text1 and Text2) generated from the famous 20-newsgroups data set². For the text datasets, the original number of features (words) is 8,014. We apply principal component analysis (PCA) to reduce the input dimensionality by projecting the data onto its leading principal components, where the number of principal component is determined such that it accounts for 95% of its total variance. For each example, we normalize it into a vector with unit ℓ_2 -norm.

5.1 EXPERIMENTAL SETUP AND BASELINES

In order to randomize the experiments, in each run of experiments, we use 50% data as the training examples. The remaining 50% data is used as test set. We use the training set for active learning and evaluate the prediction performance on the fixed test set. This random split was repeated 20 times, thus we can do statistical significance test. We study a difficult case of active learning, where we start with one randomly selected example per class. All the algorithms start with the same initial labeled set, unlabeled set and test set.

To demonstrate the effectiveness of our proposed method, we compare it with existing state-of-the-art algorithms, including one fully sequential active learning approach, one non-adaptive active learning algorithm, and three batch-mode active learning methods. We summarize these methods as follows:

Random Sampling (**Random**): It is the simplest baseline, which uniformly selects examples from the candidate set as training data.

Query the informative and representative examples (**QUIRE**) [22]: it is a fully sequential active learning algorithm.

Transductive experiment design (**TED**) [29]: it is a non-adaptive active learning method. Note that it selects all the examples to label at one shot.

SVM batch-mode active learning (**SVM BMAL**) [21]: in our empirical study, we found that it consistently outperforms SVM active learning [27], so we only demonstrate its results while omit the results of SVM active learning. We use linear kernel for SVM. In fact, SVM active learning can be seen as a special case of SVM BMAL, where the batch size is equal to 1.

Discriminative batch-mode active learning (**Disc**) [17]: it is a batch-mode active learning algorithm based on logistic regression.

Fisher information of logistic regression (**Fisher**) [20]: It is also a batch-mode active learning based on logistic regression. However, it is derived from non-asymptotic analysis of logistic regression.

For our method, the validation set \mathbf{V} is set to the same as the pool of unlabeled examples. Recall that our method does not require the labels of the validation set either.

For each dataset, we let the active learning methods incrementally choose $b = 5$ examples to label, and perform $T = 20$ iterations in total (except for wpbc, where we only perform $T = 19$ iterations due to limited examples). We did not compare with [16], because we were not able to acquire a working implementation of this algorithm. According to the experimental results (Table 1) reported in [16], its performance is statistically similar to Disc [17]. We did not use semi-supervised classifiers. Hence the approach proposed in [14] reduces to TED. Most of the implementations are provided by the authors of the corresponding papers.

One issue with most of the active learning methods we investigated is that they are invented based on different classifiers. For example, TED is designed for ridge regression. Disc and Fisher are developed based on logistic regression. We use different classifiers for different active learning approaches, because we found that using the classifier based on which the active learning method is derived can lead to better results than using other classifiers. Furthermore, for each active learning method, its parameter and the parameter of its corresponding classifier are tuned by 5-fold cross validation on the labeled set through searching the grid $\{10^{-3}, 10^{-2}, \dots, 10^3\}$.

5.2 RESULTS AND DISCUSSIONS

The experimental results are shown in Figure 1. In all sub-figures, the x-axis represents the number of labeled examples, while the y-axis is the averaged classification accuracy on the test data over 20 runs.

We compare all the active learning methods during the entire query process. Recall that in Figure 1, there are 20 query points (except for wpbc, which has only 19), with 20 results on each of them. We therefore run a 2-sided paired t-test at each query point, at 95% significance level. The results of t-test can be categorized into three cases: (i) our method outperforms a specific algorithm significantly, denoted by “win”; (ii) our method is significantly worse than a specific algorithm, denoted by “lose”; (iii) otherwise, denoted by “tie”. We summarize the t-test results in terms of the count of “win”, “tie” and “lose” in Table 1.

We observe that the proposed method outperforms the other methods significantly at most cases. SVM_BMAL and QUIRE are often the worst. The reason is probably that their criteria are not related to prediction performance. The

performance of Disc is satisfactory. Yet it performs well on some datasets while not very well on other datasets. The performance of TED and Fisher are comparable. Although TED aims to minimize the variance of prediction, [14] showed that it is actually consistent with minimizing the out-of-sample error of ridge regression. This explains its good performance. However, since TED is a nonadaptive active learning method, it cannot fully utilize the label information during the query process. This limits its performance on many datasets. Fisher minimizes the uncertainty of the model, which does not necessarily lead to small generalization error. However, it happens that the uncertain reduction criterion for logistic regression derived in [30] is a little similar to our criterion. This may interpret its general good performance. The superior performance of our method is attributed to its theoretical foundation, which guarantees that the classifier can achieve small prediction error on the unseen data. Lastly, we found that the performance of random sampling is not bad. As an unbiased label selection procedure, random sampling is at least a consistent algorithm to choose the training sample, as is widely done in passive learning. This is consistent with the result reported in [17].

5.3 STUDY ON THE BATCH SIZE

In previous experiments, we fixed the batch size to 5, which could be biased in comparison. So we will compare our method with those batch-mode active learning algorithms under different settings of batch size here. We vary the batch size using the grid $\{1, 5, 10, 20, 30, 60\}$ and show the results with 60 labeled examples in Figure 2. We only show the results on three datasets (Sonar, Heart and Text1). Similar results can be observed on the other datasets.

It can be seen that under different batch sizes, our method outperforms the other batch-mode active learning algorithms in most cases. This strengthens the superiority of our method over the others. In addition, we also observe some interesting results. For example, for some batch-mode active learning algorithms such as SVM_BMAL and Disc, their performance of using a batch size of more than one example sometimes seems not as good as choosing a single example at each round. This implies that they may not be able to address the information overlap among examples very well. In contrast, our method is able to exploit the interdependence among examples, because our method usually achieves better results with batch-size larger than one.

In addition, we found that our method obtains the best result when the batch size is either not too small ($b = 1$) nor too large ($b = 60$). This is quite reasonable, because when $b = 1$, it is a fully sequential strategy, and we cannot utilize the dependence among examples. On the contrary, if the batch size is too large (such as one-short active learning in

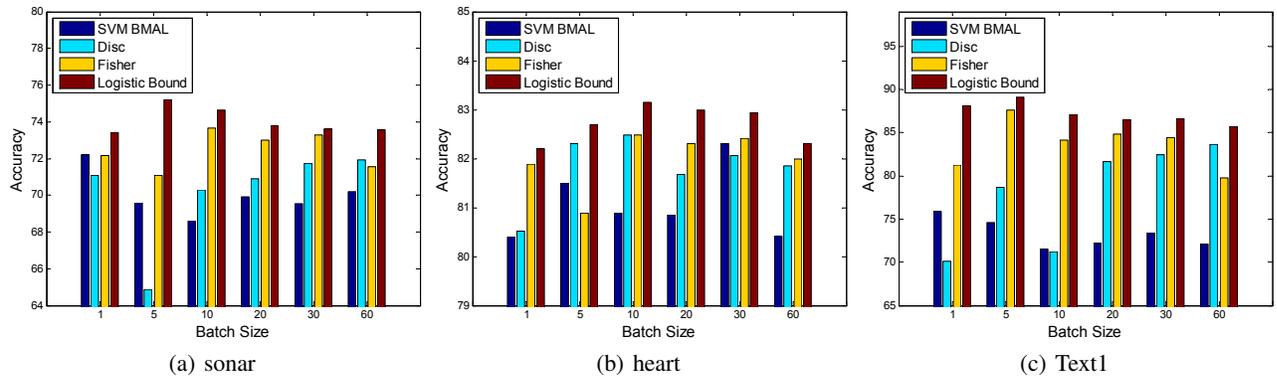

Figure 2: Comparison of batch-mode active learning methods on three datasets with different batch size ranging from $b = 1$ to $b = 60$. The x-axis represents the batch size, and the y-axis is the classification accuracy (%) with 60 labeled examples.

the extreme SVM case), the information contained in the newly labeled examples cannot be immediately exploited through updating the classifier, which may limit its performance. This somehow implies the superiority of batch-mode active learning against both fully sequential and one-shot active learning. It also suggests us to choose a medium size of batch in practice. More rigorous analysis is required in the future work.

6 CONCLUSIONS AND FUTURE WORK

In this paper, we present a novel active learning method based on out-of-sample error bound minimization. We use logistic regression as a running example to derive the algorithm. We would like to emphasize that the derivation technique developed in this paper applies to other generalized linear models, or even more sophisticated graphical models. In our future work, we will study these alternatives. We also plan to conduct comparisons with some other batch-mode active learning methods proposed recently [4, 10, 28]. On the other hand, we aim to develop an algorithm solving Eq. (5) with provable guarantee.

Abstract

This paper presents a Bayesian generative model for dependent Cox point processes, alongside an efficient inference scheme which scales as if the point processes were modelled independently. We can handle missing data naturally, infer latent structure, and cope with large numbers of observed processes. A further novel contribution enables the model to work effectively in higher dimensional spaces. Using this method, we achieve vastly improved predictive performance on both 2D and 1D real data, validating our structured approach.

1 INTRODUCTION

Point processes are effectively used to model a variety of event data, and have also shown a recent popularity within the Machine Learning community as priors over sets. The most fundamental example of such a stochastic model for random sets is the homogenous Poisson process. This is defined via an intensity which describes the expected number of points found in any bounded region of some arbitrary domain. An inhomogenous Poisson process allows the intensity to vary throughout the domain over which the process is defined. As we do not know the functional form of this intensity given only event data, another stochastic process is typically used to model it nonparametrically. This is then termed a doubly-stochastic Poisson process, a type of renewal process also known as a Cox process. In our particular construction, we use transformed Gaussian processes to model the intensity functions of the individual dependent point processes, in such a manner as to enable fully nonparametric Bayesian inference (Adams et al., 2009; Murray et al., 2010). While we only explicitly consider the doubly

stochastic Poisson process, any general renewal process (Rao and Teh, 2011) could be incorporated into the framework we define.

There are many occasions when we have multiple point processes which we expect to be dependent: If the domain is temporal, then an example would be individual clients making trades with a specific financial services provider, or individual customers purchasing items from a specific vendor. If the domain is spatial, we might consider different categories of crime defined over some geographic region. Defining a flexible model for inter-process dependency structure, alongside an efficient inference scheme allows us to learn the underlying intensity functions which drive the typical behaviour. These can then be used to make more accurate predictions, especially during periods of unobservability for an individual process.

In order to maximise the flexibility of our approach, we specifically assume that the individual intensity functions arise via a weighted summation of convolutions of latent functions with a kernel. Intuitively this means that we take a small number of latent functions, individually smooth and scale them, and then add them together to yield an intensity function. This approach allows a wide range of intensities to arise from only a few latent functions.

We will present and validate the following novel contributions:

- The first generative model for dependent Cox process data (Section 2).
- An efficient, parallelised inference scheme, which scales benignly with the number of observed point processes (Section 3).
- A new adaptation of thinning (Lewis, 1979), which we term ‘adaptive thinning’. This introduces multiple uniformisation levels over the space, making the model viable for higher dimensional spaces and larger datasets (Section 4).

2 THE MODEL

We first formally review the Cox process, before describing the innovative nonparametric Bayesian model outlined in Adams et al. (2009) as the Sigmoidal Gaussian Cox Process (SGCP), which allows a full Gaussian process to be used as a prior over an individual intensity function. We then move on to review the convolution process (Álvarez and Lawrence, 2011), a method of modelling dependent functions and the underlying latent processes which govern them. Our novel combination of these constituent elements represents the first model for dependent Cox point processes.

2.1 THE INHOMOGENOUS POISSON PROCESS

For a domain $\mathcal{X} = \mathbb{R}^D$ of arbitrary dimension D , we may define an inhomogenous Poisson process via an intensity function $\lambda(x) : \mathcal{X} \rightarrow \mathbb{R}^+$, and a Lebesgue measure over the domain, dx . The number of events $N(\mathcal{T})$ found over a subregion $\mathcal{T} \subset \mathcal{X}$ will be Poisson distributed with parameter $\lambda_{\mathcal{T}} = \int_{\mathcal{T}} \lambda(x) dx$. Furthermore, we define $N(\mathcal{T}_i)$ to be independent random variables, where \mathcal{T}_i are disjoint subsets of \mathcal{X} (Kingman, 1993).

If we bound the region to be considered, and assume there are K observed events, labelled as $\{x_k\}_{k=1}^K$, then the inhomogenous Poisson process likelihood function may be written as

$$p(\{x_k\}_{k=1}^K | \lambda(x)) = \exp \left\{ - \int_{\mathcal{T}} dx \lambda(x) \right\} \prod_{k=1}^K \lambda(x_k). \quad (1)$$

2.2 THE SIGMOIDAL GAUSSIAN COX PROCESS

In order to model the intensity nonparametrically, we place a Gaussian Process (Rasmussen and Williams, 2006) prior over a random scalar function $g(x) : \mathcal{X} \rightarrow \mathbb{R}$. This means that the prior over any finite set of function values $\{g(x_n)\}_{n=1}^N$ is a multivariate Gaussian distribution, defined by a positive definite covariance function $C(.,.) : \mathcal{X} \times \mathcal{X} \rightarrow \mathbb{R}$ and a mean function $m(.) : \mathcal{X} \rightarrow \mathbb{R}$. The mean and covariance function are parameterised by a set of hyperparameters, which we denote γ .

In the SGCP, a Gaussian Process is transformed into a prior over the intensity function by passing it through a sigmoid function and scaling it against a maximum intensity λ^* : $\lambda(x) = \lambda^* \sigma(g(x))$, where $\sigma(.)$ is the logistic function. This forms the basis of a generative prior, whereby exact Poisson data can be generated from $\lambda(x)$ via thinning (Lewis, 1979), which involves

adding M events, such that the joint point process over the $M + K$ events is homogenous with fixed rate λ^* .

As we are using an infinite dimensional proxy for $\lambda(x)$, the integral in Equation 1 is intractable. Furthermore, using Bayes' theorem with this likelihood yields a posterior with intractable integrals in both the numerator and denominator. These challenges are overcome by making use of the generative prior, and augmenting the variable set to include the number of thinned points, M , and their locations, $\{\tilde{x}_m\}_{m=1}^M$. This then means that the value of the intensity function need only be inferred at the $M + K$ point locations, $\mathbf{g}_{M+K} = \{g(x_k)\}_{k=1}^K \cup \{g(\tilde{x}_m)\}_{m=1}^M$. Noting that $\sigma(-z) = 1 - \sigma(z)$, the joint likelihood over the data, function values and latent variables is

$$\begin{aligned} p(\{x_k\}_{k=1}^K, M, \{\tilde{x}_m\}_{m=1}^M, \mathbf{g}_{M+K} | \lambda^*, \mathcal{T}, \theta) = \\ (\lambda^*)^{M+K} \exp \{-\lambda^* \mu(\mathcal{T})\} \\ \times \prod_{k=1}^K \sigma(g(x_k)) \prod_{m=1}^M \sigma(-g(\tilde{x}_m)) \\ \times \mathcal{GP}(\mathbf{g}_{M+K} | \{x_k\}_{k=1}^K, \{\tilde{x}_m\}_{m=1}^M, \gamma), \quad (2) \end{aligned}$$

where we have defined $\mu(\mathcal{T}) = \int_{\mathcal{T}} dx$.

Notably, this likelihood equation does not involve any intractable integrals. This means that inference is now possible in this model, albeit subject to the cost of an augmented variable set.

2.3 THE CONVOLUTION PROCESS

The convolution process framework is an elegant way of constructing dependent output processes. Instead of assuming the typical instantaneous (Teh et al., 2005) mixing of a set of independent processes to construct correlated output processes, we generalise to allow a blurring of the latent functions achieved via convolution with a kernel, $G(x, z)$, prior to mixing. z is typically defined on the same domain as x . If we place a Gaussian process prior over the latent function, the output function turns out to also be a Gaussian process (Álvarez and Lawrence, 2011). Specifically, given D dependant intensity functions $g_d(x)$ and Q latent processes $u_q(x)$, (where typically $Q < D$), the stochastic component of the d th intensity is

$$g_d(x) = \sum_{q=1}^Q \int_{\mathcal{T}} G_d(x, z) u_q(z) dz. \quad (3)$$

Given full knowledge of the latent functions, the $g_d(x)$ are independent and deterministic. The $G_d(x, z)$ encode the observed process specific characteristics, and the $u_q(z)$ can be thought of as encoding the latent driving forces.

The convolution process has strong links with the Bayesian kernel method, as described in (Pillai et al., 2007). This allows a function $f(x)$ on \mathcal{X} to arise as

$$f(x) = \int_{\mathcal{X}} K(x, z)U(dz), \quad (4)$$

where $U(dz) \in \mathcal{M}(\mathcal{X})$ is a signed measure on \mathcal{X} . The integral operator $\mathcal{L}_K : U(dz) \rightarrow f(x)$ maps the space of signed measures $\mathcal{M}(\mathcal{X})$ into \mathcal{H}_K , a reproducing kernel Hilbert space (RKHS) defined by the kernel, $K(x, z)$. This mapping is dense in \mathcal{H}_K . If we place a Gaussian process prior on the random signed measure $U(dz)$, rather than directly over $f(x)$, then any draw of $f(x)$ will provably lie in \mathcal{H}_K . As \mathcal{H}_K is equivalent to the span of functions expressible as kernel integrals, this approach allows us to properly construct distributions over specific parts of function space. Using prior domain knowledge to restrict inference to plausible areas of function space is valuable, particularly for point process intensities where the likelihood linking function to data is weak and non-trivial, and we wish to only consider smooth intensities while using a sampling based inference scheme.

The convolution process is also known as a latent force model (Alvarez et al., 2009). In this guise, it is used to infer the solution of a differential equation when there is uncertainty in the forcing function. The convolution kernel is the Green’s function of a particular differential equation, and the Gaussian process prior is placed on the driving function. This representation lets us consider the latent functions as driving forces, which are viewed through the intensity function specific convolution kernel. The convolution kernel can, for example, be used to model differing speeds of information propagation from the latent factors to each of the observed processes.

It is worth noting that any general Lévy process prior can be used over the latent functions, however in this particular case we use a pure Gaussian process primarily for reasons of tractability.

2.4 SPARSE LATENT FUNCTIONS

To make the model tractable, we make use of the property that the intensities are independent conditioned on the latent functions. This is made clear from the perspective of a generative model with only one latent function: we first draw a sample of the object $u(z)$, before solving the integral in equation 3, where uncertainty about $u(z)$ is propagated through the convolution. Now instead of maintaining the full, infinite dimensional object $u(z)$, let us condition on a finite dimensional draw of $u(z)$, $u(Z) = [u(z_1), \dots, u(z_J)]^T$ where $Z = \{z_j\}_{j=1}^J$. We can then sample from $p(u(z) | u(Z))$, as this is a conditional Gaussian distribution,

and use this function to solve the convolution integral. With multiple latent functions we can approximate each $u_q(z)$ by $\mathbb{E}[u_q(z) | u_q(Z)]$, replacing Equation 3 with

$$g_d(x) \approx \sum_{q=1}^Q \int_{\mathcal{X}} G_d(x, z) \mathbb{E}[u_q(z) | u_q(Z)] dz. \quad (5)$$

This is reasonable as long as each $u_q(z)$ is smooth, in the sense that it is well approximated given the covariance function and the finite dimensional sample $u_q(Z)$. In Section 3, we use the approximation in Equation 5 along with the conditional independence assumption to build a tractable inference scheme.

2.5 CONSTRUCTING THE MODEL

Let the Q latent functions $u_q(z)$ be modelled as Gaussian processes with Gaussian covariance functions such that

$$u_q | \phi_q \sim \mathcal{GP}(0, K_q(z, z')), \quad (6)$$

where $K_q(z, z')$ is simply the Gaussian kernel

$$K_q(z, z') = \mathcal{N}(z; z', \phi_q). \quad (7)$$

We use a scaled Gaussian convolution kernel

$$G_d(x, z) = \kappa_d \mathcal{N}(x; z, \theta_d). \quad (8)$$

This restricts $g_d(x)$ to be at least as smooth as the random draws from $u_q(z)$. The covariance linking $u_q(z)$ to $g_d(x)$ is

$$\begin{aligned} K_{f_d, u_q}(x, z) &= \int_{\mathcal{X}} G_d(x, z) K_q(z, z') dz \\ &= \kappa_d \mathcal{N}(x; z, \theta_d + \phi_q), \end{aligned} \quad (9)$$

and the overall covariance between output functions is

$$\begin{aligned} K_{f_d, f_{d'}}(x, x') &= \sum_{q=1}^Q \int_{\mathcal{X}} G_d(x, z) \\ &\quad \int_{\mathcal{X}} G_{d'}(x', z') K_q(z, z') dz' dz \\ K_{f_d, f_{d'}}(x, x') &= \sum_{q=1}^Q \kappa_d \kappa_{d'} \mathcal{N}(x; z, \theta_d + \theta'_{d'} + \phi_q). \end{aligned} \quad (10)$$

We could use this joint covariance function to construct one large joint Gaussian process over all the intensity functions. In doing this, however, the $u_q(z)$ have been implicitly integrated out, and the resulting inference problem will scale computationally as $\mathcal{O}(D^3 N^3)$ with storage requirements of $\mathcal{O}(D^2 N^2)$, where $N = M + K$ is the joint number of events. This

is intractable for any real problem, where we would hope to leverage many dependent point processes to learn a few latent factors with minimal uncertainty.

Let us now define some additional notation: \mathbf{K} denotes a covariance matrix obtained by evaluating the appropriate covariance function at all eligible pairs of data points. Subscripts determine which covariance is used and hence which inputs are valid, e.g. \mathbf{K}_{g_d, u_q} denotes the cross covariance between the d th output and q th input function. $\mathbf{K}_{g_d, u}$ means stack the Q \mathbf{K}_{g_d, d_q} matrices vertically, $\mathbf{K}_{u, u}$ is a block diagonal matrix where each block corresponds to \mathbf{K}_{u_q, u_q} , and \mathbf{u} is the result of stacking the draws from the finite dimensional Gaussians $p(u_q(Z))$ vertically.

We also define: $\phi = \{\phi_q\}_{q=1}^Q$, $\kappa = \{\kappa_d\}_{d=1}^D$, $\theta = \{\theta_d\}_{d=1}^D$, $X_d = \{x_{d,k}\}_{k=1}^{K_d} \cup \{\tilde{x}_{d,m}\}_{m=1}^{M_d}$. If we wish to allow the latent functions to be sampled at different points, then we define a separate Z_q for each $u_q(z)$: $Z_q = \{z_{q,j}\}_{j=1}^J$. The set of inputs over all latent functions is then $Z = \{Z_q\}_{q=1}^Q$, and similarly for the intensities: $X = \{X_d\}_{d=1}^D$.

Notation in place, we determine that given the approximation in Equation 5, the conditional likelihood for $g_d(x)$ is

$$p(g_d | u, Z, X_d, \kappa_d, \theta_d, \phi) = \mathcal{N}(\mathbf{K}_{g_d, u} \mathbf{K}_{u, u}^{-1} \mathbf{u}, \mathbf{K}_{g_d, g_d} - \mathbf{K}_{g_d, u} \mathbf{K}_{u, u}^{-1} \mathbf{K}_{g_d, u}^T). \quad (11)$$

Still conditioning on the latent functions, the joint likelihood over all D intensity functions is then simply

$$p(g_1, \dots, g_D | u, Z, X, \kappa, \theta, \phi) = \prod_{d=1}^D p(g_d | u, Z, X_d, \kappa_d, \theta_d, \phi). \quad (12)$$

Bayes' rule for Gaussians gives us the posterior over the $u_q(Z)$ as

$$p(u_1, \dots, u_Q | g_1, \dots, g_D, Z, X, \kappa, \phi, \theta) = \mathcal{N}(u_1, \dots, u_Q; \mu_p, \Sigma_p). \quad (13)$$

Where the mean and covariance are

$$\begin{aligned} \Sigma_p &= [\mathbf{K}_{u, u}^{-1} + (\mathbf{K}_{g, u} \mathbf{K}_{u, u}^{-1})^T \mathbf{D}^{-1} (\mathbf{K}_{f, u} \mathbf{K}_{u, u}^{-1})]^{-1} \\ \mu_p &= \Sigma_p (\mathbf{K}_{g, u} \mathbf{K}_{u, u}^{-1})^T \mathbf{D}^{-1} \mathbf{g} \end{aligned} \quad (14)$$

and where $\mathbf{D} = \mathbf{K}_{g, g} - \mathbf{K}_{g, u} \mathbf{K}_{u, u}^{-1} \mathbf{K}_{g, u}^T$.

The exact form of \mathbf{D} depends on the degree to which we are willing make independence assumptions in order to approximate the Gaussian processes used to model the functions. Naturally the higher the degree of approximation, the more scalable the resulting inference scheme.

Under full dependence, a single event is linked to both inter and intra-process data. We will be assuming that the dependency structure across the $g_d(x)$ is entirely contained by the latent processes, $u_q(z)$. Intuitively, this means that we maintain the full Gaussian process structure for each individual intensity function, while summarising the latent functions via a set of inducing inputs $Z = \{z_j\}_{j=1}^J$. This approximation scheme results in a functional form which is similar to what Quiñonero Candela and Rasmussen (2005) call the Partial Independence (PITC) scheme. Importantly it allows inference to scale computationally as $\mathcal{O}(DN^3)$, with storage requirements of $\mathcal{O}(DN^2)$ even in the worst case scenario of $J = N$. Further approximations may be made, and these are especially useful if the number of events per process is large, however for our purposes they are not necessary. For more information on approximation methods for Gaussian processes see Quiñonero Candela and Rasmussen (2005) and Snelson and Ghahramani (2005).

Under the PITC low rank covariance, the resulting form for \mathbf{D} is: $[\mathbf{K}_{g, g} - \mathbf{K}_{g, u} \mathbf{K}_{u, u}^{-1} \mathbf{K}_{g, u}^T] \circ \mathbf{M}$, where $\mathbf{M} = \mathbf{I}_N \otimes \mathbf{1}_N$ and $\mathbf{1}_N$ is a $N \times N$ matrix of ones. This may be more familiar as `blkdiag[D]`.

3 INFERENCE

For each of the D point processes we need to learn $|X_d|$, X_d , κ_d , θ_d , λ_d^* and $g_d(x)$. For each of the Q latent functions $u_q(Z)$ and ϕ_q must be inferred. Z_q are fixed to an evenly spaced grid which is identical across the latent processes. To find posteriors over all these variables, we choose a Markov Chain Monte Carlo (MCMC) algorithm, as detailed below.

Using the PITC approximation scheme, the likelihood over the point processes factorises conditioned on the latent functions. This means that given D compute units the updates associated with each point process may be made in parallel. This is important as the inference algorithm is computationally bottlenecked by operations associated with learning the locations of the thinning points, X .

We now give a recap of the inference scheme from the SGCP for a single point process, while listing our minor modifications. Updates for the latent functions are then given, conditioning on the D intensity functions.

3.1 LEARNING THE INTENSITY FUNCTION

Recalling Equation 2, three kinds of Markov transitions are used to draw from this joint distribution: 1) Sampling the number of thinned points, M . 2) Sampling the locations of the thinned events, $\{\tilde{x}_m\}_{m=1}^M$. 3) Resampling the intensity function, $\mathbf{g}_{\mathbf{M}+\mathbf{K}}$.

Metropolis-Hastings is used to sample M . The probability of insertion/deletion is parameterised by a Bernoulli proposal function: $b(K, M) : \mathbb{N} \times \mathbb{N} \rightarrow (0, 1)$, where the parameter has been arbitrarily set to $\frac{1}{2}$. If an insertion is required, a new x_{M+1} is drawn uniformly and at random from $\mu(\mathcal{T})$, and $g(x_{M+1})$ is drawn from the Gaussian process conditioned on the current state. A deletion results in a thinned event \tilde{x}_m being removed at random from $\{\tilde{x}_m\}_{m=1}^M$. The overall transition kernels q , and Metropolis-Hastings acceptance ratios, a , are:

$$q_{ins}(M+1 \leftarrow M) = \quad (15)$$

$$\frac{b(K, M)}{\mu(\mathcal{T})} \mathcal{GP}(g(\tilde{x}_{M+1}) \mid \{\tilde{x}_m\}_{m=1}^M, \mathbf{g}_{\mathbf{M}+\mathbf{K}}),$$

$$a_{ins} = \frac{(1 - b(K, M + 1))\mu(\mathcal{T})\lambda^*}{(M + 1)b(K, M)(1 + \exp(g(\tilde{x}_{M+1})))}, \quad (16)$$

$$q_{del}(M - 1 \leftarrow M) = \frac{1 - b(K, M)}{M} \quad (17)$$

$$a_{del} = \frac{Mb(K, M - 1)(1 + \exp(g(\tilde{x}_m)))}{(1 - b(K, M))\mu(\mathcal{T})\lambda^*}. \quad (18)$$

Sampling the locations of the thinned events also makes use of the Metropolis criterion. For each event \tilde{x}_m a move to \hat{x}_m is proposed via a Gaussian proposal density. A function value $g(\hat{x}_m)$ is then drawn conditioned on the state with $g(\tilde{x}_m)$ removed, denoted $\mathbf{g}_{\mathbf{M}-\mathbf{K}}$. This gives the move acceptance ratio

$$a_{move} = \frac{q_{move}(\tilde{x}_m \leftarrow \hat{x}_m)(1 + \exp(g(\tilde{x}_m)))}{q_{move}(\hat{x}_m \leftarrow \tilde{x}_m)(1 + \exp(g(\hat{x}_m)))}. \quad (19)$$

where q_{move} is the proposal distribution. We use a symmetric Gaussian proposal

$$q_{move}(\hat{x}_m \leftarrow \tilde{x}_m) = \mathcal{N}\left(0, \frac{\mu(\mathcal{T})}{100}\right). \quad (20)$$

To sample the function we opt to use Elliptical Slice Sampling (Murray et al., 2010). This is an algorithm specifically designed for sampling from high dimensional, highly correlated, Gaussian process posteriors. The log conditional posterior over function values is

$$\begin{aligned} \ln p(\mathbf{g}_{\mathbf{M}+\mathbf{K}} \mid M, \{x_k\}_{k=1}^K, \{\tilde{x}_m\}_{m=1}^M, \gamma) = \\ -\frac{1}{2}\mathbf{g}_{\mathbf{M}+\mathbf{K}}\mathbf{\Sigma}^{-1}\mathbf{g}_{\mathbf{M}+\mathbf{K}} - \sum_{k=1}^K \ln(1 + \exp(-g(x_k))) \\ - \sum_{m=1}^M \ln(1 + \exp(g(\tilde{x}_m))) + \text{const.} \end{aligned} \quad (21)$$

In our case, $\mathbf{\Sigma}$ is equal to the covariance in Equation 11, and naturally for each iteration we perform all the above updates in parallel for each observed point process, conditioned on the latent functions.

To infer the posteriors over the Gaussian process hyperparameters, we use Hamiltonian Monte Carlo

until *convergence* is *true*

(HMC) (Duane et al., 1987; Neal, 2010), with log-normal priors over each hyperparameter. By placing a Gamma prior with shape α and inverse scale β over λ^* , we infer the posterior conditioned on the thinned and true points using a Gibbs update as follows:

$$\alpha_{post} = \alpha + K + M, \quad \beta_{post} = \beta + \mu\mathcal{T}. \quad (22)$$

3.2 LEARNING THE LATENT FUNCTIONS

Conditioning on the point process intensity functions, $g_a(x)$, the latent functions are dependent, with conditional posterior distribution given by Equation 13.

Having drawn new values for each of the $u_q(Z_q)$, we can update the ϕ_q using a metropolis-hastings step under the following log conditional posterior which is

$$\begin{aligned} \ln p(\phi_q \mid u_q(Z_q), Z_q) = -\frac{1}{2}u_q(Z_q)\mathbf{K}_{u_q, u_q}^{-1}\frac{1}{2}u_q(Z_q) \\ -\frac{1}{2}\log \det(\mathbf{K}_{u_q, u_q}) + \text{const.} \end{aligned} \quad (23)$$

The overall procedure is summarised in algorithm 1.

4 ADAPTIVE THINNING

In higher dimensional spaces, data is typically concentrated into small, high density sub-domains. Under the current methodology, we must thin the entire empty space to a uniform concentration which matches that of the most dense subregion. If we wish to use Gaussian Process intensities this rapidly becomes infeasible, even under the most radical of sparse approximations (Snelson and Ghahramani, 2005).

Our novel solution to this problem is to model the upper bounded intensity over the space using a piecewise constant function, where each section takes a fractional proportion of the global upper bound, λ^* . This preserves the tractability of the integrals in the likelihood and posterior, and does not violate any of the properties of the point process, while simultaneously

allowing empty regions to be thinned to a far lower average density.

Consider Figure 1: this shows both the data and the thinned points, where for the left three quarters of the plot the maximum rate does not exceed 50% of λ^* . Let us assume we allow the maximum rate to take one of two values for each datapoint: $\frac{1}{2}\lambda^*$ and λ^* . For each new thinned point we sample an intensity function value, before also sampling an upper bound for the rate from the available levels. This upper bound is at least as great as the current function evaluation at that point.

In this manner we hope to infer that for the majority of Figure 1, the rate may be happily upper-bounded by half the global maximum rate, λ^* , and hence the bulk of the space may be thinned to a significantly lower density. As a result, the computational burden incurred will be significantly reduced, as far fewer expensive points need be incorporated into our GP.

In our particular implementation, we fix *a-priori* a set of B possible maximum rate ‘levels’:

$$L = \{l_i \in (0, 1] | l_i < l_{i+1}, l_B = 1\}_{i=1}^B. \quad (24)$$

We then augment the variable set to include for each thinned point \tilde{x}_m which rate level $r_m \in \{1 \dots B\}$ it is currently assigned, where we set r_m such that $\sigma(g(\tilde{x}_m)) \leq l_{r_m}$. This causes the probability of seeing a thinned point \tilde{x}_m under the sigmoid GP to become

$$p(\tilde{x}_m | r_m) = \frac{l_{r_m} - \sigma(g(\tilde{x}_m))}{l_{r_m}}, \quad (25)$$

while the probability of a non-thinned point remains unchanged. Using this relationship we modify the Metropolis acceptance criteria which now become

$$a_{ins} = \frac{(1 - b(K, M + 1))\mu(\mathcal{T})\lambda^* l_{r_{M+1}} p(\tilde{x}_{M+1} | r_{M+1})}{(M + 1)b(K, M)}, \quad (26)$$

$$a_{del} = \frac{Mb(K, M - 1)}{(1 - b(K, M))\mu(\mathcal{T})\lambda^* l_{r_m} p(\tilde{x}_m | r_m)}, \quad (27)$$

as well as the likelihood function for $p(g(\mathbf{X}_{M+K}))$, Equation 21.

In principle this scheme could slow mixing, since the function is constrained to lie below the maximum level at each point. By ensuring that there is always some slack, s , between the function and the rate level assigned we find that mixing is hardly affected. The slack is incorporated by assigning the rate as follows:

$$r_m \leftarrow \begin{cases} \underset{r}{\operatorname{argmax}} \{ \sigma(g(\tilde{x}_m)) \leq l_r \times s \}, & \sigma(g(\tilde{x}_m)) \leq s \\ 1, & \text{otherwise.} \end{cases} \quad (28)$$

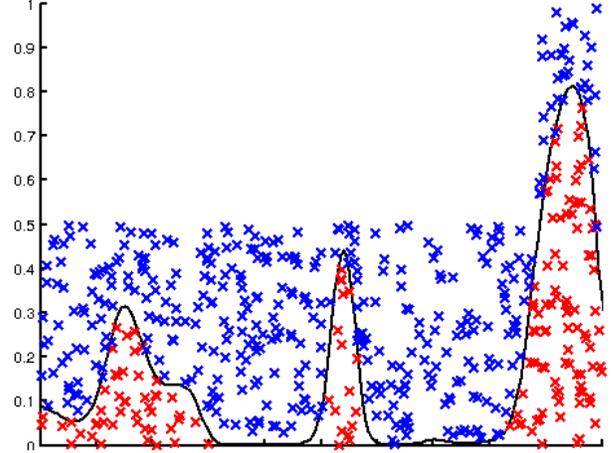

Figure 1: Graphical representation of adaptive thinning: Blue crosses indicate thinned points, red crosses represent data. The black line shows the intensity function. Each point is accepted as data with probability given by $\sigma(g(x_n))$. Fewer thinned points are required in areas of half maximum bound.

We used $s = 0.9$. The rate levels can also change at each iteration during the ‘move’ step when we compute the new rate level for jittered points and we compose the acceptance criteria as the product of the insertion and deletion criteria $a_{move} = a_{ins} \times a_{del}$.

Finally, when re-sampling λ^* we must compute an estimate of the total number of points under a single rate uniformisation of the space. This estimate is readily available because the number of points (including observed data points) with rate r is a Monte-Carlo integral of the proportion of space thinned to rate level l_r . Since the number of points in each region is scaled by l_r , the estimated total is

$$\hat{N}_{tot} = \sum_{k=1}^K \frac{1}{l_{\bar{r}_k}} + \sum_{m=1}^M \frac{1}{l_{r_m}}, \quad (29)$$

where \bar{r}_k is the notional rate of observed data computed exactly as for the thinned points. The posterior value α_{post} is therefore $\alpha + \hat{N}_{tot}$.

To validate adaptive thinning, we return to the original SGCP and modify it in the manner described above. We perform two experiments: The first in 1D and the second in 2D. In both cases we use 10 known random intensity functions to generate event data: In the 1D case we sample 15 random datasets per function, while in the 2D case we generate 10. One dataset is used to learn the model, the rest are held out for testing purposes. Two metrics of performance are used: L2-norm error as measured against the true intensity function, and average predictive log-likelihood across all held

out test datasets.

In 1D, we run each model for 6 minutes total compute time, in 2D we allow 20 minutes total. In both cases half the time is allocated to burn-in. In 1D the single rate method achieved roughly one sample per second, with the two rate case yielding just under four samples per second, and the four rate approach giving just under 8 samples per second. In 2D the number of points required was larger in all cases, with the multi-rate approach buying a factor of two speedup.

The results, (given in Tables 1 through 4), show that in almost all cases the multi-level approach performs best across both metrics. It is observed that typically the original, homogenous rate approach performs worst of all.

5 EMPIRICAL RESULTS

As this is the first model for structured point process data, the approach is initially validated on a synthetic dataset. It is then compared to both the independent SGCP, as well as a state of the art Kernel Density Estimator (Botev et al., 2010) on two real datasets.

5.1 SYNTHETIC DATA

Using the convolution process, we sample four intensity functions, using those to sample event data. The variety of intensities which may be observed given a single latent function is notable in Figure 2.

We then average over 2000 iterations after it was determined convergence had been achieved. The resulting learned intensity functions are shown in Figure 3.

It is reassuring that the original latent function is well recovered given only four observed event processes.

5.2 REAL DATA

Two datasets were selected to test the model, both of which we considered were likely to exhibit a dependency structure which could be well captured by the convolution process.

- British politicians (MPs) tweet times during the week of Nelson Mandela’s death (02/12/13-08/12/13). These were obtained using the Twitter API. Here we considered that there would naturally be a daily periodicity, however, it is not unreasonable to further postulate that some MPs may concentrate their twitter activity into a smaller segment of the day. This behaviour should be well captured by the convolution process.
- NBA player shot profiles for the 2013-2014 season, scraped from the NBA website. Here we se-

lect a diverse subset of four players: Blake Griffin, Damien Lillard, DeMar DeRozen, and Arron Afalo. It was supposed that it might be possible for a single latent function to be blurred to represent a variety of player positions and styles.

5.2.1 Twitter Data Results

Four MPs active on twitter were selected at random. Here on we call them MPs A, B, C, and D. We select data from the period covering 02/12/13 through 13/12/13, and randomly partition each dataset into 75% training data, with the remainder being used to evaluate predictive test log-likelihood.

Figure 4 depicts the average learned intensity functions for each MP (red line), along with the one standard deviation bars (grey shading) derived from the function samples. The bottom plot depicts the learned latent driving function in the same manner.

The latent function clearly shows a strong daily period, particularly evident during the working week (02/12/13 was a Monday—corresponding to ‘1’ in Figure 4). Furthermore, the largest two peaks in activity occur on the 3rd and the 5th of December. Potential contributing factors to these two spikes include a public sector strike, and the death of Nelson Mandela respectively.

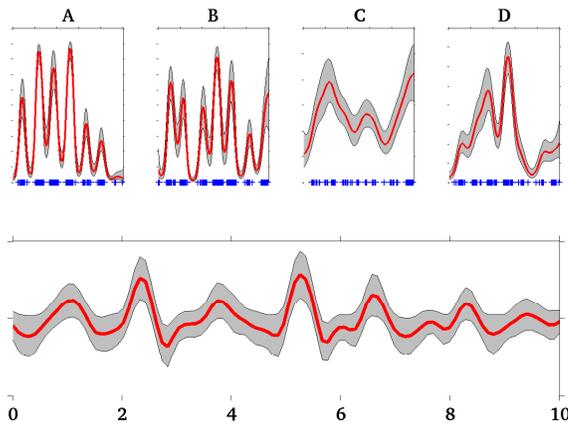

Figure 4: Learned intensities over four MP’s tweet data (A, B, C, D); learned latent function at bottom. Actual data shown in blue.

Table 5 gives predictive log-likelihood for the held out data, again evaluated across three approaches: An intensity function learned via Kernel Density Estimation (KDE) (Botev et al., 2010), the SGCP (Adams et al., 2009), and our own structured approach. Both the SGCP and our own approach use two maximum rate levels for adaptive thinning. Each intensity function is modelled using an independent SGCP/KDE. The

C	-5.4	49.6	283.4
D	-67.7	38.7	293.7

5.2.2 Basketball Data

For the basketball point shot data, the approach performed particularly well. Each player had around 600 attempted shots, of which we used 400, holding out the rest as test data. We used 3 rate boundaries: $\frac{1}{4}\lambda^*$, $\frac{1}{2}\lambda^*$, λ^* , and once again averaged over 2000 samples after convergence. We compare predictive log-likelihood to both the SGCP model (using the same set of rate boundaries) and using a rate function estimated via a state of the art KDE by Botev et al. (2010).

Figure 5 depicts the resulting intensity functions. It is clear that the latent function represents a general view of the court hotspots, the hoop and three pointer line are clearly demarcated. Furthermore the intensity functions for each player strongly match what would be expected given their playing style—e.g. Arron Affalo is a ‘shooting guard’ who is expected to spend the majority of his time inside the three pointer line,

Player	Predictive Log-Likelihood		
	KDE	SGCP	Ours
Blake Griffin	-121.8	335.6	374.7
Damien Lillard	-22.6	231.2	395.3
DeMer DeRozen	-2.9	253.1	410.7
Arron Affalo	-260.7	-76.7	84.2

Figure 6: Basketball ball shot data (top) and predictive log-likelihood for held out basketball data across models (bottom).

but has a propensity to shoot from the bottom left of the court. These effects are clearly visible on the heat map, less so on the data (see Figure 5.2.1).

As is clearly demonstrated in Table 6, our structured approach to modelling the basketball point data in a fully Bayesian fashion yields a huge improvement over both the independent SGCP as well as a modern kernel density estimator. Another point worth making is that due to the high data density around the hoop for each player, the traditional approach of thinning (used here as well as in the SGCP) would be prohibitively computationally expensive. We are only able to test on this data due to the method of adaptive thinning introduced in this paper.

6 CONCLUSION

We have introduced a fully generative model for dependent point processes, alongside an efficient, parallelised inference scheme. We have shown the appropriateness of this model on two real datasets, and introduced a new adaptation of thinning which allows the model to scale to larger datasets and in particular higher dimensional spaces. Future work entails investigating the appropriateness of manually introducing known latent drivers, exploring multiple latent functions, and replacing the MCMC inference scheme with one based on stochastic variational inference (Hensman et al., 2013).

Abstract

We present a peptide-spectrum alignment strategy that employs a dynamic Bayesian network (DBN) for the identification of spectra produced by tandem mass spectrometry (MS/MS). Our method is fundamentally generative in that it models peptide fragmentation in MS/MS as a physical process. The model traverses an observed MS/MS spectrum and a peptide-based theoretical spectrum to calculate the best alignment between the two spectra. Unlike all existing state-of-the-art methods for spectrum identification that we are aware of, our method can learn alignment probabilities given a dataset of high-quality peptide-spectrum pairs. The method, moreover, accounts for noise peaks and absent theoretical peaks in the observed spectrum. We demonstrate that our method outperforms, on a majority of datasets, several widely used, state-of-the-art database search tools for spectrum identification. Furthermore, the proposed approach provides an extensible framework for MS/MS analysis and provides useful information that is not produced by other methods, thanks to its generative structure.

1 INTRODUCTION

A fundamental problem in biology and medicine is accurately identifying the proteins present in a complex sample, such as a drop of blood. The only high-throughput method for solving this problem is *tandem mass spectrometry (MS/MS)*. Given a complex sample, an MS/MS experiment produces a collection of spectra, each of which represents a single *peptide* (protein subsequence) that was present in the original sample. Fundamental to MS/MS is the ability to accurately identify the peptide responsible for generating a particular spectrum.

The most accurate methods for identifying MS/MS spectra make use of a peptide database. Given a peptide drawn from

the database and an observed spectrum, these methods compare a *theoretical spectrum* of the peptide's idealized fragmentation events to a quantized or fixed-width thresholded observed spectrum. Such preprocessing necessarily discards potentially useful information. The spectrum identification problem is greatly complicated by experimental noise, corresponding both to the presence of unexpected peaks (insertions) and the absence of expected peaks (deletions) in the observed spectrum (Fig. 1). This paper describes a Dynamic Bayesian network for Rapid Identification of Peptides (DRIP), a database search method that serves as a generative model of the process by which peptides produce spectra in MS/MS. DRIP explicitly models insertions and deletions, without quantization or thresholding of the observed spectra.

We note that a DBN-based database search method, called Didea, was recently proposed [1], but this method does not model the underlying process by which peptides produce MS/MS spectra. Rather, in Didea both theoretical and observed spectra are observed, and the model contains only a single hidden variable, which is devoid of any physical meaning relative to the underlying MS/MS process. The theoretical spectrum in DRIP, by contrast, is hidden; insertions and deletions are explicitly modeled as latent variables (as in [2]), and the most probable alignment between the theoretical and observed spectra can be efficiently calculated (detailed in Section 4). Furthermore, Didea has a single hyperparameter that is optimized via grid search, making the model poorly adaptable to the wide range of machines with widely varying characteristics, a problem addressed by the highly trainable nature of DRIP.

We demonstrate, in fact, that against four state-of-the-art benchmarked competitors, DRIP is the most frequent top performer, dominating the others on four out of nine separate datasets. By contrast, other competitors, such as Didea, dominate on at most two datasets. Furthermore, DRIP, thanks to its generative approach, provides valuable auxiliary information, such as which observed peaks are most likely spurious, which theoretical peaks are most likely present, and the ability to calculate posteriors of interest via sum-product inference [3, 4]. Such posteriors include the probability of post-translational modifications given the observed spec-

trum, a task which previously required post-processing the results of a database search [5].

We first give a brief overview of a typical tandem mass spectrometry experiment and an overview of database search in Section 2. Readers are directed to [6] for further background in this area. Next, the four benchmarked competitors are described in Section 3. DRIP is described in detail in Section 4. Results are presented in Section 5, and we conclude and discuss future work in Section 6.

2 TANDEM MASS SPECTROMETRY AND DATABASE SEARCH

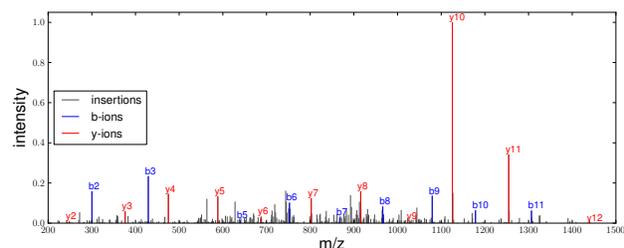

Figure 1: Sample tandem mass spectrum, where the peptide responsible for generating the spectrum is $x = \text{LWEPLLDVLVQTK}$, the precursor charge c^s is 2, and the most probable alignment computed in DRIP is plotted. The b-ion peaks are colored blue, y-ion peaks are colored red, and insertions are colored gray. Note that fragment ions b_1, y_1, b_4, b_{12} correspond to deletions.

Although we are typically interested in the protein content of a complex mixture, the fundamental unit of observation in tandem mass spectrometry is the peptide, because peptides are more amenable to liquid chromatography and mass spectrometry analysis[6, 7]. Thus, a typical MS/MS experiment begins by digesting the proteins into peptides using a cleavage agent such as the enzyme trypsin. MS/MS then proceeds with two rounds of mass spectrometry. The first round measures the mass-to-charge ratio (m/z) of the intact peptide (called the *precursor m/z*), and the second round fragments the peptide and measures the m/z values of the resulting prefixes and suffixes. Each of these fragment m/z values is associated with an intensity value, which is roughly proportional to the number of copies of that peptide fragment. Figure 1 displays a sample tandem mass spectrum, along with the theoretical fragment ions (described below) of the generating peptide. A single unit along the m/z axis is called a *Thomson (Th)*, and the intensity (y-axis) is unitless but can be seen as a measure of abundance or count.

Let \mathbb{P} be the set of all possible peptides and S be the set of all tandem mass spectra. Given an observed spectrum $s \in S$ with observed precursor m/z m^s and precursor charge c^s , our task is to identify the peptide x from a given peptide database $\mathcal{D} \subseteq \mathbb{P}$ that is responsible for generating s . Any given mass spectrometry device is capable of isolating

peptides with a specified precision on the precursor m/z ; therefore, we may constrain the search to only consider peptides with precursor $m/z \pm w$ of m^s . The set of *candidate peptides* to be scored is then

$$D(m^s, c^s, \mathcal{D}, w) = \left\{ x : x \in \mathcal{D}, \left| \frac{m(x)}{c^s} - m^s \right| \leq w \right\}, \quad (1)$$

where $m(x)$ is the calculated mass of peptide x . The goal of database search, then, is to return the highest scoring candidate peptide

$$x^* = \underset{x \in D(m^s, c^s, \mathcal{D}, w)}{\operatorname{argmax}} \psi(x, s),$$

where $\psi : \mathbb{P} \times S \rightarrow \mathbb{R}$ is a function that assigns higher scores to higher quality matches and the pair (x, S) is referred to as a *peptide-spectrum match (PSM)*. The primary distinguishing characteristic of any database search procedure is its choice of score function ψ .

2.1 THEORETICAL SPECTRA

Many score functions, including the one employed by the very first database search algorithm, SEQUEST [8], work by comparing the observed spectrum to a *theoretical spectrum* that is derived from a candidate peptide using basic rules of biochemistry. Let $x \in D(m^s, c^s, \mathcal{D}, w)$ be an arbitrary candidate peptide of length n . Note that $x = x_0x_1 \dots x_{n-1}$ is a string of *amino acids*, i.e. characters in a dictionary of size 20. For convenience, let $\tilde{n} = n - 1$. Our goal is to produce a theoretical spectrum v^x containing the fragment m/z values that we expect x to produce. In this work, we assume that the mass spectrometer employs collision-induced dissociation, which is the most widely employed method of peptide fragmentation. The model can be modified in a straightforward fashion to accommodate other fragmentation modes.

The first type of fragment m/z value corresponds to prefixes or suffixes of the candidate peptide, referred to respectively as *b-ions* and *y-ions*. In this work, we assume that the precursor charge c^s is 2, because this is the charge state of the high-quality set of PSMs used for training [9]. For $c^s = 2$, these b- and y-ions can be represented as functions $b(\cdot, \cdot)$ and $y(\cdot, \cdot)$, respectively, that take as input a peptide x and integer $k < n$:

$$b(x, k) = \sum_{i=0}^{k-1} m(x_i) + 1, \quad y(x, k) = \sum_{i=\tilde{n}-k}^{\tilde{n}} m(x_i) + 19. \quad (2)$$

Note that the whole peptide mass is not considered and that, for $1 < k < n$, we have the recurrence relations $b(x, k) = b(x, k-1) + m(x_{k-1})$ and $y(x, k) = y(x, k-1) + m(x_{\tilde{n}-k})$. In Equation 2, the b-ion unit offset corresponds to the mass of a hydrogen atom while the y-ion offset corresponds to the masses of a water molecule as well as a hydrogen atom.

Thus, the b- and y-ions are simply the shifted prefix sums and suffix sums of x , respectively. When there is no ambiguity as to the peptide being described, it is typical to represent the b- and y-ion pairs as (b_k, y_{n-k}) for $k = 1, \dots, \tilde{n}$, where the subscript denotes the number of amino acids utilized in the ion computation. As an example, for peptide $x = \text{EALK}$, $(b_1, y_3) = (b(x, 1), y(x, 3)) = (130, 331)$. Denoting the number of unique b- and y-ions as n^x and, for convenience, letting $\tilde{n}^x = n^x - 1$, our theoretical spectrum is a sorted vector $v^x = (v_0, \dots, v_{\tilde{n}^x})$ consisting of the unique b- and y-ions of x . Figure 2 displays the theoretical spectrum for $x = \text{EALK}$, and Figure 1 displays an observed spectrum with annotated b- and y-ions.

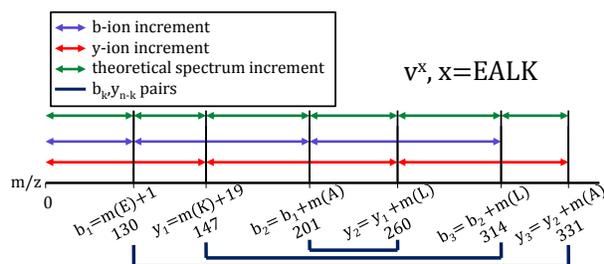

Figure 2: Theoretical spectrum of the peptide $x = \text{EALK}$. Note that the b- and y-ions correspond to prefix and suffix sums, respectively, of the peptide x .

3 PREVIOUS WORK

We compare DRIP’s performance to that of four previously developed state-of-the-art methods. We describe each method briefly here, and in more detail in [10]. All four methods begin by binning the observed spectrum. The first database search algorithm, SEQUEST [8], uses a scoring function called XCorr, consisting of a dot-product minus a cross-correlation term that provides an empirical null model for a random match. The second approach, the Open Mass Spectrometry Search Algorithm (OMSSA) [11] counts, the b- and y-ions present in the observed spectrum and then estimates a p-value by fitting this count to a Poisson distribution with mean parameter derived from the properties of the observed spectrum. The third algorithm, MasS Generating Function DataBase (MS-GFDB) [12], computes a score by taking a dot product between a Boolean theoretical vector and a processed observed spectrum and then computes a p-value for this score using dynamic programming. The fourth algorithm that we consider, Didea [1], is most closely related to DRIP, in the sense that both methods employ a DBN. However, Didea differs from DRIP in four quite significant ways:

- **Notion of “time.”** In Didea, each frame of the DBN corresponds to one amino acid from the candidate peptide sequence. Accordingly, Didea must copy the entire observed spectrum in every frame in order to score these observations. By contrast, each frame in DRIP

instead corresponds to a peak in the observed spectrum, such that a single m/z value and intensity value are observed and scored per frame.

- **Whether the theoretical spectrum is hidden or observed.** The theoretical spectrum in DRIP is hidden, and inference is run to determine the best alignment between the observed and theoretical spectra while accounting for insertions and deletions, thus providing not just a score but valuable alignment information as well. In Didea, the theoretical spectrum is not hidden because the amino acid variables in each frame are observed, so that performing inference only provides a score.
- **Observed spectrum pre-processing.** DRIP performs much less pre-processing on the observed spectrum than Didea. In particular, Didea must work with a version of the observed spectrum in which the m/z axis is discretized and the observed intensity values are reweighted using a complicated function of exponentials. DRIP instead scores m/z values in their natural resolution, without discarding information due to quantization.
- **Training of parameters.** Whereas Didea is essentially a fixed model, DRIP offers the ability to learn its parameters using training data. The only learning available in Didea is the tuning of a single hyperparameter, via grid search, which controls the reweighting of peak intensities.

4 DRIP PEPTIDE SCORING

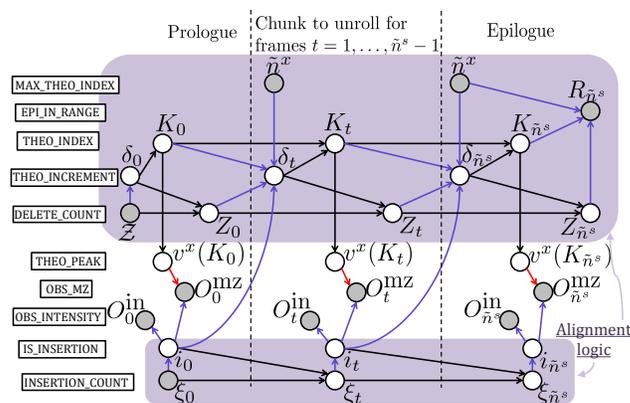

Figure 3: Graph of DRIP, where the boxed words on the far left summarize the role of the random variables on the same horizontal level to aid interpretation of the model. THEO and OBS are short for theoretical and observed, respectively.

The graph of DRIP is displayed in Figure 3, where each frame of the model corresponds to a single observed peak. Shaded nodes represent observed variables, and unshaded nodes represent hidden variables. Black edges correspond to deterministic functions of parent variables, and blue edges

represent switching parent functionality (also known as Bayesian multi-nets [13]) where the parent nodes are known as *switching parents* and the parents (and hence conditional distributions) of their children may change given the values of their switching parents. Finally, red edges denote continuous conditional distributions. Random variables are grouped into frames, indexed by $t = 0, \dots, n^s - 1$. Note that while elements of vectors are denoted using parentheses, a particular value of a sequence is denoted using subscripts, such that δ_t is a random variable in the t th frame. For convenience, let $\tilde{n}^s = n^s - 1$, and recall that \tilde{n}^x denotes the number of peaks in the theoretical spectrum minus one. The first and last frames are known as the *prologue* and *epilogue*, respectively. The middle frame is called the *chunk* and is unrolled $n^s - 2$ times to frames $t = 1, \dots, \tilde{n}^s - 1$. Each frame of the graph contains observations $O_t^{\text{m/z}}$ and O_t^{int} , the t th m/z and normalized intensity values of s , respectively. Thus, we can view traversing the graph from left to right as moving across the observed spectrum.

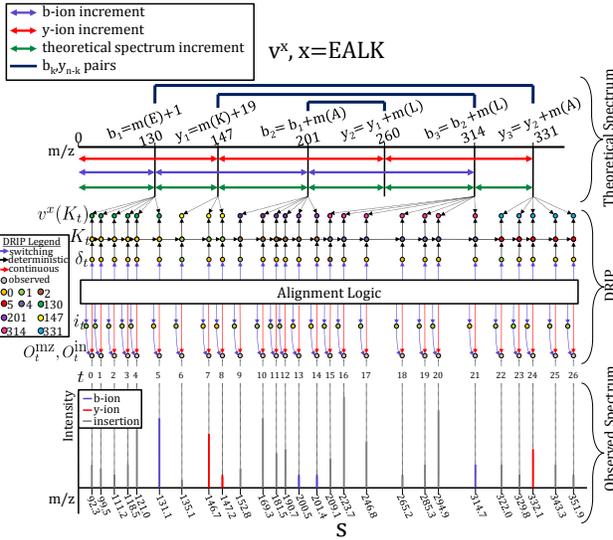

Figure 4: Illustration of a particular spectrum alignment (instantiation of random variables) in DRIP, where the node color denotes its instantiated value. The observed spectrum peaks serve as the observations in each frame while the theoretical spectrum is hidden. DRIP thus serves as a sequencer through all possible alignments between the theoretical and observed spectra, made efficient via dynamic programming.

The goal of DRIP is to calculate the most probable alignment between the observed and theoretical spectra, where an alignment is an instantiation of the random variables in the graph and the scoring of observed peaks as dictated by this instantiation. This concept is detailed in Figure 4 for a particular alignment, where random variable values are denoted by node colors, and the alignment corresponds to a traversal of both the theoretical (upper portion) and observed spectra (lower portion). In the center portion of Figure 4, the random variable K_t denotes the theoretical peak index and, given the increment random variable δ_t , moves us down the

theoretical spectrum, while further alignment logic in DRIP constrains the manner in which the theoretical and observed spectra may be aligned. Figure 5 illustrates the scoring of observed peaks (discussed in Section 4.2) in this alignment, and the instantiation of random variables may be found in Table 1. We now discuss the details of how DRIP aligns the theoretical and observed spectra.

4.1 TRAVERSING THE THEORETICAL SPECTRUM

The variable K_t is the index of the theoretical peak used to score peaks in frame t , such that

$$p(K_0 = \delta_0 | \delta_0) = 1, \quad (3)$$

$$p(K_t = K_{t-1} + \delta_t | K_{t-1}, \delta_t) = 1, \quad t > 0. \quad (4)$$

From (3) and (4), we see that δ_t is the number of theoretical peaks we traverse between frames t and $t + 1$. Note that a deletion thus occurs when $\delta_0 > 0$ and $\delta_t > 1$ for $t > 0$, i.e., the *hypotheses* such that one or more theoretical peaks are not accessed, where a hypothesis is an assignment of all random variables in the graph. The number of deletions occurring in a single frame is then δ_0 for the prologue and $(\delta_t - 1)\mathbf{1}\{\delta_t > 1\}$ for all subsequent frames, where $\mathbf{1}\{\cdot\}$ is the indicator function which returns 1 if its argument is true and 0 otherwise. The total number of allowed deletions is \mathcal{Z} and counts down in subsequent frames such that, denoting the number of deletions left in a frame as Z_t , we have

$$p(Z_0 = \mathcal{Z} - \delta_0 | \mathcal{Z}, \delta_0) = 1$$

$$p(Z_t = Z_{t-1} - (\delta_t - 1)\mathbf{1}\{\delta_t > 1\} | Z_{t-1}, \delta_t) = 1, \quad t > 0.$$

The allowable number of insertions counts down in a similar manner to the deletions. ξ_0 is the maximum allowable insertions for all frames, i_t is a Bernoulli random variable which signifies whether the peak in frame t is an insertion, and $p(\xi_t = \xi_{t-1} - i_{t-1} | \xi_{t-1}, i_{t-1}) = 1$. Furthermore, the role of ξ_t as a switching parent of i_t is such that $p(i_t = 0 | \xi_t = 0) = 1$. Thus, when there are no insertions left, i_t is 0 for all remaining frames.

The hidden multinomial δ_t is such that $p(\delta_0 > \mathcal{Z}) = 0$, i.e. it respects the maximum deletion constraint of the first frame, and for $t > 0$, $p(\delta_t) = \sum_{i_{t-1}} p(\delta_t | \delta_{t-1}, Z_{t-1}, \tilde{n}^x, i_{t-1}) p(i_{t-1})$, where

$$p(\delta_t = 0 | \delta_{t-1}, Z_{t-1}, \tilde{n}^x, i_{t-1} = 1) = 1, \quad (5)$$

$$p(\delta_t > \tilde{n}^x - (K_t - Z_t) | \tilde{n}^x, K_t, Z_t, i_{t-1}) = 0. \quad (6)$$

Equation (5) prohibits DRIP from moving down the theoretical spectrum in a frame following an insertion. This constraint ensures that the theoretical spectrum may not be trivially traversed while observed peaks are scored as insertions, or equivalently that some observed peak must not be scored as an insertion in order to move down the theoretical spectrum for frames $t > 0$. Equation (6) constrains DRIP from incrementing past the range of valid theoretical peak indices.

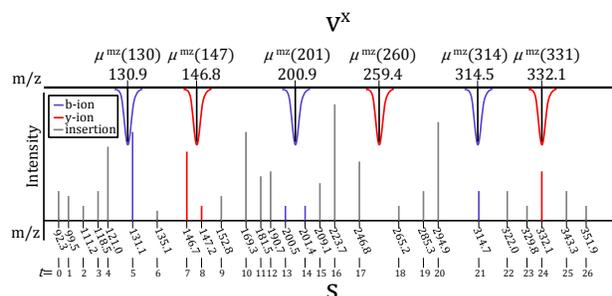

Table 1: Random variable hypothesis for alignment displayed in Figure 5. Recall the deterministic relationships $K_0 = \delta_0$, $K_t = K_{t-1} + \delta_t$ for $t > 0$, and given the theoretical peak index K_t we have the theoretical peak $v^x(K_t)$. For instance, from the theoretical spectrum of $x = \text{EALK}$ in Figure 4, we have $K_6 = K_5 + \delta_6$ and $v^x(K_6) = v^x(1) = 147$.

t	0	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15	16	17	18	19	20	21	22	23	24	25	26
δ_t	0	0	0	0	0	0	1	0	0	1	0	0	0	0	0	2	0	0	0	0	0	1	0	0	0	0	0
K_t	0	0	0	0	0	0	1	1	1	2	2	2	2	2	2	4	4	4	4	4	4	4	5	5	5	5	5
i_t	1	1	1	1	1	0	1	0	0	1	1	1	1	0	0	1	1	1	1	1	1	0	1	1	0	1	1

In order to discourage the use of deletions unless absolutely necessary, the distribution over δ_t is constrained to be monotone decreasing, such that for $i_{t-1} = 1$, $K_t - Z_t < \tilde{n}^x$, and $0 < h < \tilde{n}_t^x - (K_t - Z_t) - 1$, we have $p(\delta_t = h | \tilde{n}^x, K_t, Z_t, i_{t-1}) < p(\delta_t = h - 1 | \tilde{n}^x, K_t, Z_t, i_{t-1})$.

The epilogue variable $R_{\tilde{n}^s}$, observed to 1, constrains which theoretical peaks may occur in the final frame. If the number of theoretical peaks left unexplored in the epilogue is greater than the number of remaining deletions, then such a hypothesis of random variables receives probability zero. Thus, we have $p(R_{\tilde{n}^s} = 1 | \tilde{n}^x, K_{\tilde{n}^s}, Z_{\tilde{n}^s}) = \mathbf{1}\{\tilde{n}^x - K_{\tilde{n}^s} \leq Z_{\tilde{n}^s}\}$. This boundary condition limits the number of valid hypotheses in DRIP which have non-zero probability, and by forcing the traversal of the theoretical spectrum from prologue to epilogue ensures that a peptide cannot align trivially well to the observed spectrum. Figure 4 and Table 1 detail the theoretical spectrum traversal for the alignment depicted in Figure 5.

4.2 SCORING OBSERVED PEAKS

only 22 of 324 peaks correspond to fragment ions. Furthermore, these fragment ions only occur within a sufficiently small Th window of their theoretical values. Indeed, the learned variance σ^2 dictates that 99.9937% of the mass for a theoretical Gaussian peak lies within an approximately 1Th range, so that attempting to score all m/z observations with theoretical Gaussian peaks would see a majority of peptides score poorly for almost all observed spectra. Such an approach would also make the comparison of scores across different spectra in the same dataset difficult, because the variance among the PSMs would be incredibly high. Thus, when $i_t = 1$, the observations are scored as

$$\begin{aligned} \mathbb{p}(O_t^{\text{mz}}|v^x(K_t), i_t = 1) &= \mathbb{p}(O_t^{\text{mz}}|i_t = 1) = a \\ \mathbb{p}(O_t^{\text{in}}|i_t = 1) &= b, \end{aligned}$$

where a and b are constants.

The insertion constant a imposes a tradeoff between, on the one hand, receiving exponentially bad scores from scoring observed peaks far from theoretical Gaussian peaks and, on the other hand, simply receiving an arbitrarily large constant penalty. To balance this tradeoff, a is set to the score received evaluating an m/z observation 4 standard deviations from the theoretical Gaussian peak mean, $\mu^{\text{mz}}(v^x(K_t))$, i.e., $a = f(4\sigma - \mu^{\text{mz}}(v^x(K_t))|\mu^{\text{mz}}(v^x(K_t)), \sigma^2)$, where $f(z|\mu, \bar{\sigma}^2)$ is the scalar Gaussian with mean μ and variance $\bar{\sigma}^2$, evaluated at $z \in \mathbb{R}$. Thus, scoring an m/z observation score is greater than a so long as the observation remains within 99.9937% of the centered mass of $\mathcal{N}(\mu^{\text{mz}}(v^x(K_t)), \sigma^2)$. Similarly, the penalty b is set such that an intensity observation score is greater than b so long as it is within a specified percentage of the centered mass of $\mathcal{N}(\mu^{\text{in}}, \bar{\sigma}^2)$. The percentage used for the results in Section 5 was 20%, prioritizing aligning the observed and theoretical peaks over simply scoring high intensity peaks. Furthermore, the number of allowable insertions is limited per peptide (described in [10]), restricting the ability of arbitrary peptides to score observed peaks well.

4.3 DRIP SCORING FUNCTION

Peptides are scored by their optimal alignment using their per-frame log-Viterbi Score,

$$\psi(s, x) = \frac{1}{n^s} \max_{\delta_t, i_t, \forall t} \log \mathbb{p}(s|x) = \frac{1}{n^s} \log \mathbb{p}^*(s|x). \quad (7)$$

Dividing by the number of frames allows comparability of PSMs from different spectra. In order to further analyze the scoring function, assume inference has been completed and we have computed the Viterbi path, using $*$ to denote a variable's Viterbi value. Let $\lambda = \sum_{t=0}^{\tilde{n}^s} i_t^*$ denote the number of used insertions and note that $\mathbb{p}(i_t = 0) = \mathbb{p}(i_0 =$

0). DRIP's score is then

$$\begin{aligned} \log \mathbb{p}^*(s|x) &= \quad (8) \\ \lambda[\log(ab) + 3 \log \mathbb{p}(i_0 = 1)] + 3(n^s - \lambda) \log \mathbb{p}(i_0 = 0) + \\ &\sum_{t=0}^{\tilde{n}^s} \left[\log \mathbb{p}(\delta_t^*) + \log f(O_t^{\text{in}}|\mu^{\text{in}}, \sigma^2) \right] + \\ &\mathbf{1}\{i_t^* = 0\}(\log f(O_t^{\text{mz}}|\mu^{\text{mz}}(v^x(K_t^*)), \sigma^2)) \end{aligned}$$

where, as before, $f(z|\mu, \bar{\sigma}^2)$ is the scalar Gaussian with mean μ and variance $\bar{\sigma}^2$, evaluated at $z \in \mathbb{R}$. The learned model variances are such that $\sigma^2 < \bar{\sigma}^2$, i.e., there is more uncertainty in intensity measurements than m/z measurements. Thus, it is easy to see that when a peptide does not align well with the observed spectrum (i.e., many observed peaks are far from the closest theoretical peak), then the $\log f(O_t^{\text{mz}}|\mu^{\text{mz}}(v^x(K_t^*)), \sigma^2)$ term severely penalizes the score. Furthermore, this score decreases quickly as the distance between the observed peak and theoretical peak mean increases. This also implies that peptides which arbitrarily match intense peaks will still receive poor scores if they do not align well.

4.4 APPROXIMATE INFERENCE

Table 2: DRIP per-peptide run-times (in seconds) for 3 yeast spectra, 1000 scored candidate peptides each.

Spec.	Exact Inf.	$k = 1500$	$k = 1000$	$k = 500$
s_1	0.07816	0.01056	0.00779	0.00436
s_2	0.30003	0.02070	0.01496	0.00820
s_3	3.61777	0.04105	0.02861	0.01586

The state space of the random variables in DRIP grows rapidly as the number of observed and theoretical peaks increases. Although the observed variables $\tilde{n}^x, R_{\tilde{n}^s}, \mathcal{Z}, \xi_0$ greatly decrease the number of states necessary to explore by limiting the hypotheses in DRIP which receive non-zero probability, there are still an exponentially large number of states to score in order to find the Viterbi path. However, the problem of interest is ideally suited for approximate inference techniques, specifically beam pruning [16]. In beam pruning, assuming a beam width of $k \in \mathbb{N}$, only the top k most probable states in a frame are allowed to persist. Although under this methodology we are no longer theoretically guaranteed to find the Viterbi path, the structure of the problem and the value of the learned theoretical Gaussian variances ensures that, per frame, many of the hypotheses will be of extremely low probability.

For instance, the hypothesis that the first theoretical peak matches the last observed peak is highly improbable. In general, the hypothesis that a theoretical peak centered many Thomsons away from an observed peak is also highly improbable. Thus, we can retain the k most probable states in a frame without deleteriously affecting the Viterbi score.

However, care must be taken such that k is not too small or else globally good alignments where a frame must be explained by a low probability event may not be allowed to persist. Table 2 displays the per-peptide run times for 3 randomly chosen yeast spectra, scoring 1000 candidate peptides per spectrum using exact inference and various k values. Each test was performed on the same machine with an Intel Core 2 Quad Q9550 and 8GB RAM. For $k \in \{1500, 1000\}$, all peptide scores were equal to their exact scores. For $k = 500$, 0.1% of the peptide scores differed from their exact scores. The top ranking PSM scores did not change for all beam widths. The results found in Section 5 were generated using $k = 1500$.

4.5 DRIP OBSERVED SPECTRUM PREPROCESSING

As with all other search algorithms, we score database peptides of at most a fixed maximum length, specified prior to run time. Practical values of the maximum peptide length (the maximum peptide length considered for all results in Section 5 is 50) mean that the number of observed peaks is typically an order of magnitude larger than the number of theoretical peaks for any scored peptide. Furthermore, most of these peaks are noise peaks [17], and as such we filter all but the most l intense peaks, where in practice, $l = 300$.

After filtering peaks, the observed spectrum is renormalized as in SEQUEST [8], the steps of which are as follows. Firstly, all observed peak intensity values are replaced with their square root. Secondly, the observed spectrum is partitioned into 10 equally spaced regions along the m/z axis and all peaks in a region are normalized to some globally maximum intensity, which in our case is 1. Steps 1 and 2 greatly decrease the high variance of observed intensities, and step 2 helps ensure that scoring is not severely biased by many large peaks lying arbitrarily close to one another. Lastly, any peak with intensity less than $1/20$ of the most intense peak is filtered. Note that through all of these preprocessing steps, the m/z values for all remaining observed peaks remain unaltered and, as discussed in Section 4.3, the scoring of these unaltered values dominates the returned DRIP score.

5 RESULTS

We compared the performance of DRIP to four competing database search methods (Section 3). In these evaluations, we do not have an independently labeled gold standard set of identified spectra. Although it is possible to send a purified sample of known peptides through the MS/MS pipeline to obtain high confidence identifications, the low complexity of the input sample yields spectra that are less noisy than real spectra. Therefore, as is common in this field, we estimate for each search procedure the *false discovery rate* (i.e., the proportion of spectra above a given threshold that are incorrectly identified, or $1 - \text{precision}$) by searching a decoy

database of peptides [18]. These decoys are generated by shuffling the peptides in the target database. Because FDR is not monotonically related to the underlying score, we compute a q -value for each scored spectrum, defined as the minimum FDR threshold at which that score is deemed significant. Once the target and decoy PSMs are calculated, we plot the number of identified targets as a function of q -value threshold. In practice, search results with an $\text{FDR} > 10\%$ are not practically useful, so we only plot $q \in [0, 0.1]$.

We use eight previously described datasets [1] as well as another yeast dataset (yeast-03) taken from the same repository, considering only spectra with charge $2+$. All benchmark methods were searched using the same target and decoy databases, and all parameters across search algorithms were set as equivalently as possible. All datasets and reported PSMs per benchmark method may be found at <http://noble.gs.washington.edu/proj/drip>. As seen in the results panel in Figure 5, DRIP outperforms SEQUEST and OMSSA at all q -value thresholds on all datasets. DRIP is the most frequent top performer, beating all other methods on four datasets, compared to MS-GFDB and Didea, each of which is top performer on only two datasets. Furthermore, DRIP individually outperforms MS-GFDB and Didea on six of the nine datasets. DRIP also offers the most consistent performance compared to MS-GFDB and Didea across the different organisms: DRIP is always ranked first or second, whereas MS-GFDB and Didea rank third on many datasets. Both DRIP and Didea only model b- and y-ions, whereas the other algorithms [8, 11, 12] use more complicated models of peptide fragmentation (further discussed in [10]).

5.1 INSERTION, DELETION COUNT-BASED SCORES

Once a peptide’s Viterbi path has been decoded, the total number of insertions and deletions used by a peptide to score an observed spectrum may be calculated. These two quantities may be used as quality measures for a PSM, as well as to exactly compute the signal-to-noise ratio per observed spectrum. To illustrate the utility of these two quantities, we show that using both as scoring functions allows some discriminative power to differentiate between target and decoy peptides, outperforming OMSSA and SEQUEST as well as MS-GFDB over some datasets. Plotted in Figure 6, DRIP-NotDel and DRIP-NotIns correspond to scoring functions utilizing the number of a peptide’s theoretical peaks not deleted and the number of observed peaks a peptide did not consider an insertion, respectively. Note the piece-wise linear behavior, which is caused by scoring ties due to the scoring functions being integer based.

It is worth noting that scoring methods, such as SEQUEST and Didea, which perform binning typically do so by taking the maximum observed peak intensity falling within a bin. Under such binning schemes, the number of theoretical peaks not deleted is equal to the number of observed peaks which are not insertions. In DRIP, where quantization is

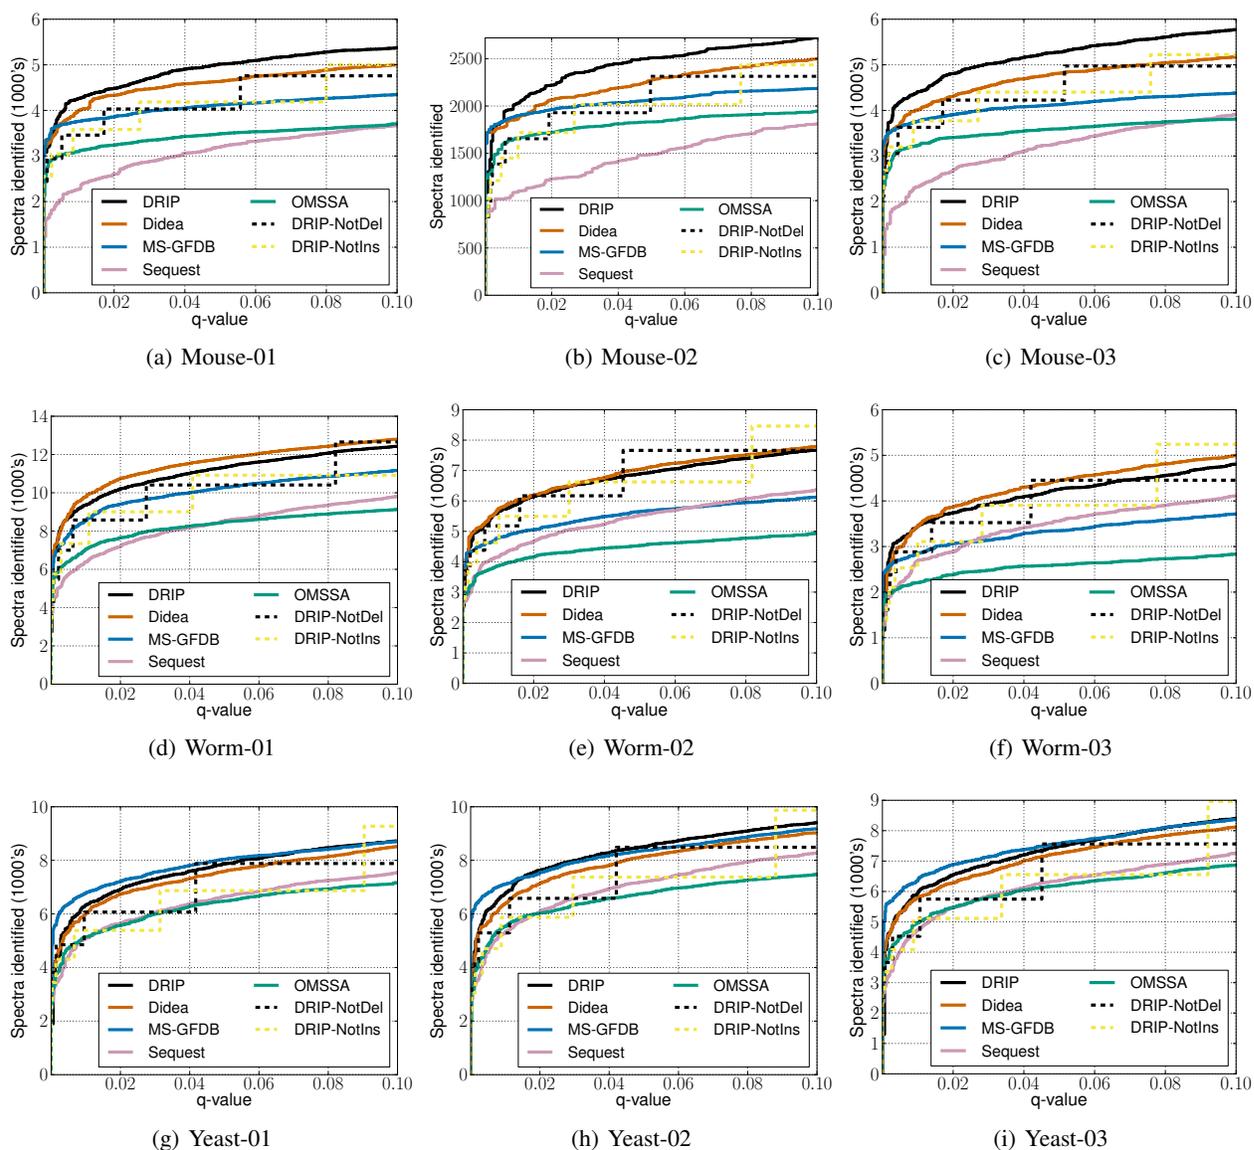

Figure 6: Performance curves for DRIP. The x-axis may be thought of as the significance threshold, and the y-axis the number of correctly identified spectra at a threshold. Thus, higher on the y-axis denotes better performance. DRIP-NotDel and DRIP-NotIns utilize the decoded DRIP Viterbi path to calculate the number of theoretical peaks not deleted and number of observed peaks not inserted, respectively, as scoring functions.

not performed, these two quantities are not equal (Figure 6). Such quantities are typically used by post-processors as features for the task of reranking target and decoy scores for improved accuracy [19, 20], and these quantities (and potentially others) calculated from DRIP’s Viterbi path may similarly be used as features.

5.2 IMPACT OF LEARNED PARAMETERS ON PERFORMANCE

The use of Gaussians allows DRIP to avoid quantization of m/z measurements, unlike all existing competitors. Learning the Gaussian means and variances in DRIP provides both a tool to study the nonlinear m/z offsets caused by machine error [15] as well as a significant increase in performance. As previously mentioned, the Gaussian parameters are learned using EM and a high-confidence set of charge 2 PSMs used in [9]. Figure 7 displays the performance benefits of jointly learning these parameters.

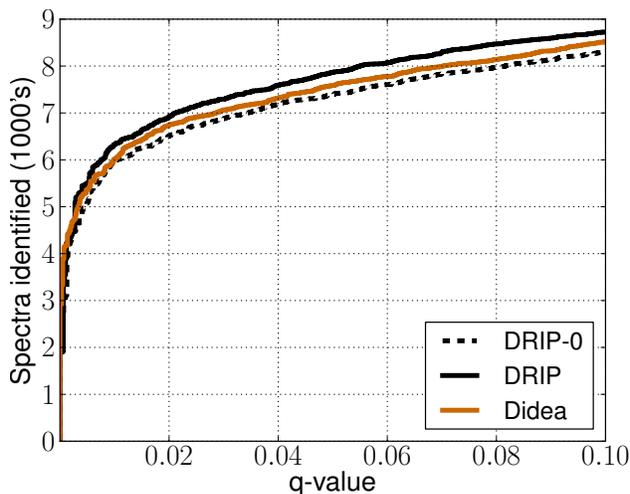

Figure 7: DRIP run with different model parameters over Yeast-01, where DRIP-0 consists of hand-tuned Gaussian parameters and DRIP consists of EM jointly learned Gaussian means and variances.

DRIP-0 consists of setting the Gaussian means to values halfway between integer units along the m/z axis and setting the intensity variance to an order of magnitude larger than the m/z variance, so as to penalize misalignment between the theoretical and observed spectra greater than small intensities. DRIP consists of jointly learning both the Gaussian means and variances, the parameters used for testing over all datasets in Figure 6. Interestingly, the learned intensity variance is larger than the learned m/z variance, so that the learned parameters dictate m/z measurements have the largest impact when scoring. Jointly learning both the means and variances improves performance compared to hand-tuned parameters, leading to improved performance relative to Didea. This trend of improved performance via learning the Gaussian parameters is observed on the other

datasets, as well.

6 CONCLUSIONS AND FUTURE WORK

We have presented DRIP, a generative model of peptide fragmentation in MS/MS. Through DRIP, a database peptide is scored by maximally aligning the peptide’s theoretical spectrum to the observed MS/MS spectrum via Viterbi decoding. Unlike previous database search methods, the observed spectrum is not quantized; instead, the m/z measurements are scored in their natural resolution. Considering the recent push in the field toward high-resolution data [21], for which other search methods must reevaluate their quantization schemes, DRIP’s handling of m/z values at full resolution is particularly important.

DRIP’s scoring function outperforms state-of-the-art algorithms on many of the presented datasets, and is far superior to the popular search algorithms SEQUEST and OMSSA. Furthermore, unlike a recent DBN-based database search method [1], DRIP is a highly trainable model which allows it a great deal of adaptability to the wide variety of machines and experimental conditions. The Viterbi path calculated in DRIP also provides a large amount of information, which otherwise typically requires post-processing after database search. Finally, via sum-product inference, DRIP may be used to calculate posteriors of particular interest to end users, a task which has previously required complicated post-processing [5].

We plan to pursue several avenues for future work. Initially, we will collect high-quality training sets of PSMs charge states other than 2 and for high-resolution spectra. Perhaps the most exciting avenue for future work is that a minor change to the DRIP model will allow it to align an observed spectrum to not just one but many different peptides simultaneously. We plan to investigate sequential variants of algebraic decision diagrams [22] to represent (potentially exponentially) large collections of peptides in polynomial space and to exploit the dynamic programming nature of DBNs to be able to score such peptide collections efficiently. Such a framework will also generalize to de novo sequencing, in which we search over the set of all possible peptides as opposed to simply a database. Finally, we plan to investigate generalizing the use of algebraic decision diagrams to allow DRIP to calibrate its scores relative to the entire peptide set. This would be similar in spirit to the dynamic programming calibration employed by methods like MS-GFDB.

Off-policy TD(λ) with a true online equivalence

Hado van Hasselt

Abstract

Van Seijen and Sutton (2014) recently proposed a new version of the linear TD(λ) learning algorithm that is exactly equivalent to an online forward view and that empirically performed better than its classical counterpart in both prediction and control problems. However, their algorithm is restricted to on-policy learning. In the more general case of off-policy learning, in which the policy whose outcome is predicted and the policy used to generate data may be different, their algorithm cannot be applied. One reason for this is that the algorithm bootstraps and thus is subject to instability problems when function approximation is used. A second reason true online TD(λ) cannot be used for off-policy learning is that the off-policy case requires sophisticated importance sampling in its eligibility traces. To address these limitations, we generalize their equivalence result and use this generalization to construct the first online algorithm to be exactly equivalent to an off-policy forward view. We show this algorithm, named *true online GTD(λ)*, empirically outperforms GTD(λ) (Maei, 2011) which was derived from the same objective as our forward view but lacks the exact online equivalence. In the general theorem that allows us to derive this new algorithm, we encounter a new general eligibility-trace update.

1 Temporal difference learning

Eligibility traces improve learning in temporal-difference (TD) algorithms by efficiently propagating credit for later observations back to update earlier predictions (Sutton, 1988), and can help speed up learning significantly. A good way to interpret these traces, the extent of which is regulated by a trace parameter $\lambda \in [0, 1]$, is to consider the eventual updates to each prediction. For $\lambda = 1$ the up-

date for the prediction at time t is similar to a Monte Carlo update towards the full return following t . For $\lambda = 0$ the prediction is updated toward only the immediately (reward) signal, and the rest of the return is estimated with the prediction at the next state. Such an interpretation is called a forward view, because it considers the effect of future observations on the updates. In practice, learning is often fastest for intermediate values of λ (Sutton & Barto, 1998).

Traditionally, the equivalence to a forward view was known to hold only when the predictions are updated offline. In practice TD algorithms are more commonly used online, during learning, but then this equivalence was only approximate. Recently, van Seijen and Sutton (2014) developed true online TD(λ), the first algorithm to be exactly equivalent to a forward view under online updating. For $\lambda = 1$ the updates by true online TD(λ) eventually become exactly equivalent to a Monte Carlo update towards the full return. As demonstrated by van Seijen and Sutton, such an online equivalence is more than a theoretical curiosity, and leads to lower prediction errors than when using the traditional TD(λ) algorithm that only achieves an offline equivalence. In this paper, we generalize this result and show exact online equivalences are possible for a wide range of forward views, leading to computationally efficient online algorithms by exploiting a new generic trace update.

A limitation of the true online TD(λ) algorithm by van Seijen and Sutton (2014) is that it is only applicable to on-policy learning, when the learned predictions correspond to the policy that is used to generate the data. Off-policy learning is important to be able to learn from demonstrations, to learn about many things at the same time (Sutton et al., 2011), and ultimately to learn about the unknown optimal policy. A natural next step is therefore to apply our general equivalence result to an off-policy forward view. We construct such a forward view and derive an equivalent new off-policy gradient TD algorithm, that we call *true online GTD(λ)*. This algorithm is constructed to be equivalent for $\lambda = 0$, by design, to the existing GTD(λ) algorithm (Maei, 2011). We demonstrate empirically that for higher λ the new algorithm is much better behaved due to its exact

equivalence to a desired forward view. In addition to the practical potential of the new algorithm, this demonstrates the usefulness of our general equivalence result and the resulting new trace update.

2 Problem setting

We consider a learning agent in an unknown environment where at each time step t the agent performs an action A_t after which the environment transitions from the current state S_t to the next state S_{t+1} . We do not assume the state itself can be observed and the agent instead observes a feature vector $\phi_t \in \mathbb{R}^n$, which is typically a function of the state S_t such that $\phi_t \doteq \phi(S_t)$. The agent selects its actions according to a behavior policy b , such that $b(a|S_t)$ denotes the probability of selecting action $A_t = a$ in state S_t . Typically $b(a|s)$ depends on s through $\phi(s)$.

After performing A_t , the agent observes a scalar (reward) signal R_{t+1} and the process can either terminate or continue. We allow for soft terminations, defined by a potentially time-varying state-dependent termination factor $\gamma_t \in [0, 1]$ (cf. Sutton, Mahmood, Precup & van Hasselt, 2014). With weight $1 - \gamma_{t+1}$ the process terminates at time $t + 1$ and R_{t+1} is considered the last reward in this episode. With weight γ_{t+1} we continue to the next state and observe $\phi_{t+1} \doteq \phi(S_{t+1})$. The agent then selects a new action A_{t+1} and this process repeats. A special case is the episodic setting where $\gamma_t = 1$ for all non-terminating times t and $\gamma_T = 0$ when the episode ends at time T . The termination factors are commonly called *discount factors*, because they discount the effect of later rewards.

The goal is to predict the sum of future rewards, discounted by the probabilities of termination, under a target policy π . The optimal prediction is thus defined for each state s by

$$v_\pi(s) \doteq \mathbb{E}_\pi \left[\sum_{t=1}^{\infty} R_t \prod_{k=1}^t \gamma_k \mid S_0 = s \right],$$

where $\mathbb{E}_\pi[\cdot] \doteq \mathbb{E}[\cdot \mid A_t \sim \pi(\cdot|S_t), \forall t]$ is the expectancy conditional on the policy π . We estimate the values $v_\pi(s)$ with a parameterized function of the observed features. In particular we consider linear functions of the features, such that $\theta_t^\top \phi_t \approx v_\pi(S_t)$ is the estimated value of the state at time t according to a weight vector θ_t . The goal is then to improve the predictions by updating θ_t .

We desire online algorithms with a constant $O(n)$ per-step complexity, where n is the number of features in ϕ . Such computational considerations are important in settings with a lot of data or when ϕ_t is a large vector. For instance, we want our algorithms to be able to run on a robot with many sensors and limited on-board processing power.

3 General online equivalence between forward and backward views

We can think about what the ideal update would be for a prediction after observing all relevant future rewards and states. Such an update is called a forward view, because it depends on observations from the future. A concrete example is the on-policy Monte Carlo return, consisting of the discounted sum of all future rewards.

In practice, full Monte Carlo updates can have high variance. It can be better to augment the return with the then-current predictions at the visited states. When we continue after some time step t , with weight γ_{t+1} , we replace a portion of $1 - \lambda_{t+1}$ of the remaining return with our current prediction of this return at S_{t+1} . Making use of later predictions to update earlier predictions in this way is called *bootstrapping*. The process then continues to the next action and reward with total weight $\gamma_{t+1}\lambda_{t+1}$, where again we terminate with $1 - \gamma_{t+2}$ and then bootstrap with $1 - \lambda_{t+2}$, and so on. When $\lambda_{t+1} = 0$ we get the usual one-step TD return $R_{t+1} + \gamma_{t+1}\phi_{t+1}^\top \theta_t$. If $\lambda_t = 1$ for all t , we obtain a full (discounted) Monte Carlo return. In the on-policy setting, when we do not have to worry about deviations from the target policy, we can then update the prediction made at time t towards the on-policy λ -return defined by

$$G_t^\lambda = R_{t+1} + \gamma_{t+1} \left[(1 - \lambda_{t+1}) \phi_{t+1}^\top \theta_t + \lambda_{t+1} G_{t+1}^\lambda \right].$$

The discount factors γ_t are normally considered a property of the problem, but the bootstrap parameters λ_t can be considered tunable parameters. The full return (obtained for $\lambda = 1$) is an unbiased estimate for the value of the behavior policy, but its variance can be high. The value estimates are typically not unbiased, but can be considerably less variable. As such, one can interpret the λ parameters as trading off bias and variance. Typically, learning is fastest for intermediate values of λ .

If termination never occurs, G_t^λ is never fully defined. To construct a well-defined forward view, we can truncate the recursion at the current data horizon (van Seijen & Sutton, 2014; Sutton et al., 2014) to obtain interim λ -returns. If we have data up to time t , all returns are truncated as if $\lambda_t = 0$ and we bootstrap on the most recent value estimate $\phi_t^\top \theta_{t-1}$ of the current state. This gives us, for each $0 \leq k < t$

$$G_{k,t}^\lambda = R_{k+1} + \gamma_{k+1} \left[(1 - \lambda_{k+1}) \phi_{k+1}^\top \theta_k + \lambda_{k+1} G_{k+1,t}^\lambda \right]$$

and $G_{t,t}^\lambda = \phi_t^\top \theta_{t-1}$. In this definition of $G_{k,t}^\lambda$, for each time step j with $k < j \leq t$ the value of state S_j is estimated using $\phi_j^\top \theta_{j-1}$, because θ_{j-1} is the most up-to-date weight vector at the moment we reach this state.

Using these interim returns, we can construct an interim forward view which, in contrast to conventional forward

views, can be computed before an episode has concluded or even if the episode never fully terminates. For instance, when we have data up to time t the following set of linear updates for all times $k < t$ is an interim forward view:

$$\boldsymbol{\theta}_{k+1}^t = \boldsymbol{\theta}_k^t + \alpha_k (G_{k,t}^\lambda - \boldsymbol{\phi}_k^\top \boldsymbol{\theta}_k^t) \boldsymbol{\phi}_k, \quad k < t, \quad (1)$$

where $\boldsymbol{\theta}_0^t \doteq \boldsymbol{\theta}_0$ is the initial weight vector. The subscript on $\boldsymbol{\theta}_k^t$ (first index on $G_{k,t}^\lambda$) corresponds to the state for the k th update, the superscript (second index on $G_{k,t}^\lambda$) denotes the current data horizon.

The forward view (1) is well-defined and computable at every time t , but it is not very computationally efficient. For each new observation, when t increments to $t+1$, we potentially have to recompute all the updates, as $G_{k,t+1}^\lambda$ might differ from $G_{k,t}^\lambda$ for arbitrary many k . The resulting computational complexity is $O(nt)$ per time step, which is problematic when t becomes large. Therefore, forward views are not meant to be implemented as is. They serve as a conceptual update, in which we formulate what we want to achieve after observing the relevant data.

In the next theorem, we prove that for many forward views an efficient and fully equivalent *backward view* exists that exploits eligibility traces to construct online updates that use only $O(n)$ computation per time step, but that still result in exactly the same weight vectors. The theorem is constructive, allowing us to find such backward views automatically for a given forward view.

Theorem 1 (Equivalence between forward and backward views). *Consider any forward view that updates towards some interim targets Y_k^t with*

$$\boldsymbol{\theta}_{k+1}^t = \boldsymbol{\theta}_k^t + \eta_k (Y_k^t - \boldsymbol{\phi}_k^\top \boldsymbol{\theta}_k^t) \boldsymbol{\phi}_k + \mathbf{x}_k, \quad 0 \leq k < t,$$

where $\boldsymbol{\theta}_0^t = \boldsymbol{\theta}_0$ for some initial $\boldsymbol{\theta}_0$ and where $\mathbf{x}_k \in \mathbb{R}^n$ is any vector that does not depend on t . Assume that the temporal differences $Y_k^{t+1} - Y_k^t$ for different k are related through

$$Y_k^{t+1} - Y_k^t = c_k (Y_{k+1}^{t+1} - Y_{k+1}^t), \quad \forall k < t, \quad (2)$$

where c_k is a scalar that does not depend on t . Then, the final weights $\boldsymbol{\theta}_t^t$ at each t are equal to the weights $\boldsymbol{\theta}_t$ as defined by $\mathbf{e}_0 = \eta_0 \boldsymbol{\phi}_0$ and the backward view

$$\begin{aligned} \boldsymbol{\theta}_{t+1} &= \boldsymbol{\theta}_t + (Y_t^{t+1} - Y_t^t) \mathbf{e}_t + \eta_t (Y_t^t - \boldsymbol{\phi}_t^\top \boldsymbol{\theta}_t) \boldsymbol{\phi}_t + \mathbf{x}_t, \\ \mathbf{e}_t &= c_{t-1} \mathbf{e}_{t-1} + \eta_t (1 - c_{t-1} \boldsymbol{\phi}_t^\top \mathbf{e}_{t-1}) \boldsymbol{\phi}_t, \quad t > 0. \end{aligned} \quad (3)$$

Proof. We introduce the fading matrix $\mathbf{F}_t \doteq \mathbf{I} - \eta_t \boldsymbol{\phi}_t \boldsymbol{\phi}_t^\top$, such that $\boldsymbol{\theta}_{k+1}^t = \mathbf{F}_k \boldsymbol{\theta}_k^t + \eta_k Y_k^t \boldsymbol{\phi}_k$. We subtract $\boldsymbol{\theta}_t^t$ from $\boldsymbol{\theta}_{t+1}^t$ to find the change when t increments. Expanding

$\boldsymbol{\theta}_{t+1}^{t+1}$, we get

$$\begin{aligned} \boldsymbol{\theta}_{t+1}^{t+1} - \boldsymbol{\theta}_t^t &= \mathbf{F}_t \boldsymbol{\theta}_t^{t+1} - \boldsymbol{\theta}_t^t + \eta_t Y_t^{t+1} \boldsymbol{\phi}_t + \mathbf{x}_t \\ &= \mathbf{F}_t (\boldsymbol{\theta}_t^{t+1} - \boldsymbol{\theta}_t^t) + \eta_t Y_t^{t+1} \boldsymbol{\phi}_t + (\mathbf{F}_t - \mathbf{I}) \boldsymbol{\theta}_t^t + \mathbf{x}_t \\ &= \mathbf{F}_t (\boldsymbol{\theta}_t^{t+1} - \boldsymbol{\theta}_t^t) + \eta_t Y_t^{t+1} \boldsymbol{\phi}_t - \eta_t \boldsymbol{\phi}_t \boldsymbol{\phi}_t^\top \boldsymbol{\theta}_t^t + \mathbf{x}_t \\ &= \mathbf{F}_t (\boldsymbol{\theta}_t^{t+1} - \boldsymbol{\theta}_t^t) + \eta_t (Y_t^{t+1} - \boldsymbol{\phi}_t^\top \boldsymbol{\theta}_t^t) \boldsymbol{\phi}_t + \mathbf{x}_t. \end{aligned} \quad (4)$$

We now repeatedly expand both $\boldsymbol{\theta}_t^{t+1}$ and $\boldsymbol{\theta}_t^t$ to get

$$\begin{aligned} \boldsymbol{\theta}_t^{t+1} - \boldsymbol{\theta}_t^t &= \mathbf{F}_{t-1} (\boldsymbol{\theta}_{t-1}^{t+1} - \boldsymbol{\theta}_{t-1}^t) + \eta_{t-1} (Y_{t-1}^{t+1} - Y_{t-1}^t) \boldsymbol{\phi}_{t-1} \\ &= \mathbf{F}_{t-1} \mathbf{F}_{t-2} (\boldsymbol{\theta}_{t-1}^{t+1} - \boldsymbol{\theta}_{t-1}^t) \\ &\quad + \eta_{t-2} (Y_{t-2}^{t+1} - Y_{t-2}^t) \mathbf{F}_{t-1} \boldsymbol{\phi}_{t-2} \\ &\quad + \eta_{t-1} (Y_{t-1}^{t+1} - Y_{t-1}^t) \boldsymbol{\phi}_{t-1} \\ &= \dots \text{(Expand until reaching } \boldsymbol{\theta}_0^{t+1} - \boldsymbol{\theta}_0^t = \mathbf{0}.) \\ &= \mathbf{F}_{t-1} \cdots \mathbf{F}_0 (\boldsymbol{\theta}_0^{t+1} - \boldsymbol{\theta}_0^t) \\ &\quad + \sum_{k=0}^{t-1} \eta_k \mathbf{F}_{t-1} \cdots \mathbf{F}_{k+1} (Y_k^{t+1} - Y_k^t) \boldsymbol{\phi}_k \\ &= \sum_{k=0}^{t-1} \eta_k \mathbf{F}_{t-1} \cdots \mathbf{F}_{k+1} (Y_k^{t+1} - Y_k^t) \boldsymbol{\phi}_k \\ &= \sum_{k=0}^{t-1} \eta_k \mathbf{F}_{t-1} \cdots \mathbf{F}_{k+1} c_k (Y_{k+1}^{t+1} - Y_{k+1}^t) \boldsymbol{\phi}_k \quad \text{(Using (2))} \\ &= \dots \text{(Apply (2) repeatedly.)} \\ &= c_{t-1} \underbrace{\sum_{k=0}^{t-1} \eta_k \left(\prod_{j=k}^{t-2} c_j \right) \mathbf{F}_{t-1} \cdots \mathbf{F}_{k+1} \boldsymbol{\phi}_k (Y_t^{t+1} - Y_t^t)}_{\doteq \mathbf{e}_{t-1}} \\ &= c_{t-1} \mathbf{e}_{t-1} (Y_t^{t+1} - Y_t^t). \end{aligned} \quad (5)$$

The vector \mathbf{e}_t can be computed with the recursion

$$\begin{aligned} \mathbf{e}_t &= \sum_{k=0}^t \eta_k \left(\prod_{j=k}^{t-1} c_j \right) \mathbf{F}_t \cdots \mathbf{F}_{k+1} \boldsymbol{\phi}_k \\ &= \sum_{k=0}^{t-1} \eta_k \left(\prod_{j=k}^{t-1} c_j \right) \mathbf{F}_t \cdots \mathbf{F}_{k+1} \boldsymbol{\phi}_k + \eta_t \boldsymbol{\phi}_t \\ &= c_{t-1} \mathbf{F}_t \sum_{k=0}^{t-1} \eta_k \left(\prod_{j=k}^{t-2} c_j \right) \mathbf{F}_{t-1} \cdots \mathbf{F}_{k+1} \boldsymbol{\phi}_k + \eta_t \boldsymbol{\phi}_t \\ &= c_{t-1} \mathbf{F}_t \mathbf{e}_{t-1} + \eta_t \boldsymbol{\phi}_t \\ &= c_{t-1} \mathbf{e}_{t-1} + \eta_t (1 - c_{t-1} \boldsymbol{\phi}_t^\top \mathbf{e}_{t-1}) \boldsymbol{\phi}_t. \end{aligned}$$

We plug (5) back into (4) and obtain

$$\begin{aligned}
& \boldsymbol{\theta}_{t+1}^{t+1} - \boldsymbol{\theta}_t^t \\
&= c_{t-1} \mathbf{F}_t \mathbf{e}_{t-1} (Y_t^{t+1} - Y_t^t) + \eta_t (Y_t^{t+1} - \boldsymbol{\phi}_t^\top \boldsymbol{\theta}_t) \boldsymbol{\phi}_t + \mathbf{x}_t \\
&= (\mathbf{e}_t - \eta_t \boldsymbol{\phi}_t) (Y_t^{t+1} - Y_t^t) + \eta_t (Y_t^{t+1} - \boldsymbol{\phi}_t^\top \boldsymbol{\theta}_t) \boldsymbol{\phi}_t + \mathbf{x}_t \\
&= (Y_t^{t+1} - Y_t^t) \mathbf{e}_t + \eta_t (Y_t^t - \boldsymbol{\phi}_t^\top \boldsymbol{\theta}_t) \boldsymbol{\phi}_t + \mathbf{x}_t.
\end{aligned}$$

Because $\boldsymbol{\theta}_{0,t} \doteq \boldsymbol{\theta}_0$ for all t , the desired result follows through induction. \square

The theorem shows that under condition (2) we can turn a general forward view into an equivalent online algorithm that only uses $O(n)$ computation per time step. Compared to previous work on forward/backward equivalences, this grants us two important things. First, the obtained equivalence is both online and exact; most previous equivalences were only exact under offline updating, when the weights are not updated during learning (Sutton & Barto, 1998; Sutton et al., 2014). Second, the theorem is constructive, and gives an equivalent backward view directly from a desired forward view, rather than having to prove such an equivalence in hindsight (as in, e.g., van Seijen & Sutton, 2014). This is perhaps the main benefit of the theorem: rather than relying on insight and intuition to construct efficient online algorithms, Theorem 1 can be used to derive an exact backward view directly from a desired forward view. We exploit this in Section 6 when we turn a desired off-policy forward view into an efficient new online off-policy algorithm.

We refer to traces of the general form (3) as *dutch traces*. The trace update can be interpreted as first shrinking the traces with c , for instance $c = \gamma\lambda$, and then updating the traces for the current state, $\boldsymbol{\phi}_t^\top \mathbf{e}$, towards one with a step size of η . In contrast, traditional accumulating traces, defined by $\mathbf{e}_t = c_{t-1} \mathbf{e}_{t-1} + \boldsymbol{\phi}_t$, add to the trace value of the current state rather than updating it toward one. This can cause the accumulating traces to grow large, potentially resulting in high-variance updates.

To demonstrate one advantage of Theorem 1, we apply it to the on-policy TD(λ) forward view defined by (1).

Theorem 2 (Equivalence for true online TD(λ)). *Define $\boldsymbol{\theta}_0^0 = \boldsymbol{\theta}_0$. Then, $\boldsymbol{\theta}_t^t$ as defined by (1) equals $\boldsymbol{\theta}_t$ as defined by the backward view*

$$\begin{aligned}
\delta_t &= R_{t+1} + \gamma \boldsymbol{\phi}_{t+1}^\top \boldsymbol{\theta}_t - \boldsymbol{\phi}_t^\top \boldsymbol{\theta}_{t-1}, \\
\mathbf{e}_t &= \gamma\lambda \mathbf{e}_{t-1} + \alpha_t (1 - \gamma\lambda \boldsymbol{\phi}_t^\top \mathbf{e}_{t-1}) \boldsymbol{\phi}_t, \\
\boldsymbol{\theta}_{t+1} &= \boldsymbol{\theta}_t + \delta_t \mathbf{e}_t + \alpha_t (\boldsymbol{\phi}_t^\top \boldsymbol{\theta}_{t-1} - \boldsymbol{\phi}_t^\top \boldsymbol{\theta}_t) \boldsymbol{\phi}_t.
\end{aligned}$$

Proof. In Theorem 1, we substitute $\mathbf{x}_t = \mathbf{0}$, $c_t = \gamma\lambda$ and $Y_k^t = G_{k,t}^\lambda$, such that $Y_t^{t+1} - Y_t^t = \delta_t$ and $Y_t^t = \boldsymbol{\phi}_t^\top \boldsymbol{\theta}_{t-1}$. The desired result follows immediately. \square

The backward view in Theorem 2 is true online TD(λ), as proposed by van Seijen and Sutton (2014). Using Theorem 1, we have proved equivalence to its forward view with a few simple substitutions, whereas the original proof is much longer and more complex.

4 Off-policy learning

In this section, we turn to off-policy learning with function approximation. In constructing an off-policy forward view two issues arise that are not present in the on-policy setting. First, we need to estimate the value of a policy that is different than the one used to obtain the observations. Second, using a forward view such as (1) under off-policy sampling can cause it to be unstable, potentially resulting in divergence of the weights (Sutton et al., 2008). These issues can be avoided by constructing our off-policy algorithms to minimize a mean-squared projected Bellman error (MSPBE) with gradient descent (Sutton et al., 2009; Maei & Sutton, 2010; Maei, 2011).

The MSPBE was previously used to derive GTD(λ) (Maei, 2011), which is an online algorithm that can be used to learn off-policy predictions. GTD(λ) was not constructed to be exactly equivalent to any forward view and it is a natural question whether the algorithm can be improved from having such an equivalence, just as was the case with TD(λ) and true online TD(λ). In this section, we introduce an off-policy MSPBE and show how GTD(λ) can be derived. In the next section, we use the same MSPBE to construct a new off-policy forward view from which we will derive an exactly equivalent online backward view.

To obtain estimates for one distribution when the samples are generated under another distribution, we can weight the observations by the relative probabilities of these observations occurring under the target policy, as compared to the behavior distribution. This is called *importance sampling* (Rubinstein, 1981; Precup, Sutton & Singh, 2000). Recall that $b(a|s)$ and $\pi(a|s)$ denote the probabilities of selecting action a in state s according to the behavior policy and the target policy, respectively. After selecting an action A_t in a state S_t according to b , we observe a reward R_{t+1} . The expected value of this reward is $\mathbb{E}_b[R_{t+1}]$, but if we multiply the reward with the importance-sampling ratio $\rho_t \doteq \pi(A_t|S_t)/b(A_t|S_t)$ the expected value is

$$\begin{aligned}
\mathbb{E}_b[\rho_t R_{t+1} | S_t] &= \sum_a b(a|S_t) \frac{\pi(a|S_t)}{b(a|S_t)} \mathbb{E}[R_{t+1} | S_t, A_t = a] \\
&= \sum_a \pi(a|S_t) \mathbb{E}[R_{t+1} | S_t, A_t = a] \\
&= \mathbb{E}_\pi[R_{t+1} | S_t].
\end{aligned}$$

Therefore $\rho_t R_{t+1}$ is an unbiased sample for the reward under the target policy. This technique can be applied to all the rewards and value estimates in a given λ -return.

For instance, if we want to obtain an unbiased sample for the reward under the target policy n steps after the current state S_t , the total weight applied to this reward should be $\rho_t \rho_{t+1} \cdots \rho_{t+n-1}$. An off-policy λ -return starting from state S_t is given by

$$G_t^{\lambda\rho}(\boldsymbol{\theta}) = \rho_t \left(R_{t+1} + \gamma_{k+1}(1 - \lambda_{k+1}) \boldsymbol{\phi}_{k+1}^\top \boldsymbol{\theta} + \gamma_{k+1} \lambda_{k+1} G_{k+1}^\lambda(\boldsymbol{\theta}) \right). \quad (6)$$

In contrast to G_t^λ , this return is defined as a function of a single weight vector $\boldsymbol{\theta}$. This is useful later, when we wish to determine the gradient of this return with respect to $\boldsymbol{\theta}$.

When using function approximation it is generally not possible to estimate the value of each state with full accuracy or, equivalently, to reduce the conditional expected TD error for each state to zero at the same time. More formally, let v_θ be a parameterized value function defined by $v_\theta(s) = \boldsymbol{\theta}^\top \boldsymbol{\phi}(s)$ and let T_π^λ be a parametrized Bellman operator defined, for any $v : \{s\} \rightarrow \mathbb{R}$, by

$$(T_\pi^\lambda v)(s) = \mathbb{E}_\pi [R_1 + \gamma_1(1 - \lambda_1)v(S_1) + \gamma_1 \lambda_1 (T_\pi^\lambda v)(S_1) \mid S_0 = s].$$

In general, we then cannot achieve $v_\theta = T_\pi^\lambda v_\theta$, because $T_\pi^\lambda v_\theta$ is not guaranteed to be a function that we can represent with our chosen function approximation. It is, however, possible to find the fixed point defined by

$$v_\theta = \Pi T_\pi^\lambda v_\theta. \quad (7)$$

where Πv is a projection of v into the space of representable functions $\{v_\theta \mid \boldsymbol{\theta} \in \mathbb{R}^n\}$. Let d be the steady-state distribution of states under the behavior policy. The projection of any v is then defined by

$$\Pi v = v_{\boldsymbol{\theta}_v}, \quad \text{where} \quad \boldsymbol{\theta}_v = \arg \min_{\boldsymbol{\theta}} \|v_\theta - v\|_d^2,$$

where $\|\cdot\|_d^2$ is a norm defined by $\|f\|_d^2 \doteq \sum_s d(s) f(s)^2$. Following Maei (2011), the projection is defined in terms of the steady-state distribution resulting from the behavior policy, which means that $d(s) = \lim_{t \rightarrow \infty} \mathbb{P}(S_t = s \mid A_j \sim b(\cdot | S_j), \forall j)$. This implies our objective weights the importance of the accuracy of the prediction in each state according to the relative frequency that this state occurs under the behavior policy, which is a natural choice for online learning.

The fixed point in (7) can be found by minimizing the MSPBE defined by (Maei, 2011)

$$J(\boldsymbol{\theta}) = \|v_\theta - \Pi T_\pi^\lambda v_\theta\|_d^2 = \mathbb{E}_b [\delta_k^\pi(\boldsymbol{\theta}) \boldsymbol{\phi}_k]^\top \mathbb{E}_b [\boldsymbol{\phi}_k \boldsymbol{\phi}_k^\top]^{-1} \mathbb{E}_b [\delta_k^\pi(\boldsymbol{\theta}) \boldsymbol{\phi}_k], \quad (8)$$

where $\delta_k^\pi(\boldsymbol{\theta}) \doteq (T_\pi^\lambda v_\theta)(S_k) - v_\theta(S_k)$ and where the expectancies are with respect to the steady-state distribution

d , as induced by the behavior policy b . The ideal gradient update for time step k is then

$$\boldsymbol{\theta}_{k+1} = \boldsymbol{\theta}_k - \frac{1}{2} \alpha \nabla_{\boldsymbol{\theta}} J(\boldsymbol{\theta})|_{\boldsymbol{\theta}_k}, \quad (9)$$

where

$$\begin{aligned} & - \frac{1}{2} \nabla_{\boldsymbol{\theta}} J(\boldsymbol{\theta})|_{\boldsymbol{\theta}_k} \\ &= - \mathbb{E}_b [\nabla_{\boldsymbol{\theta}} \delta_k^\pi(\boldsymbol{\theta}) \boldsymbol{\phi}_k^\top] \mathbb{E}_b [\boldsymbol{\phi}_k \boldsymbol{\phi}_k^\top]^{-1} \mathbb{E}_b [\delta_k^\pi(\boldsymbol{\theta}_k) \boldsymbol{\phi}_k] \\ &= \mathbb{E}_b [(\boldsymbol{\phi}_k - \nabla_{\boldsymbol{\theta}} G_k^{\lambda\rho}(\boldsymbol{\theta})) \boldsymbol{\phi}_k^\top] \mathbb{E}_b [\boldsymbol{\phi}_k \boldsymbol{\phi}_k^\top]^{-1} \mathbb{E}_b [\delta_k^\pi(\boldsymbol{\theta}_k) \boldsymbol{\phi}_k] \\ &= \mathbb{E}_b [\delta_k^\pi(\boldsymbol{\theta}_k) \boldsymbol{\phi}_k] \\ &\quad - \mathbb{E}_b [\nabla_{\boldsymbol{\theta}} G_k^{\lambda\rho}(\boldsymbol{\theta}) \boldsymbol{\phi}_k^\top] \mathbb{E}_b [\boldsymbol{\phi}_k \boldsymbol{\phi}_k^\top]^{-1} \mathbb{E}_b [\delta_k^\pi(\boldsymbol{\theta}_k) \boldsymbol{\phi}_k] \\ &= \mathbb{E}_b [\delta_k^\pi(\boldsymbol{\theta}_k) \boldsymbol{\phi}_k] - \mathbb{E}_b [\nabla_{\boldsymbol{\theta}} G_k^{\lambda\rho}(\boldsymbol{\theta}) \boldsymbol{\phi}_k]^\top \mathbf{w}_*, \end{aligned} \quad (10)$$

with $G_k^{\lambda\rho}$ as defined in (6), and where

$$\mathbf{w}_* \doteq \mathbb{E}_b [\boldsymbol{\phi}_k \boldsymbol{\phi}_k^\top]^{-1} \mathbb{E}_b [\delta_k^\pi(\boldsymbol{\theta}_k) \boldsymbol{\phi}_k].$$

Update (9) can be interpreted as an expected forward view.

The derivation of the GTD(λ) algorithm proceeds by exploiting the expected equivalences (Maei, 2011)

$$\begin{aligned} & \mathbb{E}_b [\nabla_{\boldsymbol{\theta}} G_k(\boldsymbol{\theta}) \boldsymbol{\phi}_k^\top] \\ &= \mathbb{E}_b [\rho_k \gamma_{k+1} (1 - \lambda_{k+1}) \boldsymbol{\phi}_{k+1} \boldsymbol{\phi}_k^\top] \\ &\quad + \mathbb{E}_b [\rho_k \gamma_{k+1} \lambda_{k+1} \nabla_{\boldsymbol{\theta}} G_{k+1}(\boldsymbol{\theta}) \boldsymbol{\phi}_k^\top] \\ &= \mathbb{E}_b [\rho_k \gamma_{k+1} (1 - \lambda_{k+1}) \boldsymbol{\phi}_{k+1} \boldsymbol{\phi}_k^\top] \\ &\quad + \mathbb{E}_b [\rho_{k-1} \gamma_k \lambda_k \nabla_{\boldsymbol{\theta}} G_k(\boldsymbol{\theta}) \boldsymbol{\phi}_{k-1}^\top] \\ &= \mathbb{E}_b [\rho_k \gamma_{k+1} (1 - \lambda_{k+1}) \boldsymbol{\phi}_{k+1} \boldsymbol{\phi}_k^\top] \\ &\quad + \mathbb{E}_b [\rho_{k-1} \gamma_k \lambda_k \rho_k \gamma_{k+1} (1 - \lambda_{k+1}) \boldsymbol{\phi}_{k+1} \boldsymbol{\phi}_{k-1}^\top] \\ &\quad + \mathbb{E}_b [\rho_{k-1} \gamma_k \lambda_k \rho_k \gamma_{k+1} \lambda_{k+1} \nabla_{\boldsymbol{\theta}} G_{k+1}(\boldsymbol{\theta}) \boldsymbol{\phi}_{k-1}^\top] \\ &= \mathbb{E}_b [\rho_k \gamma_{k+1} (1 - \lambda_{k+1}) \boldsymbol{\phi}_{k+1} \boldsymbol{\phi}_k^\top] \\ &\quad + \mathbb{E}_b [\rho_{k-1} \gamma_k \lambda_k \rho_k \gamma_{k+1} (1 - \lambda_{k+1}) \boldsymbol{\phi}_{k+1} \boldsymbol{\phi}_{k-1}^\top] \\ &\quad + \mathbb{E}_b [\rho_{k-2} \gamma_{k-1} \lambda_{k-1} \rho_{k-1} \gamma_k \lambda_k \nabla_{\boldsymbol{\theta}} G_k(\boldsymbol{\theta}) \boldsymbol{\phi}_{k-2}^\top] \\ &= \dots \text{(Repeat until we reach } \boldsymbol{\phi}_0) \\ &= \mathbb{E}_b \left[\gamma_{k+1} (1 - \lambda_{k+1}) \boldsymbol{\phi}_{k+1} \rho_k \underbrace{\sum_{j=0}^k \left(\prod_{i=j+1}^k \rho_{i-1} \gamma_i \lambda_i \right)}_{\doteq (\mathbf{e}_k^\nabla)^\top} \boldsymbol{\phi}_j^\top \right] \\ &= \mathbb{E}_b [\gamma_{k+1} (1 - \lambda_{k+1}) \boldsymbol{\phi}_{k+1} (\mathbf{e}_k^\nabla)^\top], \end{aligned} \quad (11)$$

and, similarly, $\mathbb{E}_b [\delta_k^\pi(\boldsymbol{\theta}_k) \boldsymbol{\phi}_k] = \mathbb{E}_b [\delta_k(\boldsymbol{\theta}_k) \mathbf{e}_k^\nabla]$, where

$$\begin{aligned} \mathbf{e}_t^\nabla &= \rho_t (\gamma_t \lambda_t \mathbf{e}_{t-1}^\nabla + \boldsymbol{\phi}_t), \\ \delta_t(\boldsymbol{\theta}) &= R_{t+1} + \gamma_{t+1} \boldsymbol{\phi}_{t+1}^\top \boldsymbol{\theta} - \boldsymbol{\phi}_t^\top \boldsymbol{\theta}. \end{aligned} \quad (12)$$

The auxiliary vector $\mathbf{w}_t \approx \mathbf{w}_*$ can be updated with least mean squares (LMS) (Sutton et al., 2009; Maei, 2011), using the sample $\delta_t(\boldsymbol{\theta}_t) \mathbf{e}_t^\nabla \approx \mathbb{E}_b [\delta_t(\boldsymbol{\theta}_t) \mathbf{e}_t^\nabla] = \mathbb{E}_b [\delta_t^\pi(\boldsymbol{\theta}_t) \boldsymbol{\phi}_t]$

and the update

$$\mathbf{w}_{t+1} = \mathbf{w}_t + \beta_t \delta_t(\boldsymbol{\theta}_t) \mathbf{e}_t^\nabla - \beta_t \boldsymbol{\phi}_t^\top \mathbf{w}_t \boldsymbol{\phi}_t.$$

The complete GTD(λ) algorithm is then defined by¹

$$\begin{aligned} \delta_t &= R_{t+1} + \gamma_{t+1} \boldsymbol{\phi}_{t+1}^\top \boldsymbol{\theta}_t - \boldsymbol{\phi}_t^\top \boldsymbol{\theta}_t, \\ \mathbf{e}_t^\nabla &= \rho_t (\gamma_t \lambda_t \mathbf{e}_{t-1}^\nabla + \boldsymbol{\phi}_t), \\ \boldsymbol{\theta}_{t+1} &= \boldsymbol{\theta}_t + \alpha_t \delta_t \mathbf{e}_t^\nabla - \alpha_t \gamma_{t+1} (1 - \lambda_{t+1}) \mathbf{w}_t^\top \mathbf{e}_t^\nabla \boldsymbol{\phi}_{t+1}, \\ \mathbf{w}_{t+1} &= \mathbf{w}_t + \beta_t \delta_t \mathbf{e}_t^\nabla - \beta_t \boldsymbol{\phi}_t^\top \mathbf{w}_t \boldsymbol{\phi}_t. \end{aligned}$$

5 An off-policy forward view

In this section, we define an off-policy forward view which we turn into a fully equivalent backward view in the next section, using Theorem 1. GTD(λ) is derived by first turning an expected forward view into an expected backward view, and then sampling. We propose instead to sample the expected forward view directly and then invert the sampled forward view into an equivalent online backward view. This way we obtain an exact equivalence between forward and backward views instead of the expected equivalence of GTD(λ). This was previously not known to be possible, but it has the advantage that we can use the precise (potentially discounted and bootstrapped) sample returns consisting of all future rewards and state values in each update. This can result in more accurate predictions, as confirmed by our experiments in Section 7.

The new forward view derives from the MSPBE, as defined in (8), and more specifically from the gradient update defined by (9) and (10). To find an implementable interim forward view, we need sampled estimates of all three parts in (10). We discuss each of these parts separately.

Our interim forward view is defined in terms of a data horizon t , so the gradient of the MSPBE is taken to $\boldsymbol{\theta}_k^t$ rather than $\boldsymbol{\theta}_k$. Furthermore, δ_k^π is defined as the error between a λ -return and a current estimate, and therefore we need to construct an interim λ -return. To estimate the first term of (10) we therefore need an estimate for $\mathbb{E}_b[\delta_k^\pi(\boldsymbol{\theta}_k^t) \boldsymbol{\phi}_k] = \mathbb{E}_b[G_{k,t}^{\lambda\rho} - \boldsymbol{\phi}_k^\top \boldsymbol{\theta}_k^t]$, for some suitably defined $G_{k,t}^{\lambda\rho}$.

The variance of off-policy updates is often lower when we weight the errors (that is, the difference between the return and the current estimate) with the importance-sampling ratios, rather than weighting the returns (Sutton et al., 2014). Let $\delta_k = R_{k+1} + \gamma_{k+1} \boldsymbol{\phi}_{k+1}^\top \boldsymbol{\theta}_k - \boldsymbol{\phi}_k^\top \boldsymbol{\theta}_{k-1}$ denote a one-step TD error. The on-policy return used in the forward view (1) can then be written as a sum of such errors:

$$G_{k,t}^\lambda = \boldsymbol{\phi}_k^\top \boldsymbol{\theta}_{k-1} + \sum_{j=k}^{t-1} \left(\prod_{i=k+1}^j \gamma_i \lambda_i \right) \delta_j.$$

¹Dann, Neumann and Peters (2014) call this algorithm TDC(λ), but we use the original name by Maei (2011).

We apply the importance-sampling weights to the one-step TD errors, rather than just to the reward and bootstrapped value estimate.² This does not affect the expected value, because $\mathbb{E}_b[\rho_k \boldsymbol{\phi}_k^\top \boldsymbol{\theta}_{k-1} | S_k] = \mathbb{E}_b[\boldsymbol{\phi}_k^\top \boldsymbol{\theta}_{k-1} | S_k]$, but it can have a beneficial effect on the variance of the resulting updates. A sampled off-policy error is then

$$G_{k,t}^{\lambda\rho} - \rho_k \boldsymbol{\phi}_k^\top \boldsymbol{\theta}_k^t \approx \mathbb{E}_b[\delta_k^\pi(\boldsymbol{\theta}_k^t) \boldsymbol{\phi}_k], \quad (13)$$

where

$$G_{k,t}^{\lambda\rho} \doteq \rho_k \boldsymbol{\phi}_k^\top \boldsymbol{\theta}_{k-1} + \rho_k \sum_{j=k}^{t-1} \left(\prod_{i=k+1}^j \gamma_i \lambda_i \rho_i \right) \delta_j.$$

An equivalent recursive definition for $G_{k,t}^{\lambda\rho}$ is

$$\begin{aligned} G_{k,t}^{\lambda\rho} &= \rho_k \left(R_{k+1} + \gamma_{k+1} (1 - \lambda_{k+1} \rho_{k+1}) \boldsymbol{\phi}_{k+1}^\top \boldsymbol{\theta}_k \right. \\ &\quad \left. + \gamma_{k+1} \lambda_{k+1} G_{k+1,t}^{\lambda\rho} \right), \quad (14) \end{aligned}$$

for $k < t$, and $G_{t,t}^{\lambda\rho} \doteq \rho_t \boldsymbol{\phi}_t^\top \boldsymbol{\theta}_{t-1}$. In the on-policy case, when $\rho_k = 1$ for all k , $G_{k,t}^{\lambda\rho}$ reduces exactly to $G_{k,t}^\lambda$, as used in the forward view (1) for true online TD(λ). Furthermore, $\mathbb{E}_b[G_{k,t}^{\lambda\rho} | S_k = s] = \mathbb{E}_\pi[G_{k,t}^\lambda | S_k = s]$ for any s .

For the second term in (10), which can be thought of as the gradient correction term, we need an estimate $\mathbf{w}_k \approx \mathbf{w}_*$. As in the derivation of GTD(λ), we use a LMS update. Assuming we have data up to t , the ideal forward-view update for \mathbf{w}_k^t is then

$$\mathbf{w}_{k+1}^t = \mathbf{w}_k^t + \beta_k (\delta_{k,t}^{\lambda\rho} - \boldsymbol{\phi}_k^\top \mathbf{w}_k^t) \boldsymbol{\phi}_k, \quad (15)$$

for some appropriate sample $\delta_{k,t}^{\lambda\rho} \approx \mathbb{E}_b[\delta_k^\pi(\boldsymbol{\theta}_k)]$. A natural interim estimate is defined by

$$\delta_{k,t}^{\lambda\rho} = \rho_k (\delta_k + \gamma \lambda \delta_{k+1,t}^{\lambda\rho}), \quad (16)$$

where $\delta_{t,t}^{\lambda\rho} = 0$ and

$$\delta_k = R_{k+1} + \gamma \boldsymbol{\theta}_k^\top \boldsymbol{\phi}_{k+1} - \boldsymbol{\theta}_k^\top \boldsymbol{\phi}_k.$$

This is not the only possible way to estimate \mathbf{w}_* , but this choice ensures the resulting algorithm is equivalent to GTD(0) when $\lambda = 0$, allowing us to investigate the effects of the true online equivalence and the resulting new trace updates in some isolation without having to worry about other potential differences between the algorithms. In the next section we construct an equivalent backward view for (15) to compute the sequence $\{\mathbf{w}_t\}$, where $\mathbf{w}_t = \mathbf{w}_t^t, \forall t$.

²For the PTD(λ) and PQ(λ) algorithms, Sutton et al. (2014) propose another weighting based on weighting flat return errors containing multiple rewards. In contrast, our weighting is chosen to be consistent with GTD(λ). True online versions of PTD(λ) and PQ(λ) exist, but we do not consider them further in this paper.

Finally, we use the expected equivalence proved in (11), and then sample to obtain

$$\gamma_{k+1}(1 - \lambda_{k+1})\phi_{k+1}(\mathbf{e}_k^\nabla)^\top \approx \mathbb{E}_b[\nabla_{\boldsymbol{\theta}} G_k(\boldsymbol{\theta})\phi_k^\top], \quad (17)$$

with \mathbf{e}_k^∇ as defined in (12).

We now have all the pieces to state the off-policy forward view for $\boldsymbol{\theta}$. We approximate the expected forward view as defined by (9) and (10) by using the sampled estimates (13), (17) and $\mathbf{w}_k = \mathbf{w}_k^k \approx \mathbf{w}_*$, with \mathbf{w}_k^k as defined by (15). This gives us the interim forward view

$$\begin{aligned} \boldsymbol{\theta}_{k+1}^t &= \boldsymbol{\theta}_k^t + \alpha_k(G_{k,t}^{\lambda\rho} - \rho_k\phi_k^\top\boldsymbol{\theta}_k^t)\phi_k \\ &\quad - \alpha_k\gamma_{k+1}(1 - \lambda_{k+1})\phi_{k+1}\mathbf{w}_k^\top\mathbf{e}_k^\nabla, \end{aligned} \quad (18)$$

with $G_{k,t}^{\lambda\rho}$ as defined in (14).

6 Backward view: true online GTD(λ)

In this section, we apply Theorem 1 to convert the off-policy forward view as given by (18) into an efficient online backward view. First, we consider \mathbf{w} .

Theorem 3 (Auxiliary vectors). *The vector \mathbf{w}_t^t , as defined by the forward view in (15), is equal to \mathbf{w}_t as defined by the backward view*

$$\begin{aligned} \mathbf{e}_t^w &= \rho_{t-1}\gamma_t\lambda_t\mathbf{e}_{t-1}^w + \beta_t(1 - \rho_{t-1}\gamma_t\lambda_t\phi_t^\top\mathbf{e}_{t-1}^w)\phi_t, \\ \mathbf{w}_{t+1} &= \mathbf{w}_t + \rho_t\delta_t\mathbf{e}_t^w - \beta_t\phi_t^\top\mathbf{w}_t\phi_t, \end{aligned}$$

where $\mathbf{e}_0^w = \beta_0\phi_0$, $\mathbf{w}_0 = \mathbf{w}_0^t, \forall t$, and

$$\delta_t \doteq R_{t+1} + \gamma\phi_{t+1}^\top\boldsymbol{\theta}_t - \phi_t^\top\boldsymbol{\theta}_t.$$

Proof. We apply Theorem 1 by substituting $\boldsymbol{\theta}_t = \mathbf{w}_t, \eta_t = \beta_t, \mathbf{x}_t = \mathbf{0}$ and $Y_k^t = \delta_{k,t}^{\lambda\rho}$ as defined in (16). Then

$$\delta_{k,t+1}^{\lambda\rho} - \delta_{k,t}^{\lambda\rho} = \rho_k\gamma_{k+1}\lambda_{k+1}(\delta_{k+1,t+1}^{\lambda\rho} - \delta_{k+1,t}^{\lambda\rho}),$$

which implies $c_k = \rho_k\gamma_{k+1}\lambda_{k+1}$. Finally, $Y_t^t = \delta_{t,t}^{\lambda\rho} = 0$ and $Y_t^{t+1} - Y_t^t = \delta_{t,t+1}^{\lambda\rho} = \rho_t\delta_t$. Inserting these substitutions into the backward view in Theorem 1 immediately yields the backward view in the current theorem. \square

Theorem 4 (True online GTD(λ)). *For any t , the weight vector $\boldsymbol{\theta}_t^t$ as defined by forward view in (18) is equal to $\boldsymbol{\theta}_t$, as defined by the backward view*

$$\begin{aligned} \mathbf{e}_t &= \rho_t(\gamma_t\lambda_t\mathbf{e}_{t-1} + \alpha_t(1 - \rho_t\gamma_t\lambda_t\phi_t^\top\mathbf{e}_{t-1})\phi_t), \\ \mathbf{e}_t^\nabla &= \rho_t(\gamma_t\lambda_t\mathbf{e}_{t-1}^\nabla + \phi_t), \\ \boldsymbol{\theta}_{t+1} &= \boldsymbol{\theta}_t + \delta_t\mathbf{e}_t + (\mathbf{e}_t - \alpha_t\rho_t\phi_t)(\boldsymbol{\theta}_t - \boldsymbol{\theta}_{t-1})^\top\phi_t \\ &\quad - \alpha_t\gamma_{t+1}(1 - \lambda_{t+1})\mathbf{w}_t^\top\mathbf{e}_t^\nabla\phi_{t+1}, \end{aligned}$$

with \mathbf{w}_t and δ_t as defined in Theorem 3.

Proof. Again, we apply Theorem 1. Substitute $\eta_t = \rho_t\alpha_t, \mathbf{x}_k = -\alpha_k\gamma_{k+1}(1 - \lambda_{k+1})\phi_{k+1}\mathbf{w}_k^\top\mathbf{e}_k^\nabla, Y_t^t = \boldsymbol{\theta}_{t-1}^\top\phi_t$ and

$$Y_k^t = R_{k+1} + \gamma_{k+1}(1 - \lambda_{k+1}\rho_{k+1})\boldsymbol{\theta}_k^\top\phi_{k+1} + \gamma\lambda G_{k+1,t}^{\lambda\rho}.$$

This last substitution implies

$$Y_k^{t+1} - Y_k^t = \gamma_{k+1}\lambda_{k+1}\rho_{k+1}(Y_{k+1}^{t+1} - Y_{k+1}^t),$$

so that $c_k = \gamma_{k+1}\lambda_{k+1}\rho_{k+1}$. Furthermore,

$$\begin{aligned} Y_t^{t+1} - Y_t^t &= R_{t+1} + \gamma\boldsymbol{\theta}_t^\top\phi_{t+1} - \boldsymbol{\theta}_{t-1}^\top\phi_t \\ &= \delta_t + (\boldsymbol{\theta}_t - \boldsymbol{\theta}_{t-1})^\top\phi_t. \end{aligned}$$

Applying Theorem 1 with these substitutions, and replacing \mathbf{w}_t^t with the equivalent \mathbf{w}_t , yields the backward view

$$\begin{aligned} \boldsymbol{\theta}_{t+1} &= \boldsymbol{\theta}_t + (\delta_t + (\boldsymbol{\theta}_t - \boldsymbol{\theta}_{t-1})^\top\phi_t)\mathbf{e}_t \\ &\quad + \alpha_t\rho_t(\boldsymbol{\theta}_{t-1}^\top\phi_t - \boldsymbol{\theta}_t^\top\phi_t)\phi_t \\ &\quad - \alpha_t\gamma_{t+1}(1 - \lambda_{t+1})\mathbf{w}_t^\top\mathbf{e}_t^\nabla\phi_{t+1}, \\ &= \boldsymbol{\theta}_t + \delta_t\mathbf{e}_t + (\mathbf{e}_t - \alpha_t\rho_t\phi_t)\phi_t^\top(\boldsymbol{\theta}_t - \boldsymbol{\theta}_{t-1}) \\ &\quad - \alpha_t\gamma_{t+1}(1 - \lambda_{t+1})\mathbf{w}_t^\top\mathbf{e}_t^\nabla\phi_{t+1}, \end{aligned}$$

where $\mathbf{e}_0 = \alpha_0\rho_0\phi_0$ and

$$\mathbf{e}_t = \rho_t\gamma_t\lambda_t\mathbf{e}_{t-1} + \alpha_t\rho_t(1 - \rho_t\gamma_t\lambda_t\mathbf{e}_{t-1}^\top\phi_t)\phi_t. \quad \square$$

True online GTD(λ) algorithm is then defined by

$$\begin{aligned} \delta_t &= R_{t+1} + \gamma\phi_{t+1}^\top\boldsymbol{\theta}_t - \phi_t^\top\boldsymbol{\theta}_t, \\ \mathbf{e}_t &= \rho_t(\gamma_t\lambda_t\mathbf{e}_{t-1} + \alpha_t(1 - \rho_t\gamma_t\lambda_t\phi_t^\top\mathbf{e}_{t-1})\phi_t), \\ \mathbf{e}_t^\nabla &= \rho_t(\gamma_t\lambda_t\mathbf{e}_{t-1}^\nabla + \phi_t), \\ \mathbf{e}_t^w &= \rho_{t-1}\gamma_t\lambda_t\mathbf{e}_{t-1}^w + \beta_t(1 - \rho_{t-1}\gamma_t\lambda_t\phi_t^\top\mathbf{e}_{t-1}^w)\phi_t, \\ \boldsymbol{\theta}_{t+1} &= \boldsymbol{\theta}_t + \delta_t\mathbf{e}_t + (\mathbf{e}_t - \alpha_t\rho_t\phi_t)(\boldsymbol{\theta}_t - \boldsymbol{\theta}_{t-1})^\top\phi_t \\ &\quad - \alpha_t\gamma_{t+1}(1 - \lambda_{t+1})\mathbf{w}_t^\top\mathbf{e}_t^\nabla\phi_{t+1}, \\ \mathbf{w}_{t+1} &= \mathbf{w}_t + \rho_t\delta_t\mathbf{e}_t^w - \beta_t\phi_t^\top\mathbf{w}_t\phi_t. \end{aligned}$$

The traces \mathbf{e}_t and \mathbf{e}_t^w are dutch traces. The trace \mathbf{e}_t^∇ is an accumulating trace that follows from the gradient correction, as discussed in Section 4. It might be possible to adapt the forward view to replace \mathbf{e}_t^∇ with \mathbf{e}_t . This is already possible in practice and in preliminary experiments the resulting algorithm performed similar to true online GTD(λ). A more detailed investigation of this possibility is left for future work.

For $\lambda = 0$ the algorithm reduces to

$$\begin{aligned} \boldsymbol{\theta}_{t+1} &= \boldsymbol{\theta}_t + \alpha_t\rho_t\delta_t\phi_t - \alpha_t\rho_t\gamma_{t+1}\mathbf{w}_t^\top\phi_t\phi_{t+1}, \\ \mathbf{w}_{t+1} &= \mathbf{w}_t + \beta_t\rho_t\delta_t\phi_t - \beta_t\phi_t^\top\mathbf{w}_t\phi_t, \end{aligned}$$

which is precisely GTD(0).³

³The on-policy variant of this algorithm, with $\rho_t = 1$ for all t , is known as TDC (Sutton et al., 2009; Maei, 2011).

7 Experiments

We compare true online GTD(λ) to GTD(λ) empirically in various settings. The main goal of the experiments is to test the intuition that true online GTD(λ) should be more robust to high step sizes and high λ , due to its true online equivalence and better behaved traces. This was shown to be the case for true online TD(λ) (van Seijen & Sutton, 2014), and the experiments serve to verify that this extends to the off-policy setting with true online GTD(λ). This is relevant because it implies true online GTD(λ) should then be easier to tune in practice, and because these parameters can effect the limiting performance of the algorithms as well.

Both algorithms optimize the MSPBE, as given in (8), which is a function of λ . When the state representation is of poor quality, the solution that minimizes the MSPBE can still have a high mean-squared error (MSE): $\|v_\theta - v^\pi\|_d^2$. This means that with a low λ we are not always guaranteed to reach a low MSE, even asymptotically. The closer λ is to one, the closer the MSPBE becomes to the MSE, with equality for $\lambda = 1$. In practice this implies that sometimes we need a high λ to be able to obtain an sufficiently accurate predictions, even if we run the algorithms a long time.

To illustrate these points, we investigate a fairly simple problem. The problem setting is a random walk consisting of 15 states that can be thought to lie on a horizontal line. In each state we have two actions: move one state to the left, or one state to the right. If we move left in the left-most state, s_1 , we bounce back into that state. If we move right in the right-most state, s_{15} , the episode ends and we get a reward of +1. On all other time steps, the reward is zero. Each episode starts in s_1 , which is the left-most state.

This problem setting is similar to the one used by van Seijen and Sutton (2014), with three differences. First, we use 15 rather than 11 states, but this makes little difference to the conclusions. Second, we turn it into an off-policy learning problem, as we describe in a moment. Third, we use different state representations. This last point is because we want to test the performance of the algorithm not just with features that can accurately represent the value function, as used by van Seijen and Sutton, but also with features that cannot reduce the MSE all the way to zero.

In the original problem, there was a 0.9 probability of moving right in each state (van Seijen & Sutton, 2014). Here, we interpret these probabilities as begin due to a behavior policy that selects the ‘right’ action with probability 0.9. Then, we formulate a target policy that want to move right more often, with probability 0.95. The stochastic target policy demonstrates that our algorithm is applicable to arbitrary off-policy learning tasks, and that the results do not depend on the target policy being deterministic. We did also test the performance for a deterministic policy that moves right always and the results are similar to those given

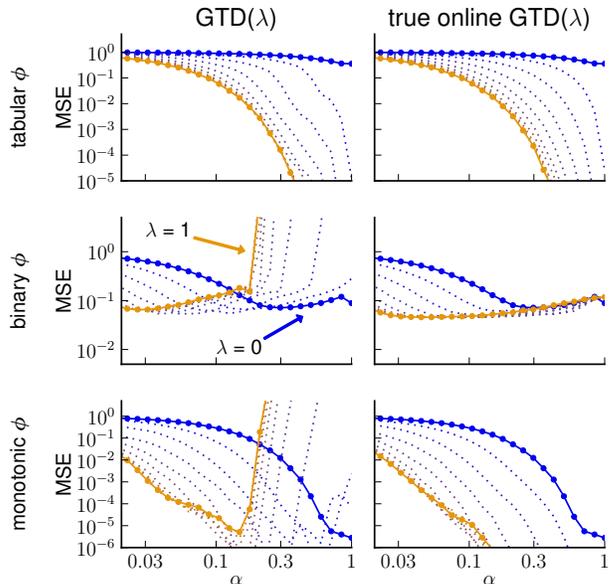

Figure 1: The MSE on the random walk of GTD(λ) (left column) and true online GTD(λ) (right column). The x -axis shows α , and the different lines are for different λ , with $\lambda = 0$ in blue and $\lambda = 1$ in orange. The top row is for 15 tabular features, the middle row for 4 binary features, and the bottom row for 2 monotonic features. The MSE is minimized over β .

below. Because this is an episodic task, $\gamma = 1$.

As stated above, we define three different state representations. In the first task, we use tabular features, such that $\phi(s_i)$ is a vector of 15 elements, with the i th element equal to one and all other elements equal to zero. In the second task the state number is turned into a binary representation, such that $\phi(s_1) = (0, 0, 0, 1)^\top$, $\phi(s_2) = (0, 0, 1, 0)^\top$, $\phi(s_3) = (0, 0, 1, 1)^\top$, and so on up to $\phi(s_{15}) = (1, 1, 1, 1)^\top$. The features are then normalized to be unit vectors, such that for instance $\phi(s_3) = (0, 0, \frac{1}{\sqrt{2}}, \frac{1}{\sqrt{2}})^\top$ and $\phi(s_{15}) = (\frac{1}{2}, \frac{1}{2}, \frac{1}{2}, \frac{1}{2})^\top$. In our final representation, we use one monotonically increasing feature and one monotonically decreasing feature, such that $\phi(s_i) = (\frac{14-i+1}{14}, \frac{i-1}{14})^\top$ for all i . These features were not normalized.

For α the range of parameters was from 2^{-8} to 1 with steps in the exponent of 0.25 so that $\alpha \in \{2^{-8}, 2^{-7.75}, \dots, 1\}$. The secondary step size β was varied over the same range, with the addition of $\beta = 0$. The trace parameter λ was varied from 0 to $1 - 2^{-10} \approx 0.999$ with steps of -1 in the exponent and with the addition of $\lambda = 1$, such that $\lambda \in \{0, 1 - 2^{-1}, \dots, 1 - 2^{-9}, 1 - 2^{-10}, 1\}$.

The MSE (averaged over 20 repetitions) after 10 episodes for all three representations are shown in Figure 1. The left graphs all correspond to GTD(λ) and the plots on the right

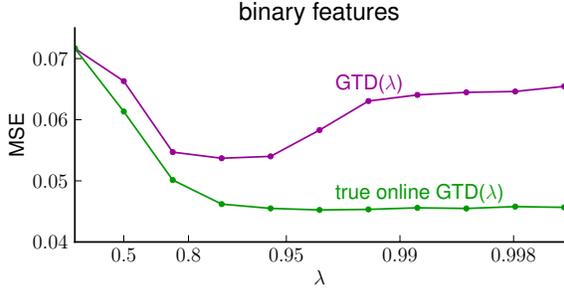

Figure 2: The MSE on the random walk for different λ of GTD(λ) and true online GTD(λ) for optimized α and β and binary features.

are for true online GTD(λ). Each graph show the MSE as a function of α , with different lines for different values of λ of which the extremes are highlighted ($\lambda = 0$ is blue; $\lambda = 1$ is orange). In all cases, the MSE was minimized for β , but this secondary step size had little impact on the performance at all in these problems. Note that the blue lines in the pair of graphs in each row are exactly equal, because by design the algorithms are equivalent for $\lambda = 0$.

In the top plots, the tabular representation was used and we see that especially with high λ both algorithms reach low prediction errors. This demonstrates that indeed learning can be faster with higher λ . When using function approximation, in the middle and bottom graphs, the benefit of having an online equivalence to a well-defined forward view becomes apparent. For both representations, the performance of GTD(λ) with higher λ begins to deteriorate around $\alpha = 0.2$. In contrast, true online GTD(λ) performs well even for $\alpha = \lambda = 1$. Note the log scale of the y -axis; the difference in MSE is many orders of magnitude.

In practice it is not always possible to fully tune the algorithmic parameters and therefore the robustness of true online GTD(λ) to different settings is important. However, it is still interesting to see what the best performance could be for a fully tuned algorithm. Therefore, in Figure 2 we show the MSE as a function of λ when minimized over both α and β . For all λ , true online GTD(λ) outperforms GTD(λ).

8 Discussion

The main theoretical contribution of this paper is a general theorem for equivalences between forward and backward views. The theorem allows us to find an efficient fully equivalent online algorithm for a desired forward view. The theorem is as general as required and as specific as possible for all applications of it in this paper, and in its current form it is limited to forward views for which an $O(n)$ backward view exists. The theorem can be generalized further, to include recursive (off-policy) LSTD(λ) (Boyan, 1999) and other algorithms that can be formulated in terms of forward

views (cf. Geist & Scherrer, 2014; Dann, Neumann & Peters, 2014), but we did not investigate these extensions.

We used Theorem 1 to construct a new off-policy algorithm named true online GTD(λ), which is the first TD algorithm to have an exact online equivalence to a off-policy forward view. We constructed this forward view to maintain equivalence to the existing GTD(λ) algorithm for $\lambda = 0$. The forward view we proposed is not the only possible, and in particular it will be interesting to investigate different methods of importance sampling. We could for instance use the importance sampling as proposed by Sutton et al. (2014). We did construct the resulting online algorithm, and in preliminary tests its performance was similar to true online GTD(λ). Likewise, if desired, it is possible to obtain a full online equivalence to off-policy Monte Carlo for $\lambda = 1$ by constructing a forward view that achieves this. For instance we could use a similar forward view as used in the paper, but then apply the importance-sampling ratios only to the returns rather than to the errors. For now, it remains an open question what the best off-policy forward view is.

True online GTD(λ) is limited to state-value estimates. It is straightforward to construct a corresponding algorithm for action values, similar to the correspondence between GTD(λ) and GQ(λ) (Maei & Sutton, 2010; Maei, 2011) and between PTD(λ) and PQ(λ) (Sutton et al., 2014). We leave such an extension for future work.

Constraint-based Causal Discovery: Conflict Resolution with Answer Set Programming

Abstract

Recent approaches to causal discovery based on Boolean satisfiability solvers have opened new opportunities to consider search spaces for causal models with both feedback cycles and unmeasured confounders. However, the available methods have so far not been able to provide a principled account of how to handle conflicting constraints that arise from statistical variability. Here we present a new approach that preserves the versatility of Boolean constraint solving *and* attains a high accuracy despite the presence of statistical errors. We develop a new logical encoding of (in)dependence constraints that is both well suited for the domain and allows for faster solving. We represent this encoding in Answer Set Programming (ASP), and apply a state-of-the-art ASP solver for the optimization task. Based on different theoretical motivations, we explore a variety of methods to handle statistical errors. Our approach currently scales to cyclic latent variable models with up to seven observed variables and outperforms the available constraint-based methods in accuracy.

1 INTRODUCTION

The search for causal relations underlies many scientific fields. Unlike mere correlational information, causal relations support predictions of how a system will behave when it is subject to an intervention. In the causal Bayes net framework (Spirtes et al., 1993; Pearl, 2000) the causal structure is represented in terms of a directed graph (see Figure 1). One of the most widely applicable approaches to discovering the causal structure uses independence and dependence constraints obtained from statistical tests to narrow down the candidate graphs that may have produced the data. Such an inference relies on the now well-understood assumptions of *causal Markov* and *causal*

faithfulness (Spirtes et al., 1993). Unlike many other approaches, these constraint-based causal discovery methods can allow for the presence of latent confounders, feedback cycles and the utilisation of several (partially overlapping) observational or experimental data sets.

Even without experimentation (or additional assumptions, such as time order), and despite the generality of the model space, constraint-based methods can infer some causal orientations on the basis of *v-structures* (unshielded colliders). A *v-structure* in a graph is a triple of variables, such as $\langle x, z, y \rangle$ in Figure 1, where z is a common child of x and y , but x and y are non-adjacent in the graph. *V-structures* can be identified because of the specific (in)dependence relations they imply (here, $x \perp\!\!\!\perp z$, $z \perp\!\!\!\perp y$ and $x \perp\!\!\!\perp y$ are jointly sufficient to identify the *v-structure*). The edges that are thus oriented provide the basis for all further orientation inferences in constraint-based algorithms such as PC and FCI (Spirtes et al., 1993); e.g. identifying the *v-structure* in Figure 1 enables the additional orientation of the zw -edge. However, when processing sample data, the above inference is often prone to error. Establishing the further dependence $x \perp\!\!\!\perp y \mid z$ would confirm the inference. If this dependence does not hold, we have a case of a *conflict*: There is no causal graph that satisfies all available (in)dependence constraints (while respecting Markov and faithfulness).

The problem of conflicting constraints is exacerbated when trying to integrate multiple observational and experimental data sets in which the sets of measured variables *overlap* only partially. Unlike the case for one passively observed data set, the characterization of the class of graphs consistent with the (in)dependence constraints is more difficult in this setting: the graphs may disagree on orientations, adjacencies, and ancestral relations (Tsamardinos et al., 2012). Triantafillou et al. (2010) and Hyttinen et al. (2013) have started using general Boolean satisfiability (SAT) solvers (Biere et al., 2009) to integrate the various constraints. The basic idea of these methods is to convert the (in)dependence constraints found in the data into logical constraints on the presence and absence of certain pathways in the underlying causal structure, and to use a

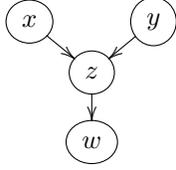

Figure 1: Example causal graph (see text for details).

SAT-solver to find the causal structures consistent with all constraints.

For pure SAT methods, conflicted constraints imply unsatisfiability. For these methods to work at all in practice, conflict handling is paramount. We address this problem at a variety of levels. We represent the task as a constraint optimization problem, and discuss in Section 3 different weighting schemes of the constraints and the theoretical motivations that support them. Then, we present in Section 5 a new encoding that relates (in)dependence constraints directly to one another via the operations of *intervening*, *conditioning* and *marginalization*. The encoding naturally captures the central ideas of constraint integration as it more directly connects constraints that refer to the same graphical neighborhood. We represent this encoding in the constraint optimization paradigm of Answer Set Programming (ASP) (Gelfond and Lifschitz, 1988; Niemelä, 1999; Simons et al., 2002). Finally, we compare the reliability of our proposed methods with available existing algorithms in Section 7.

2 PRELIMINARIES

For notational simplicity, we restrict the presentation to the setting with a single passive observational data set. However, the approach extends naturally to the general case of multiple overlapping experimental data sets; details are provided in the supplement.

We consider the class \mathcal{G} of *causal graphs* of the form $G = (\mathbf{V}, \mathbf{E})$, where \mathbf{V} is the set of nodes (associated with random variables) of G , and the edge relation $\mathbf{E} = \mathbf{E}_{\rightarrow} \cup \mathbf{E}_{\leftrightarrow}$ is composed of a set \mathbf{E}_{\rightarrow} of directed edges and a set $\mathbf{E}_{\leftrightarrow}$ of bi-directed edges. A bi-directed edge \leftrightarrow represents a *latent confounder*, i.e. an unmeasured common cause of two or more of the observed variables. In other words, we allow for the presence of feedback cycles and do not assume causal sufficiency. We define a *path* as a sequence of consecutive edges in the graph, without any restrictions on the types or orientations of the edges involved. A vertex appears as a *collider* on a path if both its adjacent edges on the path point into the vertex.

(In)dependence constraints can be brought into correspondence with structural properties of the graph using the d-separation criterion (Pearl, 2000). A path in graph G is *d-connecting* with respect to a conditioning set \mathbf{C} if every

collider c on the path is in \mathbf{C} and no other nodes on the path are in \mathbf{C} ; otherwise the path is *d-separated* (or “blocked”). A pair of nodes are d-connected given a conditioning set \mathbf{C} if there is at least one d-connecting path between them; otherwise they are d-separated.¹ Under the causal Markov and faithfulness assumptions, two variables x and y are independent conditional on a set of variables \mathbf{C} iff x and y are d-separated given \mathbf{C} in the graph G .²

Let \mathbf{D} be an i.i.d. data set sampled from a distribution that is Markov and faithful to an underlying “true” causal graph $G_t = (\mathbf{V}, \mathbf{E})$. Overall, the aim of causal discovery is to recover as many properties of G_t as possible from the data \mathbf{D} . There are a variety of ways to proceed. In light of the generality of the search space we consider, we focus on the graphical constraints implied by the conditional (in)dependencies found in the data. Our proposal is that the causal discovery problem is addressed well by solutions to the following abstract constrained optimization problem.

Problem Statement

INPUT: A set \mathbf{K} of conditional independence and dependence constraints over a set \mathbf{V} of variables, and a non-negative weight (cost) $w(k)$ for each $k \in \mathbf{K}$.

TASK: Find a causal graph G^* over the vertex set \mathbf{V} such that

$$G^* \in \arg \min_{G \in \mathcal{G}} \sum_{k \in \mathbf{K} : G \not\models k} w(k). \quad (1)$$

In words, our goal is to find a single representative graph G^* that minimizes the sum of the weights of the given conditional independence and dependence constraints *not* implied by G^* . The idea is that the constraints can be weighted according to their reliability, and that conflicts among the constraints are well-resolved when the sum of the weights of the constraints not satisfied by the output graph are minimized. We take the set \mathbf{K} to be the set of all (in)dependence constraints testable in the data \mathbf{D} .³

This formalization poses two key challenges: 1) How to define the weighting scheme $w(k)$ such that the solutions (causal graphs) are “as similar as possible” to the true graph? 2) How to actually find a representative graph G^* , i.e., how to represent the constraints efficiently such that one can minimize the objective function (an NP-hard optimization problem) defined above? In the following, we will

¹This definition is equivalent to Pearl’s standard definition (Studený, 1998; Koster, 2002).

²See Spirtes (1995), Pearl and Dechter (1996) and Neal (2000) for discussions of d-separation in cyclic models.

³When considering experimental data sets, the weights of (in)dependence constraints of the *manipulated* distributions enter into the minimization as well; see Appendix A.

propose solutions to both of these challenges. We note that once a representative graph G^* has been found, the independence oracle methods of Hyttinen et al. (2013) can be used to understand the common properties, such as adjacencies and ancestral relations, of all solutions that satisfy the same set of constraints.

3 PREVIOUS WORK

Statistical variability results in incorrect test results, but such errors are only detectable when the test results have conflicting implications. Conflicts can arise directly between test results or, more commonly, in combination with search space assumptions. Whether or not conflicts are detected depends on the tests that have been performed. Thus, one way of “handling” conflicts is to avoid performing tests whose results can conflict, or not to draw the full set of possible inferences from a set of test results. This is what the standard PC-algorithm does; it basically avoids conflicts.⁴ This approach proved to be unreliable for the detection of v-structures, so a *conservative* extension was added that checks additional tests to verify the inference to the v-structures (see example in Section 1). The resulting cPC-algorithm (Ramsey et al., 2006) marks any conflicted v-structures and abstains from the orientation inference, i.e. it returns a “don’t know” for this part of the graph. The FCI and cFCI algorithms are analogous in this regard to PC and cPC, respectively, only that the search space is enlarged to allow for latent confounders. A more generic approach, not focused on v-structures, reduces the occurrence of conflicts by controlling which test results are accepted. Li and Wang (2009) control the false discovery rate of the tests that PC performs, while Tsamardinos et al. (2012) use different p-value thresholds to infer independence vs. dependence constraints. Very recently, Triantafillou and Tsamardinos (2014) developed a scheme that uses the p-values from tests performed by FCI to rank (a specific class of) structural constraints on the underlying graph, and then use a SAT-based procedure to satisfy as many constraints as possible. The selection of tests by FCI depends on the results of earlier tests. Thus the conflict resolution (in terms of the ranked constraints) only handles conflicts between tests that were selected. This scales very well, but the theoretical account of the accuracy of the output model is unclear, as the selection of tests interacts with the conflict resolution.

Score-based algorithms take a very different approach to inconsistencies in data (Cooper and Herskovits, 1992; Chickering, 2002). Instead of explicitly determining the (in)dependence constraints (and finding them to be inconsistent) the conflicts are implicitly resolved by a direct integration of the data points into a score that identifies the

graph (or equivalence class) that maximizes the Bayesian posterior. Such an approach provides a clear theoretical account in which sense the output is “closest” to the true graph (equivalence class). Although mostly restricted to DAGs, Claassen and Heskes (2012) have transferred some of the advantages of the Bayesian approach to a constraint-based search method over models with latent confounders. Their BCCD algorithm builds on the skeleton search of PC, and computes Bayesian-style probabilities for the (conditional) independence constraints.

4 WEIGHTING SCHEMES

Given the general search space we are considering, we take a constraint-based approach. But unlike other such methods we do not select tests to perform based on previous test results. Instead, for a given data set, we consider *all* independence tests that can be performed on the set of variables, and apply the following weighting schemes to the resulting constraints.

4.1 Controlling False Negatives

One of the problems for constraint based causal discovery are false negative results, i.e. variables that are truly dependent but test as independent due to low sample sizes or several cancelling d-connecting paths between them (violations of faithfulness). Strictly speaking, classical statistical tests do not license the inference to independence when the null-hypothesis H_0 of independence fails to be rejected. Schulte et al. (2010) have developed a search procedure for causal DAGs based on *dependence* constraints, which are licensed by classical tests when H_0 is rejected. Independencies enter only as a result of a simplicity assumption. Analogously, we propose to control the false negatives with a given sufficiently low p-value threshold on the independence tests. We enforce the detected dependencies as hard constraints. Dependence constraints on their own cannot conflict, as the complete graph will satisfy all possible dependencies. But the principle of Occam’s Razor recommends choosing the simplest among the models able to produce the data. We take this here to amount to maximizing the number of independencies given the dependencies (which is closely related to the dependence minimality proposed by Pearl (2000)). Thus, if we partition the set of constraints \mathbf{K} into the independence constraints \mathbf{K}_\perp and dependence constraints $\mathbf{K}_\mathcal{I}$, then the causal discovery problem over the class of causal models \mathcal{G} amounts to solving the constrained optimization problem in (1) with a weight function

$$w(k) = \begin{cases} \infty & \text{if } k \in \mathbf{K}_\mathcal{I} \\ 1 & \text{if } k \in \mathbf{K}_\perp. \end{cases} \quad (2)$$

⁴Some PC implementations do in some cases infer the presence of a latent confounder (violating the model space) when v-structures are incorrectly detected.

4.2 Controlling False Positives and Negatives

In a slight but common abuse of classical statistics, one can treat the failure to reject H_0 as the acceptance of independence. Then one can simply find the graph that minimizes the number of disagreements between the (in)dependence constraints implied by the graph and the test results. Such an approach would then also be able to recover from false positive errors, i.e. true independencies that test as dependencies. Such false positive errors may occur, for example, if the true structure is a chain $x \rightarrow z \rightarrow y$ and we condition on a measured, but noisy, version of z , and we still get that $x \not\perp y \mid z$. The corresponding weight-function for the the constrained optimization problem in (1) is then simply

$$w(k) = 1 \quad \forall k \in \mathbf{K}. \quad (3)$$

4.3 Weighted Constraints

So far we have treated the test results as binary, but in many cases one has reason to be more confident about some test results than others, and the constraints could be weighted accordingly. One would like to associate a probability as a measure of confidence with each constraint, since then the independence test could be treated as a probabilistic classifier without a hard decision between independence and dependence. When ground truth is available the quality of probabilistic classifiers is often compared by proper scoring rules, such as the log-score. Proper scoring rules assign costs that are minimized when the tests or classifier return the true probability of class membership. We use such scoring rules here as cost functions: we find the graph G^* such that if it were the ground truth, the results of the probabilistic classifier would be optimal – minimizing the cost assigned by the proper score. Given a data set \mathbf{D} , for each constraint k the classifier returns the probability $P(k \mid \mathbf{D})$ for k to hold in G^* . If in fact k holds in G^* , then the classifier should only suffer the cost $-\log P(k \mid \mathbf{D})$, otherwise the cost is $-\log[1 - P(k \mid \mathbf{D})]$. As the minimum of these costs will always be suffered, it is sufficient to let

$$w(k) = \log P(k \mid \mathbf{D}) - \log[1 - P(k \mid \mathbf{D})], \quad (4)$$

which is positive, since only the constraint with higher probability is included in \mathbf{K} .⁵

It is not straightforward, neither in terms of theoretical foundation nor actual implementation, to turn p-values from classical tests into probability estimates, as the distribution of p-values under H_0 is uniform and only known to be decreasing under H_1 .⁶ Instead, Margaritis and Bromberg (2009) use a Bayesian paradigm to assign proba-

bilities to the (in)dependence statements.⁷ Following them, for each independence statement $x \perp y \mid \mathbf{C}$, we consider two models M_{\perp} and $M_{\not\perp}$, where $M_{\perp} : P(x, y \mid \mathbf{C}) = P(x \mid \mathbf{C})P(y \mid \mathbf{C})$ postulates independence, while $M_{\not\perp} : P(x, y \mid \mathbf{C}) = P(x \mid \mathbf{C})P(y \mid x, \mathbf{C})$ postulates dependence. Given data \mathbf{D} and a prior $P(M_{\perp}) = \alpha$ the probability associated with $k = x \perp y \mid \mathbf{C}$ simplifies to

$$P(k \mid \mathbf{D}) = \frac{P(y \mid \mathbf{C})\alpha}{P(y \mid \mathbf{C})\alpha + P(y \mid x, \mathbf{C})(1 - \alpha)}.$$

The marginal likelihoods $P(y \mid \mathbf{C})$ and $P(y \mid x, \mathbf{C})$ correspond to local scores in the score-based learning framework and have a closed form for categorical variables using a Dirichlet prior (Cooper and Herskovits, 1992) or for continuous variables with linear relations and Gaussian disturbances using an inverse Wishart Gaussian prior (Geiger and Heckerman, 1994).

5 A RECURSIVE VIEW TO CAUSAL GRAPHS

Given a set of (in)dependence constraints, finding an optimal graph G^* (in the sense of the problem statement’s objective function Eq. 1) requires a formulation of the d-connection property that is suitable for constraint solvers. Hyttinen et al. (2013) provided such a formulation in terms of propositional logic, but that proves to be inefficient for the computationally more demanding case with conflicted constraints (see Section 7).

Our new formulation is based on the two central graph operations that relate the underlying causal graph to the (in)dependence constraints obtained from an observational data set: *conditioning* and *marginalization*. (Intervening is treated in the supplementary material.) We define these operations over objects that we call *d-connection graphs* rather than MAGs/PAGs (Richardson and Spirtes, 2002), as we want allow for the complete generality of the model space.

A *d-connection graph* $H = (\mathbf{V}, \mathbf{E})_{\mathbf{C}}$ is defined relative to a set \mathbf{C} such that: (i) \mathbf{V} is the set of variables in the graph, (ii) the edge relation $\mathbf{E} = \mathbf{E}_{\rightarrow} \cup \mathbf{E}_{\leftrightarrow} \cup \mathbf{E}_{-}$ is composed of directed, bidirected and undirected edges among \mathbf{V} , and (iii) the set \mathbf{C} denotes the set of conditioned variables with the restriction that $\mathbf{V} \cap \mathbf{C} = \emptyset$. The disjoint sets \mathbf{V} and \mathbf{C} are used to keep track of which variables have been subject to the two operations. Given a causal graph $G = (\mathbf{V}, \mathbf{E})$ (Section 2), the corresponding d-connection graph H has the same sets \mathbf{V} , \mathbf{E}_{\rightarrow} and $\mathbf{E}_{\leftrightarrow}$, but in addition the set $\mathbf{E}_{-} = \emptyset$ (no undirected edges) and $\mathbf{C} = \emptyset$ (no conditioning). The d-connection graph of the causal graph in

⁵In Appendix B we show how the log-weights can be interpreted probabilistically.

⁶Some proposals in this direction appear in a recent unpublished paper by Triantafyllou and Tsamardinos (2014).

⁷Claassen and Heskes (2012) also describe a way of obtaining Bayesian probabilities for independence statements, which is particularly accurate for finding minimal independencies in an acyclic domain.

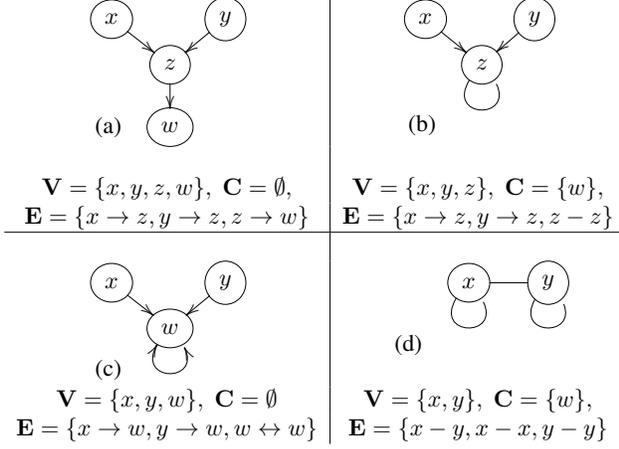

Figure 2: Graph operations on d-connection graphs: (a) original graph, (b) after conditioning on w , (c) after marginalizing z , (d) after conditioning on w and marginalizing z in either order. The xy -edge in (d) shows that x and y are dependent when conditioning on z and marginalizing w .

Figure 1 is shown in Figure 2a; the edges correspond exactly. In general, an edge $x_a - by$ in a d-connection graph $H = (\mathbf{V}', \mathbf{E}')_{\mathbf{C}'}$ denotes the existence of a path p with the given edge ends a and b at x and y in the underlying causal graph G , such that p is d-connecting with respect to \mathbf{C}' and does not go through other variables in \mathbf{V}' . Consequently, the d-connection property (as defined in Section 2) can be directly applied to any d-connection graph.

Given a d-connection graph $H = (\mathbf{V}, \mathbf{E})_{\mathbf{C}}$, the *conditioning* operation $c(H, w)$ on a variable $w \in \mathbf{V}$ results in a d-connection graph $H' = (\mathbf{V} \setminus w, \mathbf{E}')_{\mathbf{C} \cup w}$, where \mathbf{E}' is related to \mathbf{E} by (i) including in \mathbf{E}' any edges in \mathbf{E} not involving w ; (ii) adding to \mathbf{E}' an edge $x_a - by$ if there are edges $x_a \rightarrow w$ and $w \leftarrow by$ in \mathbf{E} , and (iii) not permitting any other edges in \mathbf{E}' (x and y can be equal above).

The graphs in the right column of Figure 2 are formed by applying the operation $c(\cdot, w)$ to the graphs in the left column of Figure 2. The conditioning operation is a little unusual because the conditioned variable is removed from the graph and undirected edges and undirected self-cycles are introduced. As is well-known, conditioning on a collider or a child of a collider results in a d-connection between the collider’s parents. For example, if w is conditioned on in $x \rightarrow w \leftarrow y$, we have a d-connecting path between x and y with a tail at either end. Since the encoding also removes the conditioned variable from the graph, we just have an undirected edge $x - y$, the parents are “moralized”. The undirected self-loop represents the same idea, just in case of the child of a collider: each parent of a conditioned variable receives an undirected self-loop to indicate that it can provide a d-connection between two incoming paths. In Figure 2a-b this is illustrated for variable z when w is added

to the conditioning set (and removed from the graph). The graph in (b) indicates that there is a tail to tail d-connection at z , which implies that x and y are now d-connected when w , the child of collider z , is in the conditioning set. The (perhaps unintuitive) removal of the conditioning variable from the graph achieves two goals: it reduces the size of the graph to be encoded, but more importantly, it incrementally represents the effect of conditioning on the d-connections among the other variables.

Given a d-connection graph $H = (\mathbf{V}, \mathbf{E})_{\mathbf{C}}$, the *marginalization* operation $m(H, z)$ for variable $z \in \mathbf{V}$ results in a d-connection graph $H' = (\mathbf{V} \setminus z, \mathbf{E}')_{\mathbf{C}}$, where \mathbf{E}' is related to \mathbf{E} by (i) including in \mathbf{E}' any edges in \mathbf{E} not involving z ; (ii) adding to \mathbf{E}' an edge $x_a - by$ if there are edges $x_a \rightarrow z$ and $z \leftarrow by$ in \mathbf{E} ; (iii) adding to \mathbf{E}' an $x_a - by$ if there are edges $x_a \rightarrow z$, $z - z$ and $z \leftarrow by$ in \mathbf{E} , and (iv) not permitting any other edges in \mathbf{E}' (x and y can be equal above). Marginalization follows the standard graphical procedures used elsewhere, except that a little more book-keeping is required to track the d-connections resulting from self-loops and undirected edges (see Figure 2 top to bottom).

The following theorem shows that the operations preserve the d-connection properties among the variables still present in the graph after the operation (proof in Appendix D).

Theorem 1 *Let $H' = (\mathbf{V}', \mathbf{E}')_{\mathbf{C}'}$ be the d-connection graph obtained from a d-connection graph $H = (\mathbf{V}, \mathbf{E})_{\mathbf{C}}$ by applying the conditioning operation on w , i.e. $H' = c(H, w)$ (or by applying the marginalization operation on z , thus $H' = m(H, z)$). Then there is a path of type $x_a \dots by$ that is d-connecting given $\mathbf{C}'' \supseteq \mathbf{C}'$ in H' if and only if there is a path of type $x_a \dots by$ that is d-connecting given \mathbf{C}'' in H .*

Consequently, a dependence $x \not\perp\!\!\!\perp y \mid \mathbf{C}$ in (the true causal graph) $G = (\mathbf{V}, \mathbf{E})$ is equivalent to having an edge of some type in the d-connection graph $H = (\mathbf{V}', \mathbf{E}')_{\mathbf{C}}$ when $\mathbf{V}' = \{x, y\}$. This d-connection graph H can be obtained by consecutively applying the conditioning operation to all variables in \mathbf{C} , and the marginalization operation to the rest in $\mathbf{V} \setminus (\mathbf{C} \cup \{x, y\})$. For example, in Figure 2d the undirected edge between x and y represents the fact that $x \not\perp\!\!\!\perp y \mid w$ in the underlying causal graph (Figure 1).

Given a causal graph G , we can calculate all of its implied (in)dependence relations by applying the operations in any order. However, we need not apply all operations for each (in)dependence relation, since we can exploit the compact intermediary representations of the d-connections in the d-connection graphs obtained earlier. Figure 3 shows the “encoding DAG” for one set of applied operations by which we obtain all (in)dependence relations of the four variable graph in Figure 1. The true causal graph corresponds to the node in the middle, and we use the operations to move

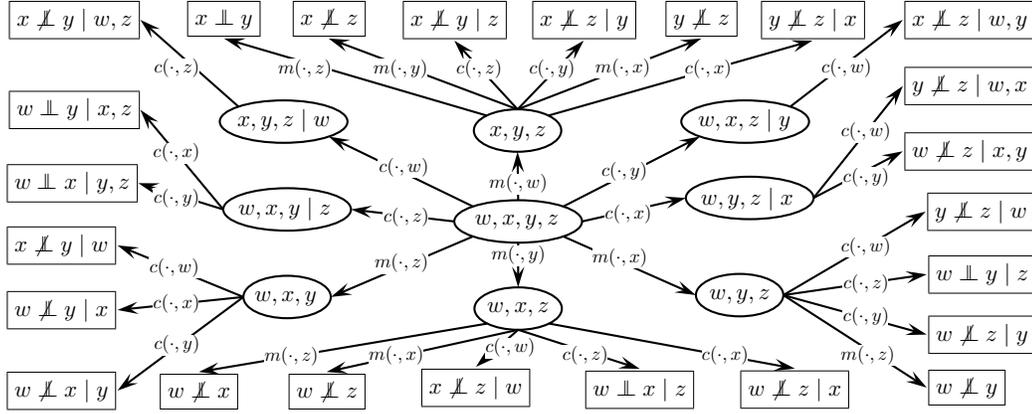

Figure 3: An “encoding DAG”: a tree connecting the causal graph (represented by the middle node) to (in)dependence constraints (leaves). The conditioning/marginalization operations are marked on the arrows. The circular nodes represent the sets $\mathbf{V} \mid \mathbf{C}$ of the corresponding d-connection graphs and the square nodes show the implied independencies for the true causal graph shown in Figure 1.

outward until we reach the implied (in)dependencies at the leaves.

For causal discovery we want to perform the backward inference. We know the (in)dependence relations at the leaves (Figure 3) and our aim is to find a causal graph in the middle node. Again we exploit the same tree structure. But this time we will have at each node several different graphs that satisfy the constraints, which are downstream from it. Moving towards the center, nodes can be combined to find the options that satisfy all constraints downstream from the node. For example, in the node ‘ x, y, z ’ all the tests relevant to identifying the v-structure $x_a \rightarrow z \leftarrow b y$ are available locally. In the general case of weighted and possibly conflicting (in)dependence constraints, the inference becomes hard. We use off-the-shelf solvers for this job. Nevertheless, as shown by the simulations, the recursive structure allows the backwards inference to work faster than for the logical formulations of d-connection in Hyttinen et al. (2013).

6 CAUSAL DISCOVERY VIA ASP

Building on Section 5, we describe here an ASP-based constraint optimization approach to optimally solving the causal structure discovery task defined in (1).

Answer set programming (ASP) is a rule-based declarative constraint satisfaction paradigm that is well-suited for representing and solving various computationally hard problems (Gelfond and Lifschitz, 1988; Niemelä, 1999; Simons et al., 2002). ASP offers an expressive declarative modelling language in terms of first-order logical rules, allowing for intuitive and compact representations of NP-hard optimization tasks. When using ASP, the first task is to model the problem in terms of ASP rules (constraints) so

that the set of solutions implicitly represented by the ASP rules corresponds to the solutions of the original problem. One or multiple solutions of the original problem can then be obtained by invoking an off-the-shelf ASP solver on the constraint declaration.

6.1 An ASP Encoding of Causal Discovery

As a self-contained explanation of ASP syntax and semantics would exceed the page limit, we only aim to give an intuitive reading of our ASP encoding. The ASP encoding, outlined in Figure 4, is based on exactly representing the conditioning and marginalization operations (defined in Section 5) in ASP.

Answer set programming can be viewed as a data-centric constraint satisfaction paradigm, in which the input data, represented as “facts” that are true via input predicates, express the instance of the original problem at hand. In our case, the problem instance consists of a set of independence and dependence constraints and their associated weights, represented via the predicates *indep* and *dep*, and the “encoding DAG”, describing which d-connection graphs can be mapped from one to the other via the conditioning and marginalization operations (predicates *cond* and *marg*). Concretely, the input predicates *indep*($x, y, \{x, y\}, \mathbf{C}, W$) and *dep*($x, y, \{x, y\}, \mathbf{C}, W$) represent as facts that the input contains an independence (resp., dependence) constraint with weight W over the variables x and y given the conditioning set \mathbf{C} .⁸ The input predicates *cond*($\mathbf{V}, \mathbf{C}, z$) and *marg*($\mathbf{V}, \mathbf{C}, z$) enable the conditioning and marginalizing of a variable z , respectively, in a d-connection graph that has exactly the variables \mathbf{V} and conditioning set \mathbf{C} . Es-

⁸In practice, the ASP language requires integer-valued weights. For sufficient precision, in our experiments we multiply the weights by 1000, and then truncate to integers.

sentially, *cond* and *marg* represent edges in the encoding DAG (recall Figure 3).

The other predicates $tt(x, y, \mathbf{V}, \mathbf{C})$, $th(x, y, \mathbf{V}, \mathbf{C})$, and $hh(x, y, \mathbf{V}, \mathbf{C})$ present the existence of different types of edges (tt: tail-tail, th: tail-head, hh: head-head) in

Conditioning on a variable $z \in \mathbf{V}, \forall x, y \in \mathbf{V} \setminus z$:
 $th(x, y, \mathbf{V} \setminus z, \mathbf{C} \cup z) :- th(x, y, \mathbf{V}, \mathbf{C}), cond(\mathbf{V}, \mathbf{C}, z).$
 $th(x, y, \mathbf{V} \setminus z, \mathbf{C} \cup z) :- th(x, z, \mathbf{V}, \mathbf{C}), hh(z, y, \mathbf{V}, \mathbf{C}),$
 $cond(\mathbf{V}, \mathbf{C}, z).$

$hh(x, y, \mathbf{V} \setminus z, \mathbf{C} \cup z) :- hh(x, y, \mathbf{V}, \mathbf{C}), cond(\mathbf{V}, \mathbf{C}, z).$
 $hh(x, y, \mathbf{V} \setminus z, \mathbf{C} \cup z) :- hh(x, z, \mathbf{V}, \mathbf{C}), hh(z, y, \mathbf{V}, \mathbf{C}),$
 $cond(\mathbf{V}, \mathbf{C}, z).$

$tt(x, y, \mathbf{V} \setminus z, \mathbf{C} \cup z) :- tt(x, y, \mathbf{V}, \mathbf{C}), cond(\mathbf{V}, \mathbf{C}, z).$
 $tt(x, y, \mathbf{V} \setminus z, \mathbf{C} \cup z) :- th(x, z, \mathbf{V}, \mathbf{C}), th(y, z, \mathbf{V}, \mathbf{C}),$
 $cond(\mathbf{V}, \mathbf{C}, z).$

Marginalizing a variable $z \in \mathbf{V}, \forall x, y \in \mathbf{V} \setminus z$:

$th(x, y, \mathbf{V} \setminus z, \mathbf{C}) :- th(x, y, \mathbf{V}, \mathbf{C}), marg(\mathbf{V}, \mathbf{C}, z).$
 $th(x, y, \mathbf{V} \setminus z, \mathbf{C}) :- tt(x, z, \mathbf{V}, \mathbf{C}), th(z, y, \mathbf{V}, \mathbf{C}),$
 $marg(\mathbf{V}, \mathbf{C}, z).$
 $th(x, y, \mathbf{V} \setminus z, \mathbf{C}) :- th(x, z, \mathbf{V}, \mathbf{C}), th(z, y, \mathbf{V}, \mathbf{C}),$
 $marg(\mathbf{V}, \mathbf{C}, z).$
 $th(x, y, \mathbf{V} \setminus z, \mathbf{C}) :- tt(x, z, \mathbf{V}, \mathbf{C}), hh(z, y, \mathbf{V}, \mathbf{C}),$
 $marg(\mathbf{V}, \mathbf{C}, z).$
 $th(x, y, \mathbf{V} \setminus z, \mathbf{C}) :- th(x, z, \mathbf{V}, \mathbf{C}), tt(z, z, \mathbf{V}, \mathbf{C}),$
 $hh(z, y, \mathbf{V}, \mathbf{C}), marg(\mathbf{V}, \mathbf{C}, z).$

$hh(x, y, \mathbf{V} \setminus z, \mathbf{C}) :- hh(x, y, \mathbf{V}, \mathbf{C}), marg(\mathbf{V}, \mathbf{C}, z).$
 $hh(x, y, \mathbf{V} \setminus z, \mathbf{C}) :- th(z, x, \mathbf{V}, \mathbf{C}), th(z, y, \mathbf{V}, \mathbf{C}),$
 $marg(\mathbf{V}, \mathbf{C}, z).$
 $hh(x, y, \mathbf{V} \setminus z, \mathbf{C}) :- hh(x, z, \mathbf{V}, \mathbf{C}), th(z, y, \mathbf{V}, \mathbf{C}),$
 $marg(\mathbf{V}, \mathbf{C}, z).$
 $hh(x, y, \mathbf{V} \setminus z, \mathbf{C}) :- th(z, x, \mathbf{V}, \mathbf{C}), hh(z, y, \mathbf{V}, \mathbf{C}),$
 $marg(\mathbf{V}, \mathbf{C}, z).$
 $hh(x, y, \mathbf{V} \setminus z, \mathbf{C}) :- hh(x, z, \mathbf{V}, \mathbf{C}), tt(z, z, \mathbf{V}, \mathbf{C}),$
 $hh(z, y, \mathbf{V}, \mathbf{C}), marg(\mathbf{V}, \mathbf{C}, z).$

$tt(x, y, \mathbf{V} \setminus z, \mathbf{C}) :- tt(x, y, \mathbf{V}, \mathbf{C}), marg(\mathbf{V}, \mathbf{C}, z).$
 $tt(x, y, \mathbf{V} \setminus z, \mathbf{C}) :- tt(x, z, \mathbf{V}, \mathbf{C}), tt(z, y, \mathbf{V}, \mathbf{C}),$
 $marg(\mathbf{V}, \mathbf{C}, z).$
 $tt(x, y, \mathbf{V} \setminus z, \mathbf{C}) :- th(x, z, \mathbf{V}, \mathbf{C}), tt(z, y, \mathbf{V}, \mathbf{C}),$
 $marg(\mathbf{V}, \mathbf{C}, z).$
 $tt(x, y, \mathbf{V} \setminus z, \mathbf{C}) :- tt(x, z, \mathbf{V}, \mathbf{C}), th(y, z, \mathbf{V}, \mathbf{C}),$
 $marg(\mathbf{V}, \mathbf{C}, z).$
 $tt(x, y, \mathbf{V} \setminus z, \mathbf{C}) :- th(x, z, \mathbf{V}, \mathbf{C}), tt(z, z, \mathbf{V}, \mathbf{C}),$
 $th(y, z, \mathbf{V}, \mathbf{C}), marg(\mathbf{V}, \mathbf{C}, z).$

Inferring failures to sat. (in)dep. $\forall x \forall y > x, \forall \mathbf{C}, \mathbf{V} = \{x, y\}$:

$fail(x, y, \mathbf{V}, \mathbf{C}, W) :- tt(x, y, \mathbf{V}, \mathbf{C}), indep(x, y, \mathbf{V}, \mathbf{C}, W).$
 $fail(x, y, \mathbf{V}, \mathbf{C}, W) :- th(x, y, \mathbf{V}, \mathbf{C}), indep(x, y, \mathbf{V}, \mathbf{C}, W).$
 $fail(x, y, \mathbf{V}, \mathbf{C}, W) :- th(y, x, \mathbf{V}, \mathbf{C}), indep(x, y, \mathbf{V}, \mathbf{C}, W).$
 $fail(x, y, \mathbf{V}, \mathbf{C}, W) :- hh(x, y, \mathbf{V}, \mathbf{C}), indep(x, y, \mathbf{V}, \mathbf{C}, W).$
 $fail(x, y, \mathbf{V}, \mathbf{C}, W) :- not th(x, y, \mathbf{V}, \mathbf{C}), not th(y, x, \mathbf{V}, \mathbf{C}),$
 $not hh(x, y, \mathbf{V}, \mathbf{C}), not tt(x, y, \mathbf{V}, \mathbf{C}),$
 $dep(x, y, \mathbf{V}, \mathbf{C}, W).$

Weak constraints $\forall x \forall y > x, \forall \mathbf{C}, \mathbf{V} = \{x, y\}$:
 $:\sim fail(x, y, \mathbf{V}, \mathbf{C}, W). [W]$

the d-connection graph with variable set \mathbf{V} and conditioning set \mathbf{C} . The rules associated with the conditioning and marginalization operations encode how the different edges in the d-connection graphs are derived from edges in other d-connection graphs through the conditioning and marginalization operations. The restrictions that the (in)dependence constraints put on the set of solutions (causal graphs) follow from these rules. As an example, the first marginalization rule

$$th(x, y, \mathbf{V} \setminus z, \mathbf{C}) :- th(x, y, \mathbf{V}, \mathbf{C}), marg(\mathbf{V}, \mathbf{C}, z).$$

allows to derive, for any choice of $\mathbf{C}, \mathbf{V}, z \in \mathbf{V}$, and $x, y \in \mathbf{V} \setminus z$, that $th(x, y, \mathbf{V} \setminus z, \mathbf{C})$ is true (i.e., that there is an edge $x \rightarrow y$ in the d-connection graph over $\mathbf{V} \setminus z$ relative to \mathbf{C}) given that (i) $th(x, y, \mathbf{V}, \mathbf{C})$ is true (there is an edge $x \rightarrow y$ in the d-connection graph over \mathbf{V} relative to \mathbf{C}), and (ii) the input contains the fact $marg(\mathbf{V}, \mathbf{C}, z)$, i.e., marginalizing z in the d-connection graph over \mathbf{V} relative to \mathbf{C} is allowed by the encoding DAG. Note that the set of derivation rules for $tt(x, y, \mathbf{V}, \mathbf{C})$, $th(x, y, \mathbf{V}, \mathbf{C})$, and $hh(x, y, \mathbf{V}, \mathbf{C})$ are very similar to each other.

Finally, the objective function under minimization (Equation 1) is expressed using the so-called *weak constraints* offered by the ASP language. First, the predicate *fail* is derived whenever the candidate solution disagrees with the input. The first four rules for *fail* denote cases where the constraints tested from the data suggest independence but an edge *tt/th/hh* is derived. The fifth rule derives *fail* whenever the input constraints suggest dependence but there are no d-connecting paths. The last rule of the encoding denotes the fact that whenever the *fail* predicate is derived, then the cost W is incurred. This implies that any solution produced by an ASP solver on the encoding is guaranteed to present an optimal solution to the causal discovery task, as stated by the following theorem.

Theorem 2 *Given a set \mathbf{K} of conditional independence and dependence constraints over a set \mathbf{V} of variables, and a non-negative weight $w(k)$ for each $k \in \mathbf{K}$, for any encoding DAG connecting the (in)dependence constraints, it holds that any optimal solution (minimizing the sum of the unsatisfied weak constraints) to the ASP encoding corresponds to a causal graph that minimizes the objective function Equation 1.*

To find optimal solutions to the encoded problem, the input facts together with the derivation rules and weak constraints are given as input to an ASP solver. The actual complete search for solutions is then performed over a propositional instantiation of the first-order rules; this process is automatized within the ASP solver and does not require involvement of the user. The search procedure implemented within state-of-the-art ASP solvers, such as Clingo (Gebser et al., 2011) used in this paper, is then based on the successful and highly-efficient Boolean satisfiability solver technology (Biere et al., 2009).

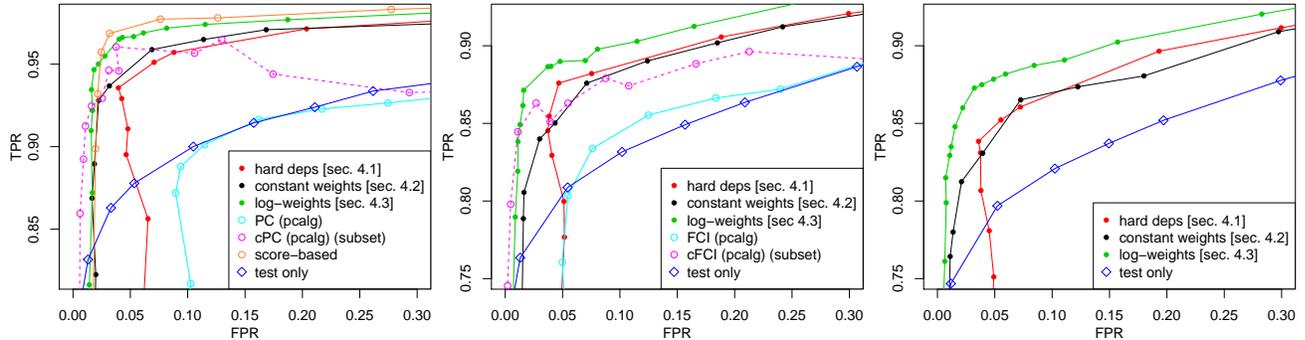

Figure 5: ROC given causally sufficient acyclic models (left), causally insufficient acyclic models (middle) and causally insufficient cyclic models (right).

7 SIMULATIONS

We first test the accuracy of our method against several competing algorithms under the restricting assumption of acyclicity (and causal sufficiency), since no other algorithms are presently available for the most general model space that we can handle. In the tests for accuracy we draw 200 linear Gaussian models over 6 variables, where the edge coefficients are drawn uniformly from $\pm[0.2, 0.8]$. The directed edges were drawn randomly such that the average degree of each node was 2 for the causally sufficient models. For models with latent confounders the average degree of the nodes for directed edges was 1, and the covariance matrix of the disturbances corresponded to the passively observed covariance matrix of another similar causally sufficient linear Gaussian model. For all methods we use a correlation based t-test, or the corresponding Bayesian test. Although our methods straightforwardly allow for experimental data sets, we only used 500 samples of passively observed data here to adhere to the restrictions of the competing methods.

Different methods represent the uncertainty in their output differently: cPC and cFCI return parts of the graphs as unknown, while score-based methods, as well as the approaches in this paper, may be used to return several high scoring graphs. We compared the methods regarding only the single ‘highest scoring’ graph (or Markov equivalence class). To account for the fact that each method returns an equivalence class based on its model space assumptions, we evaluate the d-separation and d-connection relations of the learned result against those of the true data generating graph. This includes all possible d-connection/separation relations in the passively observed setting. Each of the methods takes a parameter (such as a p-value-threshold) that adjusts the sparsity of the output. To avoid effects of a specific parameter choice, we plot the accuracy of the different methods run with different parameters in the ROC space.

Figure 5 (left) shows the accuracy of the methods for acyclic and causally sufficient data generating models. The

blue line shows the performance of the tests alone (classic t-tests almost exactly equal the Bayesian tests in the ROC space). The plain PC algorithm (implemented by Kalisch et al. (2012)) does not exceed the performance of these tests and cannot achieve high true positive rates for acceptable false positive rates. cPC returns an equivalence class of graphs without unknown parts in only 58/200 cases for the optimal p-value threshold of 0.1 (only outputs from these runs are considered in the plot for cPC). Its performance on these ‘easy instances’ is quite good. The score-based approach achieves much better accuracy (BIC score; the MAP DAG is found using exact methods). All our approaches were run by restricting the model space to acyclic and causally sufficient graphs. The surprising finding here is that the constraint-based approach using ‘log-weights’, introduced in Section 4.3, seems to be able to roughly match the performance of the score-based method. This suggests that the constraint-optimization resolves many conflicts that arise from erroneous tests, and so it is an accurate approach for causal discovery. Also, the other suggested approaches, ‘hard deps’ (Section 4.1) and ‘constant weights’ (Section 4.2), seem to be able to perform quite well. Clearly, their results are not restricted to that of the test performance. The conflict resolution is able to correct many erroneous test results.

Figure 5 (middle) shows the accuracy of the methods in the ROC-space assuming acyclicity but not causal sufficiency. Our approaches (now only restricted by acyclicity), especially the ‘log-weights’, achieve higher true positive rates than the competing methods. Again cFCI does better than FCI but only returns a fully determined result for 61/200 of the cases for the optimal p-value threshold of 0.1. For these ‘easier instances’ (again only results without unknowns are plotted for cFCI) its performance is quite good.⁹ Figure 5 (right) shows the accuracy of the proposed methods in the

⁹The BCCD algorithm (Claassen and Heskes, 2012) and the (still unpublished) approach of Triantafillou and Tsamardinos (2014) would provide the most suitable comparison in this setting. We hope to perform the comparison when implementations of the methods are made available.

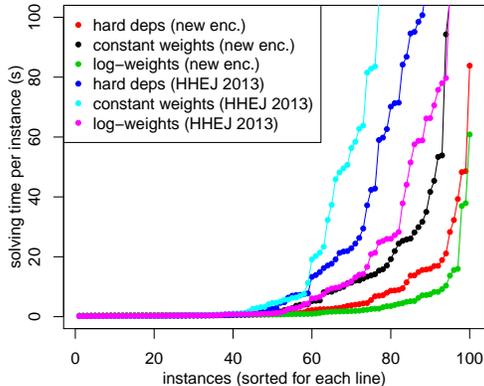

Figure 6: Solving times for (possibly) cyclic causally insufficient models (right).

most general model space allowing for cycles and latent confounders. There currently do not exist other methods that apply to such a general model space.

Figure 6 shows the solving times of `Clingo` on a 2.4-GHz Intel Core i5 processor for 100 instances of constraints obtained from 500 samples of passively observed data generated by different possibly cyclic and causally insufficient models over six variables. The solving times are sorted for each algorithm individually. The plot shows nicely the rather large variance of the solving times. Easy problems (left on the plot) are solved almost instantly, while harder problems may take considerably longer. This is a general feature of exact algorithms solving very complex problems: in the worst case the NP-complexity of the problem kicks in, but still a large number of instances are relatively easy to solve. In the figure we also compare the present encoding against a straightforward ASP-implementation of the encoding of Hyttinen et al. (2013). For all weighting schemes, and especially for the harder instances, the encoding presented in this paper seems to allow for much faster solving. Different weighting schemes also clearly affect the solving time. ‘log-weights’ and ‘hard deps’ are considerably faster than ‘constant weights’. For graphs with seven observed variable the solving times take up to half an hour (see supplement), for graphs with eight variables many instances take several hours to solve.

Finally we analyzed what actually happens in the conflict resolution. We generated data from 100 random parameterizations of the graph in Figure 1, and ran the inference with log-weights for different sample sizes (Figure 7). The redness of the background color denotes how many times the specific independence tests most prone to error (listed on the right axis) produced an incorrect result. The blue line counts the number of incorrect tests obtained from the data, which serve as input to our method. The black line shows the number of (in)dependence relations that were incorrect in the output graph of our method. The tests produce errors

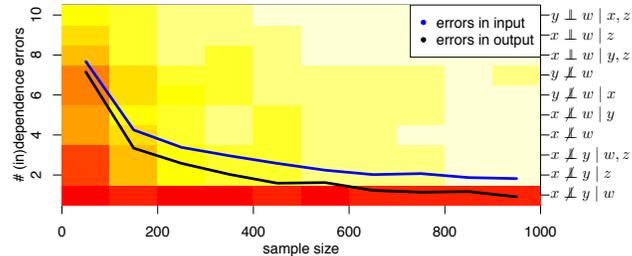

Figure 7: Conflict resolution for the graph in Figure 1.

throughout different sample sizes, but we are able to offer an output with significantly fewer errors.

8 CONCLUSION

We presented a method for causal discovery that works in a completely general search space that includes models with feedback *and* latent confounders. It accepts as input possibly inconsistent (in)dependence constraints obtained from overlapping experimental or observational data sets. It returns an *exact* output, in the sense that it finds the graph that minimizes a well-defined objective function, which characterizes how conflicted constraints should be resolved. We have considered a variety of theoretical motivations for different conflict resolution schemes, and tested them successfully against several extant algorithms.¹⁰ Although not shown explicitly in this article, the direct encoding of the d-connection properties ensures that in the infinite sample limit, our algorithm retains the completeness properties of Hyttinen et al. (2013).

The scalability of the present procedure is still quite limited, but it is similar to that of the exact graph structure discovery methods exploiting ASP of Corander et al. (2013), who search for (undirected) Markov networks. We have emphasized the exactness of our method, which provides theoretical guarantees and a very high accuracy. All other methods we are aware of that consider similar search spaces take a greedy approach in one way or another. Our results suggest that the resulting scalability may come at the price of accuracy for realistic sample sizes on anything but very sparse causal structures. We hope to use our approach as basis to explore the trade-off between scalability and accuracy in the future.

Abstract

Probabilistic latent variable models have been successfully used to capture intrinsic characteristics of various data. However, it is nontrivial to design appropriate models for given data because it requires both machine learning and domain-specific knowledge. In this paper, we focus on data with nested structure and propose a method to automatically generate a latent variable model for the given nested data, with the proposed method, the model structure is adjustable by its structural parameters. Our model can represent a wide class of hierarchical and sequential latent variable models including mixture models, latent Dirichlet allocation, hidden Markov models and their combinations in multiple layers of the hierarchy. Even when deeply-nested data are given, where designing a proper model is difficult even for experts, our method generate an appropriate model by extracting the essential information. We present an efficient variational inference method for our model based on dynamic programming on the given data structure. We experimentally show that our method generates correct models from artificial datasets and demonstrate that models generated by our method can extract hidden structures of blog and news article datasets.

1 INTRODUCTION

Probabilistic latent variable models have been successfully used for analyzing and capturing intrinsic characteristics of a wide variety of datasets. They are applied to various tasks such as dimension reduction, clustering, visualization and cluster matching [14, 28, 16, 15]. However, designing appropriate models for given data is difficult because it requires machine learning knowledge to formulate models and derive algorithms, and also domain-specific knowledge

to introduce appropriate latent variables and their dependencies.

In this paper, we focus on data with a nested structure and aim to automatically generate a latent variable model that is appropriate to the given nested data. Many data have nested structures such as hierarchies. A document contains sentences and each of the sentences contains words. Purchase data consist of purchase histories of many users, where a user history contains multiple shopping events and a shopping event is represented as a basket containing items that are purchased at the same time. Also music shows such hierarchy; many musicians compose music scores by combining multiple phrases, where each of the phrases consists of musical notes. Such nested data sometimes contain not only hierarchical information but also sequential information, that is, the order of elements in nested groups such as word order in a sentence. Even though such rich structural information is given, we do not need to incorporate all of the information in models. For example, a latent Dirichlet allocation (LDA) model [7], which is a widely-used Bayesian latent variable model for text data, assumes a document is a bag of words; it ignores word order. In contrast, a hidden Markov model (HMM), which is the most famous latent variable model for sequential data, assumes a document is a sequence of words but ignores its hierarchical information. When we design models for such structured data, we have to extract essential information and reflect that into models by introducing several modeling assumptions.

The main contribution of this paper is threefold. First, we propose a latent variable model based on a hierarchical and sequential structure of the given data, where our model can adjust its model structure by *structural parameters*. By changing the values of structural parameters, it can represent various models including mixture models, LDA models, HMMs and their combinations. Second, we propose a universal variational inference algorithm for our model based on dynamic programming on the given data structure. Even if model structures and data structures are changed, we can efficiently compute variational free energy

(VFE), which is used for a model scoring function [5], by our universal algorithm. Third, we formulate the model generation task as an optimization problem for maximizing VFE with respect to structural parameters. No matter how deep the input nested data are, our method extracts the essential information by adjusting model structure. Our method can generate complex models if necessary. Otherwise, it generates simple models.

The remainder of this paper is organized as follows. We first briefly review related work in Section 2. We then introduce an ordered tree representation for nested data in Section 3. In Section 4 we propose our latent variable model and our model generation method. We describe its efficient variational inference algorithm in Section 5. In Section 6, we illustrate our method by experiments using artificial and real-world datasets. Finally, we summarize this paper in Section 7.

2 RELATED WORK

A number of methods for automatically generating model structures from data have been proposed. Structure learning for Bayesian networks (BNs) [22] is one such example. A BN defines a joint distribution over random variables by a directed acyclic graph (DAG) and model parameters. A DAG defines conditional independencies over random variables and model parameters define their conditional distributions. BN structure learning (BNSL) [17] is a problem to find the DAG that maximizes a scoring function from a model class. Unfortunately, the problem is generally NP-hard [8, 9]. Most existing BNSL methods assume no latent variable or limit the number of latent variables [5, 24, 26, 27, 20]. Whereas our aim is to obtain appropriate latent variable models for the given data, the aim of BNSL is to obtain the exact dependencies of observable variables. It is intractable to naively apply existing BNSL methods to our aim because introducing latent variables exponentially increases the number of candidate model structures and the computation time of a scoring function. Our method avoids such intractability by restricting our model class based on the given nested structure and by introducing a universal algorithm for efficient score computation on the restricted model class.

A hierarchical latent class (HLC) model [28] is a tree-structured BN with latent variables, where its leaf nodes are observable variables and the others are latent variables. Learning HLC model structure is similar to our aim, however, it differs in the following two points. First, our method assumes that data have nested structure and exploits the data structure to generate appropriate models. Second, our method considers both hierarchical and sequential dependencies of latent variables. Model structure generated by our method includes, but are not limited to, tree structures.

A model generation method based on matrix factorization has been proposed [12]. The method defines its model class by using context-free grammar of which grammatical rules correspond to matrix factorization processes. A sentence generated by the grammar represents a hierarchical matrix factorization model. The method assumes that given data are represented as a single matrix whereas our method uses data together with its nested structure.

Several latent variable models for nested data have been proposed. The segmented topic model (STM) [11], which is a variant of probabilistic topic models [6], assumes that a document is a collection of segments and each of the segments is a collection of words. The STM captures correlations of topics over segments and segments over documents by introducing segment-level and document-level topic probabilities. The tree-informed LDA (tiLDA) [18], which is a multi-level LDA model, exploits another type of hierarchical structure of documents. The tiLDA model assumes that documents are grouped into categories and each of the categories are also grouped into another categories. Those models exploit inner-document and outer-document nested structures, respectively. Our model also copes with both inner and outer document hierarchies. It additionally exploits sequential information such as the word and segment order. By automatically extracting the essential part of such hierarchical and sequential structures, it generates appropriate models for the given nested data.

Similarly, latent variable models for sequential data have been proposed. A hidden Markov topic model (HMTM) [3], which is a natural extension of LDA models for the nonexchangeable setting, assumes that word topics are generated by a Markov chain. Each document has its own topic Markov chain, however, word emission probabilities of topics are shared by all documents. A hidden topic Markov model (HTMM) [13] introduces a Markov chain to LDA models with a different fashion from HMTM. The HTMM assumes that words in the same sentence share a common topic and each of the sentence topics is generated by a Markov chain. Similar to those methods, our method can combine LDA models and HMMs. Additionally, our method automatically chooses appropriate levels in which Markov chains should be introduced.

3 ORDERED TREE FOR NESTED DATA

We here introduce an ordered tree representation of nested data. Suppose that nested data \mathbf{D} is represented as a pair (\mathbf{x}, \mathbf{T}) , where $\mathbf{x} \equiv (x_n)_{n=1}^N$ is a sequence of observable variables and \mathbf{T} is an ordered tree representing its nested structure. An ordered tree \mathbf{T} is defined by a triplet (\mathbb{N}, par, sib) , where $\mathbb{N} = \{0, \dots, N\}$ is node indexes in the breadth first order (i.e., 0 is a root node), and $par : \mathbb{N} \rightarrow \mathbb{N}$ and $sib : \mathbb{N} \rightarrow \mathbb{N}$ define the parent and the previous sibling of each node, respectively. Thus, $par(n)$ denotes the n 's

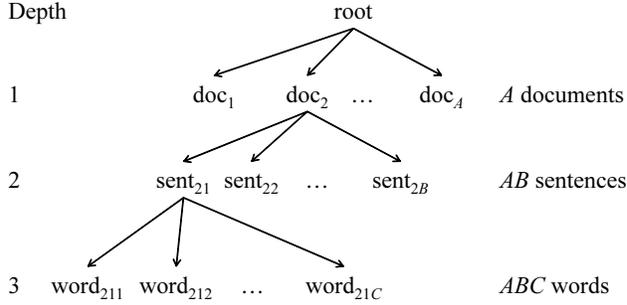

Figure 1: An ordered tree representation of a 3-layered nested structure.

parent and $sib(n)$ denotes the n 's previous sibling, where $sib(n) = 0$ denotes that n has no previous sibling. Let D be the depth of \mathbf{T} and d_n be that of n . Also let \mathbb{N}_d ($1 \leq d \leq D$) be a set of nodes n such that $d_n = d$. An observable variable x_n is associated with each node n , where variables in the same depth are assumed to share the same domain. For simplicity, we focus on the case that x_n ($n \in \mathbb{N}_d$) has a discrete domain $\{1, \dots, V_d\}$, although our method can be extended easily to the continuous case, where $V_d = 0$ denotes that $n \in \mathbb{N}_d$ has no observation.

We illustrate the ordered tree representation of a collection of documents with a 3-layered nested structure in Figure 1. Suppose that the collection contains A documents, where each document contains B sentences and each sentence consists of C words. A node in the first layer $n \in \mathbb{N}_1$ corresponds to a document, and $n \in \mathbb{N}_2$ and $n \in \mathbb{N}_3$ correspond to a sentence and a word, respectively. The tree depth is $D = 3$ and the tree size is $N = A + AB + ABC$. Each leaf node $n \in \mathbb{N}_3$ has a corresponding observation x_n which is a term in V_3 -term vocabulary. Each inter node $n \in \mathbb{N} \setminus \mathbb{N}_3$ have no observation that is denoted by $V_1 = V_2 = 0$.

When we design a latent variable model for the above nested data, we choose essential structural information and reflect it in the model. In LDA models, for example, only document-level information is preserved and the other information (the sentence and word order) is ignored. In this paper, we aim to automatically extract important information in \mathbf{T} and generate an appropriate model for given nested data \mathbf{D} .

4 OUR MODEL

In this section, we first describe our latent variable model \mathbf{M} of which dependencies among latent variables are adjustable by its *structural parameters*. We then propose a local search method to optimize the parameters for given nested data \mathbf{D} . The method generates an appropriate model structure of \mathbf{M} that captures intrinsic characteristics of \mathbf{D} .

Table 1: An assumption variable A_d and dependencies.

A_d	Explanation	Dependency
I-det	Index-deterministic	$z_n = n$
P-det	Parent-deterministic	$z_n = z_\ell$
N-dep	Non-dependent	$z_n \perp\!\!\!\perp z_\ell, z_n \perp\!\!\!\perp z_m$
P-dep	Parent-dependent	$z_n \not\perp\!\!\!\perp z_\ell, z_n \perp\!\!\!\perp z_m$
S-dep	Sibling-dependent	$z_n \perp\!\!\!\perp z_\ell, z_n \not\perp\!\!\!\perp z_m$
B-dep	Both-dependent	$z_n \not\perp\!\!\!\perp z_\ell, z_n \not\perp\!\!\!\perp z_m$

4.1 MODEL DEFINITION

We here describe our model \mathbf{M} which is a Bayesian latent variable model for nested data $\mathbf{D} = (\mathbf{x}, \mathbf{T})$. Our model \mathbf{M} is defined by a quadruplet $(\mathbf{T}, \mathbf{A}, \boldsymbol{\alpha}, \boldsymbol{\beta})$, where \mathbf{T} is the given ordered tree, \mathbf{A} is *structural parameters* which control dependencies among latent variables, and $\boldsymbol{\alpha}$ and $\boldsymbol{\beta}$ are model parameters.

We first introduce latent variables $\mathbf{z} \equiv (z_n)_{n=1}^N$ and structural parameters $\mathbf{A} \equiv (A_d)_{d=1}^D$, where A_d is an *assumption variable* which defines dependencies among latent variables in the d th layer. Our model \mathbf{M} assumes that each node $n \in \mathbb{N}_d$ has a discrete latent variable $z_n \in \{1, \dots, K_d\}$. We define $z_0 = 0$ for denoting the root 0 has no latent variable. Each observable variable x_n is generated by depending only on the corresponding latent variable z_n . Each latent variable z_n is generated by depending on latent variables of n 's parent and sibling $z_{par(n)}$ and $z_{sib(n)}$. For simplicity, let $\ell = par(n)$ and $m = sib(n)$ in this paper. An assumption variable A_d with a discrete domain $\{\text{I-det}, \text{P-det}, \text{N-dep}, \text{P-dep}, \text{S-dep}, \text{B-dep}\}$ controls the dependency of z_n ($n \in \mathbb{N}_d$) as shown in Table 1. I-det and P-det denote that z_n deterministically takes a value n and z_ℓ , respectively. N-dep denotes that z_n is independent of other latent variables. P-dep, S-dep and B-dep denote that z_n depends on z_ℓ , z_m and the both, respectively. The structural parameters \mathbf{A} control the entire model structure of \mathbf{M} which represents dependencies among all latent variables \mathbf{z} .

We next introduce model parameters $\boldsymbol{\alpha} \equiv (\boldsymbol{\alpha}_d)_{d=1}^D$ and $\boldsymbol{\beta} \equiv (\boldsymbol{\beta}_d)_{d=1}^D$, where $\boldsymbol{\alpha}_d \equiv (\alpha_{d,k})_{k=1}^{K_d}$ and $\boldsymbol{\beta}_d \equiv (\beta_{d,v})_{v=1}^{V_d}$ are parameters of Dirichlet distributions for generating $\boldsymbol{\theta}_{d,i,j} \equiv (\theta_{d,i,j,k})_{k=1}^{K_d}$ and $\boldsymbol{\phi}_{d,k} \equiv (\phi_{d,k,v})_{v=1}^{V_d}$, respectively. Here, $\boldsymbol{\theta}_{d,i,j}$ is a parameter of a categorical distribution for generating z_n ($n \in \mathbb{N}_d$) and $\boldsymbol{\phi}_{d,k}$ is that for generating x_n , that is, $\theta_{d,i,j,k}$ is a probability of $z_n = k$ given $z_\ell = i$ and $z_m = j$ and $\phi_{d,k,v}$ is a probability of $x_n = v$ given $z_n = k$. The generation process of $(\mathbf{x}, \mathbf{z}, \boldsymbol{\theta}, \boldsymbol{\phi})$ given model $\mathbf{M} \equiv (\mathbf{T}, \mathbf{A}, \boldsymbol{\alpha}, \boldsymbol{\beta})$ is as follow.

1. For each depth $d = 1, \dots, D$ and hidden class $i = 1, \dots, K_{d-1}$ and $j, k = 1, \dots, K_d$
 - (a) Draw $\boldsymbol{\theta}_{d,i,j} \sim \text{Dir}(\boldsymbol{\alpha}_d)$
 - (b) Draw $\boldsymbol{\phi}_{d,k} \sim \text{Dir}(\boldsymbol{\beta}_d)$

2. For each depth $d=1, \dots, D$ and node $n \in \mathbb{N}_d$

(a) Choose a class z_n by

case A_d
when I-det : $z_n := n$
when P-det : $z_n := z_\ell$
when N-dep : $z_n \sim \text{Cat}(\boldsymbol{\theta}_{d,0,0})$
when P-dep : $z_n \sim \text{Cat}(\boldsymbol{\theta}_{d,z_\ell,0})$
when S-dep : $z_n \sim \text{Cat}(\boldsymbol{\theta}_{d,0,z_m})$
when B-dep : $z_n \sim \text{Cat}(\boldsymbol{\theta}_{d,z_\ell,z_m})$

(b) Draw an observation $x_n \sim \text{Cat}(\boldsymbol{\phi}_{d,z_n})$

Here, $\boldsymbol{\theta}_{d,i,j}$ is a parameter for generating z_n ($n \in \mathbb{N}_d$) given $z_\ell = i$ and $z_m = j$, however, we set $i = 0$ and $j = 0$ when z_n is independent of z_ℓ and z_m , respectively. The joint probability $p(\mathbf{x}, \mathbf{z}, \boldsymbol{\theta}, \boldsymbol{\phi} | \mathbf{M})$ factorizes into

$$p(\mathbf{x}, \mathbf{z}, \boldsymbol{\theta}, \boldsymbol{\phi} | \mathbf{M}) = p(\mathbf{x} | \mathbf{z}, \boldsymbol{\phi}) p(\mathbf{z} | \mathbf{A}, \boldsymbol{\theta}) p(\boldsymbol{\theta} | \boldsymbol{\alpha}) p(\boldsymbol{\phi} | \boldsymbol{\beta}),$$

and each probability is computed as

$$p(\boldsymbol{\theta} | \boldsymbol{\alpha}) = \prod_{d=1}^D \prod_{i=0}^{K_{d-1}} \prod_{j=0}^{K_d} \text{Dir}(\boldsymbol{\theta}_{d,i,j}; \boldsymbol{\alpha}_d), \quad (1)$$

$$p(\boldsymbol{\phi} | \boldsymbol{\beta}) = \prod_{d=1}^D \prod_{k=1}^K \text{Dir}(\boldsymbol{\phi}_{d,k}; \boldsymbol{\beta}_d), \quad (2)$$

$$p(\mathbf{z} | \mathbf{A}, \boldsymbol{\theta}) = \prod_{d=1}^D \prod_{i=0}^{K_{d-1}} \prod_{j=0}^{K_d} \prod_{k=1}^{K_d} \theta_{d,i,j,k}^{c_{d,i,j,k}(\mathbf{A}, \mathbf{z})}, \quad (3)$$

$$p(\mathbf{x} | \mathbf{z}, \boldsymbol{\phi}) = \prod_{d=1}^D \prod_{k=1}^{K_d} \prod_{v=1}^{V_d} \phi_{d,k,v}^{c_{d,k,v}(\mathbf{z}, \mathbf{x})}, \quad (4)$$

where $c_{d,i,j,k}(\mathbf{A}, \mathbf{z})$ and $c_{d,k,v}(\mathbf{z}, \mathbf{x})$ are define as

$$c_{d,i,j,k}(\mathbf{A}, \mathbf{z}) \equiv \begin{cases} |\{n \in \mathbb{N}_d \mid z_n = k\}| & A_d = \text{N-dep}, i = j = 0 \\ |\{n \in \mathbb{N}_d \mid z_\ell = i, z_n = k\}| & A_d = \text{P-dep}, j = 0 \\ |\{n \in \mathbb{N}_d \mid z_m = j, z_n = k\}| & A_d = \text{S-dep}, i = 0 \\ |\{n \in \mathbb{N}_d \mid z_\ell = i, z_m = j, z_n = k\}| & A_d = \text{B-dep} \\ 0 & \text{otherwise,} \end{cases}$$

$$c_{d,k,v}(\mathbf{z}, \mathbf{x}) \equiv |\{n \in \mathbb{N}_d \mid z_n = k, x_n = v\}|.$$

Here, $c_{d,k,v}(\mathbf{z}, \mathbf{x})$ is the count of $\phi_{d,k,v}$ used in the generating process and $c_{d,i,j,k}(\mathbf{A}, \mathbf{z})$ is that of $\theta_{d,i,j,k}$.

Our model \mathbf{M} includes a variety of well-known existing models. Given text data \mathbf{x} and ordered tree \mathbf{T} shown in Figure 1 as its nested structure, we can represent various models by adjusting structural parameters \mathbf{A} as shown in Table 2, where the corresponding plate notations are shown in Figure 2.

Table 2: Example models for 3-layered text data. MMM denotes a multinomial mixture model. dX, sX and wX denote document-level X, sentence-level X and word-level X, respectively.

	$\mathbf{A} = (A_1, A_2, A_3)$	Corresponding Model
(1)	N-dep, P-det, P-det	dMMM
(2)	I-det, P-det, P-dep	dLDA
(3)	I-det, I-det, S-dep	wHMM
(4)	I-det, S-dep, P-dep	sHMM + wMMM
(5)	I-det, P-det, B-dep	dLDA + wHMM
(6)	I-det, B-dep, P-dep	dLDA+sHMM+wMMM

4.2 MODEL GENERATION

Given nested data $\mathbf{D} = (\mathbf{x}, \mathbf{T})$, we aim to generate the “best” model $\mathbf{M} = (\mathbf{T}, \mathbf{A}, \boldsymbol{\alpha}, \boldsymbol{\beta})$ for \mathbf{D} by optimizing \mathbf{A} , $\boldsymbol{\alpha}$ and $\boldsymbol{\beta}$. To define the “best”, a criterion for comparing multiple models is needed. A log marginal likelihood $\mathcal{L}[\mathbf{M}] \equiv \ln p(\mathbf{x} | \mathbf{M})$ is one of such criteria which measures how model \mathbf{M} fits to the given data \mathbf{x} [19, 10]. However, computing $\mathcal{L}[\mathbf{M}]$ is intractable because it requires an intractable summation $\sum_{\mathbf{z}} p(\mathbf{x}, \mathbf{z} | \mathbf{M})$. We instead employ the variational free energy (VFE) [5] $\mathcal{F}[\mathbf{M}]$, which is a lower bound of $\mathcal{L}[\mathbf{M}]$. The definition and an efficient computation algorithm of $\mathcal{F}[\mathbf{M}]$ are described in Section 5. The algorithm is also used for optimizing model parameters $\boldsymbol{\alpha}$ and $\boldsymbol{\beta}$ given \mathbf{D} and \mathbf{A} . Even though VFE $\mathcal{F}[\mathbf{M}]$ is computable, it is still intractable to maximize $\mathcal{F}[\mathbf{M}]$ with respect to \mathbf{A} because it requires evaluation of $\mathcal{F}[\mathbf{M}]$ for all possible instantiations for \mathbf{A} . We avoid such intractable evaluation by employing the following local search:

1. Let \mathbf{A} s.t. $A_d = \text{P-det}$ for all d and evaluate $\mathcal{F}[\mathbf{M}]$
2. Let $t := 0$ and $B_t := \{\mathbf{A}\}$
3. Let $\text{NB}_t :=$ all neighbors of $\mathbf{A} \in B_t$
4. Evaluate $\mathcal{F}[\mathbf{M}]$ for all $\mathbf{A} \in \text{NB}_t$
5. Let $B_{t+1} :=$ the w best structures w.r.t. VFE
6. Terminate if $B_{t+1} = B_t$ and return 3. otherwise

We initialize the first candidate \mathbf{A} as the simplest structure which contains only deterministic latent variables that is equivalent to no latent variable model. We then repeat generating neighbors of current candidates and choosing the w best structures as new candidates while VFE increases, where w is the search bandwidth. Here, \mathbf{A}' is a neighbor of \mathbf{A} if there exists exactly one d such that $A_d \neq A'_d$.

The above method automatically generates an appropriate latent variable model \mathbf{M} for the given nested data \mathbf{D} by optimizing its structural parameters \mathbf{A} and its model parameters $\boldsymbol{\alpha}$ and $\boldsymbol{\beta}$. It can also automatically select an appropriate K_d , which is the number of clusters in the d -th layer, by running with different K_d and choosing \mathbf{M} with the highest VFE. In the case we have a condition on models, our method can generate only expected models by skip-

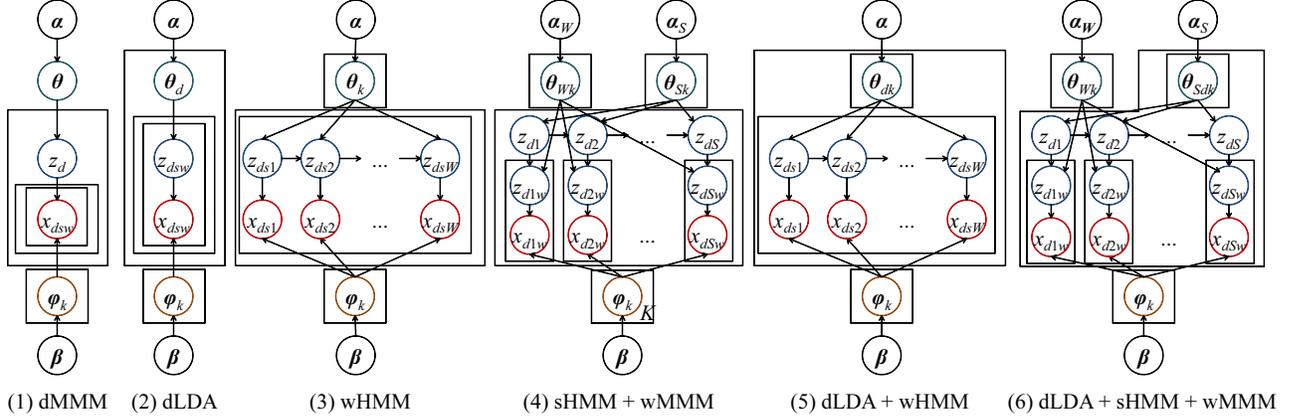

Figure 2: Plate representations of models in Table 2.

ping violated models in the search. For example, a model for the document clustering task should have a latent variable which indicates the cluster index of each document. Our method can generate a such model by excepting models which have no latent variable in the document-layer.

5 VARIATIONAL INFERENCE

We here define a variational free energy $\mathcal{F}[M]$ which is used as a measure how model M fits to given nested data D . We propose an efficient method for computing $\mathcal{F}[M]$ that employs a dynamic programming algorithm on T as its building block. The method is universal because it does not require change even if model structure A and data structure T are changed.

5.1 VARIATIONAL FREE ENERGY

Using Jensen's inequality, we obtain the following lower bound of log marginal likelihood $\mathcal{L}[M]$,

$$\begin{aligned} \ln p(\mathbf{x} | M) &\geq E_q[\ln p(\mathbf{x} | \mathbf{z}, \phi)] + E_q[\ln p(\mathbf{z} | \mathbf{A}, \theta)] \\ &\quad + E_q[\ln p(\theta | \alpha)] + E_q[\ln p(\phi | \beta)] - H[q] \\ &\equiv \mathcal{F}[q, M], \end{aligned}$$

where q is a variational distribution such that $q(\mathbf{z}, \theta, \phi) = q(\mathbf{z})q(\theta)q(\phi)$ and $H[q]$ is its entropy. By using the Euler-Lagrange equation, we obtain

$$q(\mathbf{z}) \propto \exp(E_{q(\phi)}[\ln p(\mathbf{x} | \mathbf{z}, \phi)] + E_{q(\theta)}[\ln p(\mathbf{z} | \theta)]), \quad (5)$$

$$q(\theta) \propto p(\theta | \alpha) \exp(E_{q(\mathbf{z})}[\ln p(\mathbf{z} | \mathbf{A}, \theta)]), \quad (6)$$

$$q(\phi) \propto p(\phi | \beta) \exp(E_{q(\mathbf{z})}[\ln p(\mathbf{x} | \mathbf{z}, \phi)]). \quad (7)$$

By iteratively updating q , we can maximize $\mathcal{F}[q, M]$ w.r.t. q . We can also maximize it w.r.t. model parameters α and β by fixed point iteration [21]. We use $\mathcal{F}[M]$ to denote $\mathcal{F}[q, M]$ which is computed by estimated q , α and β .

We next detail these q updates. Because $q(\theta)$ and $q(\phi)$ are approximations of (1) and (2), we define

$$q(\theta) \equiv \prod_{d=1}^D \prod_{i=0}^{K_d} \prod_{j=0}^{K_d} \text{Dir}(\theta_{d,i,j}; \mathbf{a}_{d,i,j}),$$

$$q(\phi) \equiv \prod_{d=1}^D \prod_{k=1}^K \text{Dir}(\phi_{d,k}; \mathbf{b}_{d,k}),$$

where $\mathbf{a}_{d,i,j} \equiv (a_{d,i,j,k})_{k=1}^{K_d}$ and $\mathbf{b}_{d,k} \equiv (b_{d,k,v})_{v=1}^{V_d}$ are variational parameters. By substituting (1)-(4) into (6)(7), their updates are obtained by

$$a_{d,i,j,k} = \alpha_{d,k} + E_{q(\mathbf{z})}[c_{d,i,j,k}(\mathbf{A}, \mathbf{z})], \quad (8)$$

$$b_{d,k,v} = \beta_{d,v} + E_{q(\mathbf{z})}[c_{d,k,v}(\mathbf{z}, \mathbf{x})]. \quad (9)$$

We also obtain the following updates of $q(\mathbf{z})$:

$$\begin{aligned} q(\mathbf{z}) &\propto \left(\prod_{d=1}^D \prod_{i=0}^{K_d-1} \prod_{j=0}^{K_d} \prod_{k=1}^{K_d} \theta_{d,i,j,k}^* c_{d,i,j,k}(\mathbf{A}, \mathbf{z}) \right) \\ &\quad \times \left(\prod_{d=1}^D \prod_{k=1}^{K_d} \prod_{v=1}^{V_d} \phi_{d,k,v}^* c_{d,k,v}(\mathbf{z}, \mathbf{x}) \right), \end{aligned}$$

where

$$\theta_{d,i,j,k}^* \equiv \exp \left(\Psi(a_{d,i,j,k}) - \Psi \left(\sum_{k'=1}^{K_d} a_{d,i,j,k'} \right) \right),$$

$$\phi_{d,k,v}^* \equiv \exp \left(\Psi(b_{d,k,v}) - \Psi \left(\sum_{v'=1}^{V_d} b_{d,k,v'} \right) \right),$$

and $\Psi(\cdot)$ is a digamma function. Here, $q(\mathbf{z}) = p(\mathbf{z} | \mathbf{x}, \theta^*, \phi^*)^1$ holds by the definitions of (3) and (4).

¹Even $\phi_{d,k}^*$ and $\theta_{d,i,j}^*$ are not a probability vector, $p(\mathbf{z} | \mathbf{x}, \theta^*, \phi^*)$ is a probability through the effect of a normalizing factor $p(\mathbf{x} | \theta^*, \phi^*) = \sum_{\mathbf{z}} p(\mathbf{x}, \mathbf{z} | \theta^*, \phi^*)$.

Thus, expectations in (8) and (9) are computed as

$$\mathbb{E}_{q(\mathbf{z})}[c_{d,i,j,k}(\mathbf{A}, \mathbf{z})] = \sum_{n \in \mathcal{N}_d} P_{\ell,m,n}^{i,j,k}[\mathbf{x}, \boldsymbol{\theta}^*, \boldsymbol{\phi}^*] \quad (10)$$

$$\mathbb{E}_{q(\mathbf{z})}[c_{d,k,v}(\mathbf{z}, \mathbf{x})] = \sum_{n \in \mathcal{N}_d: x_n=v} \sum_{i=0}^{K_{d-1}} \sum_{j=0}^{K_d} P_{\ell,m,n}^{i,j,k}[\mathbf{x}, \boldsymbol{\theta}^*, \boldsymbol{\phi}^*] \quad (11)$$

$$P_{\ell,m,n}^{i,j,k}[\mathbf{x}, \boldsymbol{\theta}, \boldsymbol{\phi}] \equiv p(z_\ell=i, z_m=j, z_n=k \mid \mathbf{x}, \boldsymbol{\theta}, \boldsymbol{\phi}).$$

We propose an efficient dynamic programming method for computing $P_{\ell,m,n}^{i,j,k}[\mathbf{x}, \boldsymbol{\theta}, \boldsymbol{\phi}]$ in Section 5.2.

5.2 EFFICIENT PROBABILITY COMPUTATION

For efficient computation of $P_{\ell,m,n}^{i,j,k}[\mathbf{x}, \boldsymbol{\theta}, \boldsymbol{\phi}]$, we define

$$R_{\ell,m,n}^{i,j,k}[\mathbf{x}, \boldsymbol{\theta}, \boldsymbol{\phi}] \equiv p(z_\ell=i, z_m=j, z_n=k, \mathbf{x} \mid \boldsymbol{\theta}, \boldsymbol{\phi}). \quad (12)$$

Using the above, $P_{\ell,m,n}^{i,j,k}[\mathbf{x}, \boldsymbol{\theta}, \boldsymbol{\phi}]$ is computed as

$$P_{\ell,m,n}^{i,j,k}[\mathbf{x}, \boldsymbol{\theta}, \boldsymbol{\phi}] = \frac{R_{\ell,m,n}^{i,j,k}[\mathbf{x}, \boldsymbol{\theta}, \boldsymbol{\phi}]}{p(\mathbf{x} \mid \boldsymbol{\theta}, \boldsymbol{\phi})}, \quad (13)$$

$$p(\mathbf{x} \mid \boldsymbol{\theta}, \boldsymbol{\phi}) = \sum_{i=0}^{K_{d-1}} \sum_{j=0}^{K_d} R_{\ell,m,n}^{i,j,k}[\mathbf{x}, \boldsymbol{\theta}, \boldsymbol{\phi}]. \quad (14)$$

Computing $R_{\ell,m,n}^{i,j,k}[\mathbf{x}, \boldsymbol{\theta}, \boldsymbol{\phi}]$ by naively summarizing out $z_{n'}$ ($n' \in \mathcal{N} \setminus \{\ell, m, n\}$) requires exponential time in N .

We here describe an efficient dynamic programming algorithm for computing $R_{\ell,m,n}^{i,j,k}[\mathbf{x}, \boldsymbol{\theta}, \boldsymbol{\phi}]$. Let $\text{Dec}(n)$ be all descendants of n in \mathbf{T} . Also let $\text{Sib}^-(n)$ and $\text{Sib}^+(n)$ be all younger and older siblings of n , respectively. We then introduce the following four sets, *inside set* $\text{I}(n)$, *outside set* $\text{O}(n)$, *forward set* $\text{F}(n)$ and *backward set* $\text{B}(n)$:

$$\begin{aligned} \text{I}(n) &\equiv \{n\} \cup \text{Dec}(n), & \text{F}(n) &\equiv \bigcup_{m \in \{n\} \cup \text{Sib}^-(n)} \text{I}(m), \\ \text{O}(n) &\equiv \mathcal{N} \setminus \text{Dec}(n), & \text{B}(n) &\equiv \bigcup_{m' \in \{n\} \cup \text{Sib}^+(n)} \text{I}(m'). \end{aligned}$$

Figure 3 shows examples of those sets of a 3-layered ordered tree. Using those sets, a set of all nodes \mathcal{N} factorizes into $\mathcal{N} = \text{O}(\ell) \cup \text{F}(m) \cup \text{B}(n)$. For a set $C \subseteq \mathcal{N}$, we define $\mathbf{x}_C \equiv (x_n)_{n \in C}$ and $\mathbf{z}_C \equiv (z_n)_{n \in C}$. Then, $R_{\ell,m,n}^{i,j,k}[\mathbf{x}, \boldsymbol{\theta}, \boldsymbol{\phi}]$ factorizes into

$$\begin{aligned} R_{\ell,m,n}^{i,j,k}[\mathbf{x}, \boldsymbol{\theta}, \boldsymbol{\phi}] &= p(\mathbf{x}_{\text{O}(\ell)}, z_\ell=i \mid \boldsymbol{\theta}, \boldsymbol{\phi}) \\ &\quad p(\mathbf{x}_{\text{F}(m)}, z_m=j \mid z_\ell=i, \boldsymbol{\theta}, \boldsymbol{\phi}) \\ &\quad p(\mathbf{x}_{\text{B}(n)}, z_n=k \mid z_\ell=i, z_m=j, \boldsymbol{\theta}, \boldsymbol{\phi}). \end{aligned}$$

To compute the above, we introduce the following four probabilities, *inside probability* $I_n[k]$, *outside probability*

$O_n[k]$, *forward probability* $F_n[i, k]$ and *backward probability* $B_n[i, j, k]$:

$$I_n[k] \equiv p(x_{\text{I}(n)} \mid z_n=k, \boldsymbol{\theta}, \boldsymbol{\phi}),$$

$$O_n[k] \equiv p(x_{\text{O}(n)}, z_n=k \mid \boldsymbol{\theta}, \boldsymbol{\phi}),$$

$$F_n[i, k] \equiv p(x_{\text{F}(n)}, z_n=k \mid z_\ell=i, \boldsymbol{\theta}, \boldsymbol{\phi}),$$

$$B_n[i, j, k] \equiv p(x_{\text{B}(n)}, z_n=k, \mid z_\ell=i, z_m=j, \boldsymbol{\theta}, \boldsymbol{\phi}).$$

The above probabilities can be computed in the following dynamic programming manner:

$$I_n[k] = \phi_{d,k,v} B_c[k, 0], \quad (15)$$

$$O_n[k] = \sum_{i=0}^{K_{d-1}} \sum_{j=0}^{K_d} O_n[i, j, k], \quad (16)$$

$$F_n[i, k] = I_n[k] \sum_{j=1}^{K_d} F_m[i, j] \theta_{d,i,j,k}, \quad (17)$$

$$B_n[i, j, k] = I_n[k] B_{m'}[i, k] \theta_{d,i,j,k}, \quad (18)$$

where $v = x_n$, $d = d_n$, c is the oldest child of n , m' is the next sibling of n and

$$O_n[i, j, k] \equiv O_\ell[k] F_m[i, j] B_{m'}[i, j] \phi_{d,k,v} \theta_{d,i,j,k},$$

$$B_n[i, j] \equiv \sum_{k=1}^{K_d} B_n[i, j, k].$$

Finally, the target probability is computed by

$$R_{\ell,m,n}^{i,j,k}[\mathbf{x}, \boldsymbol{\theta}, \boldsymbol{\phi}] = O_\ell[i] F_m[i, j] B_n[i, j, k]. \quad (19)$$

In summary, the variational free energy $\mathcal{F}[\mathbf{M}]$ is computed by Algorithm 1. When $K_d = K$ for all d , the complexity of this algorithm is $O(NK^3)$, however, it decreases according to structural parameters \mathbf{A} . For example, it becomes $O(NK^2)$ if \mathbf{A} represents an HMM, and also becomes $O(NK)$ if \mathbf{A} represents an LDA model. Note that the naive computation for $R_{\ell,m,n}^{i,j,k}[\mathbf{x}, \boldsymbol{\theta}, \boldsymbol{\phi}]$ requires exponential time in N but our method is polynomial.

6 EMPIRICAL RESULTS

6.1 ARTIFICIAL DATASETS

We here illustrate that our method is feasible for generating structures of latent variable models by using artificial datasets, where correct models which generate the datasets are known. We designed 12 models with the 3-layered nested structure \mathbf{T} shown in Figure 1 and generated 12 datasets from these models. Each dataset contains L documents, each document contains L sentences and each sentence contains L words. We set the cluster size of each depth as $K_1 = K_2 = K_3 = 5$ and the vocabulary size as $V_1 = V_2 = 0$ and $V_3 = 500$.

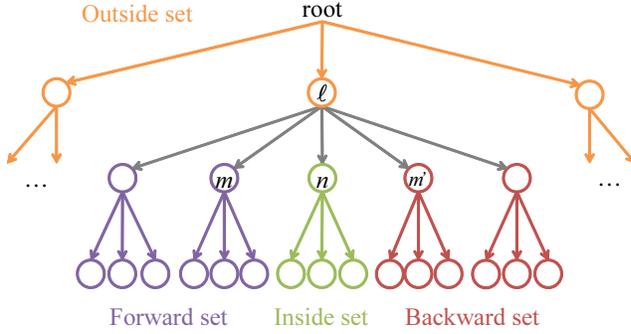

Figure 3: Inside set $I(n)$, outside set $O(\ell)$, forward set $F(m)$ and backward sets $B(m')$ of a 3-layered ordered tree, where m' is the next sibling of n .

We applied our method for the 12 datasets with search bandwidth $w = 3$. Table 3 shows the correct models and generated models. Our method generated the correct models for all dataset with $L = 50$. Even the dataset size is small, it correctly estimated simple models such as MMMs.

6.2 REAL-WORLD DATASETS

To demonstrate its applicability to real data, we applied our method for two real-world datasets, a Japanese blog dataset and an English news dataset. In both experiments, we ran our method with different $K = 10, 20, 30$ and chose the model with the highest VFE. We set search bandwidth $w = 3$ and excluded models of which complexity is $O(NK^3)$ for tractability. We also applied LDA models for the same datasets with different $K = 10, 20, \dots, 100$ and compared VFEs of LDA models and those of generated models.

Table 4: VFEs for the Japanese blog dataset.

Model	VFE
user-LDA	-5.239×10^6
article-LDA	-5.284×10^6
Generated model	-5.222×10^6

Table 6: VFEs for the English news dataset.

Model	First dataset	Second dataset
day-LDA	-8.739×10^6	-4.891×10^6
article-LDA	-8.299×10^6	-4.609×10^6
sentence-LDA	-8.554×10^6	-4.842×10^6
Generated model	-7.658×10^6	-4.555×10^6

JAPANESE BLOG DATASET. The dataset is a collection of 100 users' goo blog [1] articles from April 7th to June 27th in 2007, where each article is extracted as a sequence of nouns and verbs. We filtered out the 100 most frequent terms as stop words and used the top 5,000 terms to construct a 3-layered nested dataset consisted of 100 users, 7,687 articles and 731,065 words.

For this dataset, our method generated the same model as (5) in Figure 2, which is equivalent to an HMTM [3] that is a combination of a user-level LDA and word-level HMM. The model is better than LDA models from the aspect of VFE as shown in Table 4. In the generated model, each user has a corresponding topic transition matrix but topics are shared by all users. Table 5 shows the ten most frequent topics and their five most probable words, where words were translated from Japanese to English. We manually gave a topic name for each topic. The table shows that the generated model captured latent topics in the Japanese blog dataset.

ENGLISH NEWS DATASET. The dataset is a collection of Reuters' news articles in 1987 [2]. We extracted articles from March 1st to 31st and constructed a 4-layered nested dataset consisting of 29 days, 10,535 articles, 79,155 sentences and 31,057 terms in the vocabulary, where words including 0-9 were replaced to "NUM". We then created two datasets by extracting the 5,000 most frequent terms: the first dataset that we did not filter out any words but the second one that we filtered the first 100 terms as stop words. Those datasets contained 1,369,888 and 626,316 words, respectively.

Figure 4 shows plate representations of models generated by our method. Our method generated a word-level HMM for the first dataset and a 3-layered MMM for the second one. Table 6 shows VFEs of the generated models and LDA models. As shown, our method found better models than LDA in terms of VFE.

Figure 5 shows the ten most frequent topics, their five most probable words and the five most probable topic transi-

Table 5: The ten most frequent topics and their five most probable words obtained from the Japanese blog data.

z_{uaw}	Topic name	The five most probable words
24	Verbs 1	sleep, go, try, mind, no
5	Stock market	stock, management, company, proportion, market
16	News	book, ads, news, US, company
9	Research	psychology, perception, research, knowledge, description
28	Animation	version, animation, appearance, track, purchase
27	Travel (urban)	bus, station, Rahmen, father, taste
12	Travel (nature)	blossom, weather, Japanese cherry, park, wind
25	Software	case, screen, data, process, layout
19	International news	dictionary, multimedia, phraseology, terrorism, high concept
8	Verbs 2	receive, book, visit, try, time

tions over those topics. The generated model captured frequently-appearing grammatical patterns. A topic transition ($18 \rightarrow 7$) describes a pattern (number \rightarrow unit), and ($\{29, 13\} \rightarrow 26 \rightarrow \{17, 22\}$) describes a pattern (Preposition (1) & (2) \rightarrow Article \rightarrow {Objects, Adjective}). Because such grammatical patterns commonly appear in every sentences, our method extracted the word-layer and removed the other layers.

In contrast, our method generated a 3-layered MMM (day-article-sentence) for the second dataset. This is because grammatical patterns in the dataset were destroyed by filtering out stop words. The model performed day, article and sentence clustering; days were grouped into two clusters and articles and sentences were grouped into 30 clusters. Table 7 shows the three most probable article and sentence clusters and the five most probable words. The day clusters shared neither article cluster nor sentence cluster in the table. Sentence clusters in day cluster 3 describe periodic financial reports, budgets of IT companies and shareholder meeting, respectively. Those in day cluster 26 describe policies of executives, domestic economy and economic relations between Japan and US, respectively. It seems that day cluster 3 tends to mention about periodical events.

7 CONCLUSION

We proposed a method for generating latent variable models from nested data. We presented a latent variable model of which structure is adjustable by its structural parameters. Our model attempts to optimize the parameters by maximizing the variational free energy. We derived a universal variational inference method for our model based on dynamic programming on the given data structure. No matter how deep the input nested data are, our method extracts its essential information and generates a model with an appropriate complexity. We empirically showed that our method correctly generated model structures by synthetic datasets and also showed that it extracted hidden structures of blog and news datasets.

We note a potential direction for future work. We can extend our model to non-parametric Bayesian setting by replacing Dirichlet distributions by HDPs [23]. To the best of our knowledge, it seems difficult to provide an efficient variational inference method for the extended model because it subsumes the infinite hidden Markov model (iHMM) [4] which is a non-parametric Bayesian extension of HMM. However, we can easily derive a Gibbs sampling in the same way as that of iHMM. The beam sampling [25] is an efficient sampling method for iHMM, which com-

Abstract

It is becoming increasingly evident that many machine learning problems may be reduced to submodular optimization. Previous work addresses generic discrete approaches and specific relaxations. In this work, we take a generic view from a relaxation perspective. We show a relaxation formulation and simple rounding strategy that, based on the monotone closure of relaxed constraints, reveals analogies between minimization and maximization problems, and includes known results as special cases and extends to a wider range of settings. Our resulting approximation factors match the corresponding integrality gaps. For submodular maximization, a number of relaxation approaches have been proposed. A critical challenge for the practical applicability of these techniques, however, is the complexity of evaluating the multilinear extension. We show that this extension can be efficiently evaluated for a number of useful submodular functions, thus making these otherwise impractical algorithms viable for real-world machine learning problems.

1 INTRODUCTION

Submodularity is a natural model for many real-world problems including many in the field of machine learning. Submodular functions naturally model aspects like cooperation, complexity, and attractive potentials in minimization problems, and also notions of diversity, coverage, and information in maximization problems. A function $f : 2^V \rightarrow \mathbb{R}$ on subsets of a ground set $V = \{1, 2, \dots, n\}$ is *submodular* [37, 15] if for all subsets $S, T \subseteq V$, we have $f(S) + f(T) \geq f(S \cup T) + f(S \cap T)$. The *gain* of an element $j \in V$ with respect to $S \subseteq V$ is defined as $f(j|S) \triangleq f(S \cup j) - f(S)$. Submodularity is equivalent to *diminishing gains*: $f(j|S) \geq f(j|T), \forall S \subseteq T, j \notin T$.

A large number of machine learning problems may be

phrased as submodular minimization or maximization problems. In this paper, we address the following two very general forms of submodular optimization:

$$\text{Problem 1: } \min_{X \in \mathcal{C}} f(X), \quad \text{Problem 2: } \max_{X \in \mathcal{C}} f(X)$$

Here, \mathcal{C} denotes a family of feasible sets, described e.g., by cardinality constraints, or by combinatorial constraints insisting that the solution be a tree, path, cut, matching, or a cover in a graph.

Applications. Unconstrained submodular minimization occurs in machine learning and computer vision in the form of combinatorial regularization terms for sparse reconstruction and denoising, and MAP inference, e.g. for image segmentation [30]. Other applications are well modeled as constrained submodular minimization. For example, a rich class of models for image segmentation has been encoded as minimizing a submodular functions subject to cut constraints [28]. Similarly, [9] efficiently solves MAP inference in a sparse higher-order graphical model through submodular vertex cover, and [48] proposes to interactively segment images by minimizing a submodular function subject to connectivity constraints, i.e., the selected set of vertices must contain an s - t path. Moreover, bounded-complexity corpus construction [36] can be modeled as cardinality constrained submodular minimization. Constrained submodular maximization is a fitting model for problems such as optimal sensing [32], marketing [29], document summarization [35], and speech data subset selection [34].

Previous Work. Since most instances of Problems 1 and 2 are NP-hard, one must strive for approximations that have bounded error. Broadly speaking¹, the algorithms can be classified into discrete (*combinatorial*) and continuous *relaxation* based. The discrete approaches were initially proposed for certain *specific* constraints [17, 27, 47, 41, 12, 4, 3], but later made *general* and unified [25, 18, 24]. In the case of submodular minimization, the discrete approaches have been based on approximating the submodular function

¹ Emphasized words in this paragraph correspond to headings in Table 1, which also serves as a summary.

by tractable approximations [25, 18], while in the case of submodular maximization, they have been based on greedy and local search techniques [25, 41, 12, 4, 3]. Most of these algorithms are *fast* and scalable. The continuous relaxation techniques, on the other hand, have so far either been analyzed for very specific constraints, or when general, are too *slow* to use in practice. For example, in the case of minimization, they were studied only for the specific constraints of covers [20] and cuts [27], and in the case of maximization, the techniques though general have yet to show significant practical impact due to their prohibitive computational costs [6, 5]. Hence discrete algorithms are typically used in applications (e.g., [34]).

Constraints or Function	Operation (& speed)	Algorithm Approach	
		Combinatorial	Relaxation
Specific	Min (fast)	[17, 27]	[20, 27]
	Min (slow)	[47]	Unnecessary
	Max (fast)	[41, 12, 4, 3]	This paper
	Max (slow)	Unnecessary	[4, 5]
General	Min (fast)	[25]	This paper
	Min (slow)	[18]	Unnecessary
	Max (fast)	[25]	Open
	Max (slow)	Unnecessary	[6]

Table 1: Past work & our contributions (see text for explanation).

In the present paper, we develop a continuous relaxation methodology for Problems 1 and 2 that applies not only for multiple types of constraints but that even establishes connections between minimization and maximization problems. We summarize our contributions, in comparison to previous work, in Table 1, which lists one problem as being still open, and other problems as being unnecessary (given a “fast” approach, the corresponding “slow” approach is unnecessary). Our techniques are not only connective, but also fast and scalable. In the case of constrained minimization, we provide a formulation applicable for a large class of constraints. In the case of submodular maximization, we show how for a large class of submodular functions of practical interest, the generic slow algorithms can be made fast and scalable. We note, however, that it is still an open problem to provide a fast and scalable algorithmic framework (with theoretical guarantees) based on continuous relaxations for general submodular maximization.

The connections between minimization and maximization is based on the up- or down-monotonicity of the constraint set: up-monotone constraints are relevant for submodular minimization problems, and down-monotone constraints are relevant for submodular maximization problems. Our relaxation viewpoint, moreover, complements and improves on the bounds found in [25]. For example, where [25] may have an approximation bound of k , our results imply a bound of $n - k + 1$, where $n = |V|$, so considering both [25] and our new work presented here, we obtain combined bounds of the form $\min(k, n - k + 1)$ (more specifics are given in Table 2). This also holds for maximization – in certain cases discrete

algorithms obtain suboptimal results, while relaxation techniques obtain improved, and sometimes optimal guarantees.

The idea of our relaxation strategy is as follows: the submodular function $f(S)$, which is defined on the vertices of the n -dimensional hypercube, is extended to a function defined on $[0, 1]^n$. The two functions evaluate identically if the vector $x \in [0, 1]^n$ is the characteristic vector of a set. We then solve a continuous optimization problem subject to linear constraints. For minimization, the convex *Lovász extension* defined in Eqn. (1) is a suitable extension of f . Appropriately rounding the resulting optimal continuous solutions leads to a number of approximation guarantees. For maximization, ideally we could utilize a concave extension. Since the tightest concave extension of a submodular function is hard to characterize [49], we instead use the *multilinear extension* (see Eqn. (2)) that behaves like a concave function in certain directions [6, 5]. Our resulting algorithms often achieve better bounds than discrete greedy approaches.

Paper Roadmap. For constrained minimization (Sec. 3), we provide a generic approximation factor (Theorem 1), for the general class of constraints defined in Eq. 4. We show that many important constraints, including matroid, cardinality, covers, cuts, paths, matchings, etc. can be expressed as Eq. 4. As a corollary to our main result (Theorem 1), we obtain known results (like covers [20] and cuts [27]), and also novel ones (for spanning trees, cardinality constraints, paths, matchings etc.). We also show bounds on integrality gaps for constrained submodular minimization, which to our knowledge is novel. In the context of maximization (Sec. 4), we provide closed form multi-linear extensions for several submodular functions useful in applications. We also discuss the implications of these algorithmically. Note that this is particularly important, given that many optimal algorithms for several submodular maximization problems are based on the multilinear extension. Lastly, we extend our techniques to minimize the difference between submodular functions, and provide efficient optimization and rounding techniques for these problems (Sec. 5).

2 CONTINUOUS RELAXATIONS

Convex relaxation. The Lovász extension [37] reveals an important connection between submodularity and convexity, and is defined as follows. For each $y \in [0, 1]^n$, we obtain a permutation σ_y by ordering its elements in non-increasing order, and thereby a chain of sets $\Sigma_0^y \subseteq \dots \subseteq \Sigma_n^y$, with $\Sigma_j^y = \{\sigma_y(1), \dots, \sigma_y(j)\}$ for $j \in \{1, 2, \dots, n\}$. The Lovász extension \check{f} of f is a weighted sum of the ordered entries of y :

$$\check{f}(y) = \sum_{j=1}^n y[\sigma_y(j)] (f(\Sigma_j^y) - f(\Sigma_{j-1}^y)) \quad (1)$$

The Lovász extension is unique (despite possibly non-unique orderings if y has duplicate entries), and convex if and only if f is submodular. Since it agrees with f on the vertices of the hypercube, i.e., $f(X) = \tilde{f}(1_X)$, for all $X \subseteq V$ (where 1_X is the characteristic vector of X , i.e., $1_X(j) = I(j \in X)$), \tilde{f} is a natural convex extension of a submodular function. The Lovász extension is a non-smooth (piece-wise linear) convex function for which a subgradient $h_{\sigma_y}^f$ at y can be computed efficiently via Edmonds’s greedy algorithm [10]:

$$h_{\sigma_y}^f(\sigma_y(j)) = f(\Sigma_j^y) - f(\Sigma_{j-1}^y), \quad \forall j \in \{1, 2, \dots, n\}$$

The Lovász extension has also found applications in defining norms for structured sparsity [1] and divergences for rank aggregation [23].

Multilinear relaxations. For maximization problems, the relaxation of choice has frequently been the multilinear extension [12]

$$\tilde{f}(x) = \sum_{X \subseteq V} f(X) \prod_{i \in X} x_i \prod_{i \notin X} (1 - x_i), \quad (2)$$

where f is any set function. Since Eqn. (2) has an exponential number of terms, its evaluation in general computationally expensive, or requires approximation.

One may define at least two types of gradients for the multilinear extension. The first, “standard” gradient is

$$\nabla_j \tilde{f}(x) = \partial \tilde{f} / \partial x_j = \tilde{f}(x \vee e_j) - \tilde{f}(x \vee e_j - e_j).$$

where $e_j = 1_{\{j\}}$, and $\{x \vee y\}(i) = \max(x(i), y(i))$. A second gradient is $\nabla_j^a \tilde{f}(x) = \tilde{f}(x \vee e_j) - \tilde{f}(x)$. The two gradients are related component-wise as $\nabla_j \tilde{f}(x) = (1 - x_j) \nabla_j^a \tilde{f}(x)$, and both can be computed in $O(n)$ evaluations of \tilde{f} .

Optimization. Relaxation approaches for submodular optimization follow a two-stage procedure:

1. Find the optimal (or approximate) solution \hat{x} to the problem $\min_{x \in \mathcal{P}_C} \tilde{f}(x)$ (or $\max_{x \in \mathcal{P}_C} \tilde{f}(x)$).
2. Round the continuous solution \hat{x} to obtain the discrete indicator vector of set \hat{X} .

Here, \mathcal{P}_C denotes the polytope corresponding to the family \mathcal{C} of feasible sets – i.e., their convex hull or its approximation, which is a “continuous relaxation” of the constraints \mathcal{C} . The final approximation factor is then $f(\hat{X})/f(X^*)$, where X^* is the exact optimizer of f over \mathcal{C} .

An important quantity is the *integrality gap* that measures – over the class \mathcal{S} of all submodular (or monotone submodular) functions – the largest possible discrepancy between the optimal discrete solution and the optimal continuous solution. For minimization problems, the integrality gap is defined as:

$$\mathcal{I}_C^{\mathcal{S}} \triangleq \sup_{f \in \mathcal{S}} \frac{\min_{X \in \mathcal{C}} f(X)}{\min_{x \in \mathcal{P}_C} \tilde{f}(x)} \geq 1. \quad (3)$$

For maximization problems, we would take the supremum over the inverse ratio. In both cases, $\mathcal{I}_C^{\mathcal{S}}$ is defined only for non-negative functions. The integrality gap largely depends on the specific formulation of the relaxation. Intuitively, it provides a lower bound on our approximation factor: we usually cannot expect to improve the solution by rounding, because any rounded discrete solution is also a feasible solution to the relaxed problem. One rather only hopes, when rounding, to not worsen the cost relative to that of the continuous optimum. Indeed, integrality gaps can often be used to show tightness of approximation factors obtained from relaxations and rounding [7]. For a detailed discussion on this connection, see [26].

3 SUBMODULAR MINIMIZATION

For submodular minimization, the optimization problem in Step 1 is a convex optimization problem, and can be solved efficiently if one can efficiently project onto the polytope \mathcal{P}_C . Our second ingredient is rounding. To round, a surprisingly simple thresholding turns out to be quite effective for a large number of constrained and unconstrained submodular minimization problems: choose an appropriate $\theta \in (0, 1)$ and pick all elements with “weights” above θ , i.e., $\hat{X}_\theta = \{i : \hat{x}(i) \geq \theta\}$. We call this procedure the *θ -rounding procedure*. In the following sections, we first review relaxation techniques for unconstrained minimization (which are known), and afterwards phrase a generic framework for constrained minimization. Interestingly, both constrained and unconstrained versions essentially admit the same rounding strategy and algorithms.

3.1 UNCONSTRAINED MINIMIZATION

Continuous relaxation techniques for unconstrained submodular minimization have been well studied [1, 15]. In this case, $\mathcal{P}_C = [0, 1]^n$, and importantly, the approximation factor and integrality gap are both 1.

Lemma 1. [15] *For any submodular function f , it holds that $\min_{X \subseteq V} f(X) = \min_{x \in [0, 1]^n} \tilde{f}(x)$. Given a continuous minimizer $x^* \in \operatorname{argmin}_{x \in [0, 1]^n} \tilde{f}(x)$, the discrete minimizers are exactly those obtained by θ -rounding x^* , for any $\theta \in (0, 1)$.*

Since the Lovász extension is a non-smooth convex function, it can be minimized up to an additive accuracy of ϵ in $O(1/\epsilon^2)$ iterations of the subgradient method. This accuracy directly transfers to the discrete solution if we choose the best set obtained with any $\theta \in (0, 1)$ [1]. For special cases, such as submodular functions derived from concave functions, smoothing techniques yield a convergence rate of $O(1/t)$ [45].

3.2 CONSTRAINED MINIMIZATION

We next address submodular minimization under constraints, where rounding affects the accuracy of the discrete solution. By appropriately formulating the problem, we show that θ -rounding applies to a large class of problems. We assume that the family \mathcal{C} of feasible solutions can be expressed by a (low-order) polynomial number of linear inequalities, or at least that linear optimization over \mathcal{C} can be done efficiently, as is the case for matroid polytopes [10].

A straightforward relaxation of \mathcal{C} is the convex hull $\mathcal{P}_{\mathcal{C}} = \text{conv}(1_X, X \in \mathcal{C})$ of \mathcal{C} . Often however, it is not possible to obtain a decent description of the inequalities determining $\mathcal{P}_{\mathcal{C}}$, even in cases when minimizing a linear function over \mathcal{C} is easy (two examples are the s-t cut and s-t path polytopes [44]). In those cases, we relax \mathcal{C} to its *up-monotone* closure $\widehat{\mathcal{C}} = \{X \cup Y \mid X \in \mathcal{C} \text{ and } Y \subseteq V\}$. With $\widehat{\mathcal{C}}$, a set is feasible if it is in \mathcal{C} or a superset of a set in \mathcal{C} . The convex hull of $\widehat{\mathcal{C}}$ is the up-monotone extension of $\mathcal{P}_{\mathcal{C}}$ within the hypercube, i.e. $\mathcal{P}_{\widehat{\mathcal{C}}} = \widehat{\mathcal{P}}_{\mathcal{C}} = (\mathcal{P}_{\mathcal{C}} + \mathbb{R}_+^n) \cap [0, 1]^n$, which is often easier to characterize than $\mathcal{P}_{\mathcal{C}}$ [26]. If \mathcal{C} is already up-monotone, then $\widehat{\mathcal{P}}_{\mathcal{C}} = \mathcal{P}_{\mathcal{C}}$.

Optimization. The relaxed minimization problem $\min_{x \in \widehat{\mathcal{P}}_{\mathcal{C}}} \check{f}(x)$ is non-smooth and convex with linear constraints, and therefore amenable to, e.g., projected subgradient methods. We here assume that the submodular function f is monotone nondecreasing (which often holds in applications), and extend our results to non-monotone functions in [26].

For projected (sub)gradient methods, it is vital that the projection on $\widehat{\mathcal{P}}_{\mathcal{C}}$ can be done efficiently. Indeed, this holds with the above assumptions that we can efficiently solve a linear optimization over $\widehat{\mathcal{P}}_{\mathcal{C}}$. In this case, e.g. Frank-Wolfe [13] methods apply. The projection onto matroid polyhedra can also be cast as a form of unconstrained submodular function minimization and is hence polynomial time solvable [15]. To apply splitting methods such as the alternating directions method of multipliers (ADMM) [2], we write the problem as $\min_{x, y: x=y} \check{f}(x) + I(y \in \widehat{\mathcal{P}}_{\mathcal{C}})$. ADMM needs a projection oracle onto the constraints – discussed above – and the proximal operator of f . Computing the proximal operator of the Lovász extension is equivalent to unconstrained submodular minimization, or to solving the minimum norm point problem. In special cases, faster algorithms apply [39, 45].

Rounding. Once we have obtained a minimizer \hat{x} of \check{f} over $\widehat{\mathcal{P}}_{\mathcal{C}}$, we apply simple θ -rounding. Whereas in the unconstrained case, \hat{X}_{θ} is feasible for any $\theta \in (0, 1)$, we must now ensure $\hat{X}_{\theta} \in \widehat{\mathcal{C}}$. Hence, we pick the largest threshold θ such that $\hat{X}_{\theta} \in \widehat{\mathcal{C}}$, i.e., the smallest \hat{X}_{θ} that is feasible. This is always possible since $\widehat{\mathcal{C}}$ is up-monotone and contains V . The threshold θ can be found using $O(\log n)$ checks among the sorted entries of the continuous solution \hat{x} . The following lemma states how the threshold θ determines

a worst-case approximation:

Lemma 2. *For a monotone submodular f and any $\hat{x} \in [0, 1]^V$ and $\theta \in (0, 1)$ such that $\hat{X}_{\theta} = \{i \mid \hat{x}_i \geq \theta\} \in \widehat{\mathcal{C}}$, it holds that $f(\hat{X}_{\theta}) \leq \frac{1}{\theta} \check{f}(\hat{x})$. If, moreover, $\check{f}(\hat{x}) \leq \beta \min_{x \in \widehat{\mathcal{P}}_{\mathcal{C}}} \check{f}(x)$, then it holds that $f(\hat{X}_{\theta}) \leq \frac{\beta}{\theta} \min_{X \in \mathcal{C}} f(X)$.*

The set \hat{X}_{θ} is in $\widehat{\mathcal{C}}$ and therefore guaranteed to be a superset of a solution $\hat{Y}_{\theta} \in \mathcal{C}$. As a final step, we prune down \hat{X}_{θ} to $\hat{Y}_{\theta} \subseteq \hat{X}_{\theta}$. Since the objective function is nondecreasing, $f(\hat{Y}_{\theta}) \leq f(\hat{X}_{\theta})$, Lemma 2 holds for \hat{Y}_{θ} as well. If, in the worst case, $\theta = 0$, then the approximation bound in Lemma 2 is unbounded. Fortunately, in most cases of interest we obtain polynomially bounded approximation factors.

In the following, we will see that our $\widehat{\mathcal{P}}_{\mathcal{C}}$ provides the basis for relaxation schemes under a variety of constraints, and that these, together with θ -rounding, yield bounded-factor approximations. We assume that there exists a family $\mathcal{W} = \{W_1, W_2, \dots\}$ of sets $W_i \subseteq V$ such that the polytope $\widehat{\mathcal{P}}_{\mathcal{C}}$ can be described as

$$\widehat{\mathcal{P}}_{\mathcal{C}} = \left\{ x \in [0, 1]^n \mid \sum_{i \in W} x_i \geq b_W \text{ for all } W \in \mathcal{W} \right\}. \quad (4)$$

Analogously, this means that $\widehat{\mathcal{C}} = \{X \mid |X \cap W| \geq b_W, \text{ for all } W \in \mathcal{W}\}$. In our analysis, we do not require \mathcal{W} to be of polynomial size, but a linear optimization over $\widehat{\mathcal{P}}_{\mathcal{C}}$ or a projection onto it should be possible at least within a bounded approximation factor. This is the case for s-t paths and cuts, covering problems, and spanning trees.

The following main result (proven in [26]) states approximation bounds and integrality gaps for the class of problems described by Equation (4).

Theorem 1. *The θ -rounding scheme for constraints \mathcal{C} whose relaxed polytope $\widehat{\mathcal{P}}_{\mathcal{C}}$ can be described by Equation (4) achieves a worst case approximation bound of $\max_{W \in \mathcal{W}} |W| - b_W + 1$.*

We also show [26] that this factor matches the integrality gap for the constraints considered in this paper.

A result similar to Theorem 1 was shown in [31] for a different, greedy algorithmic technique. While their result also holds for a large class of constraints, for the constraints in Equation (4) they obtain a factor of $\max_{W \in \mathcal{W}} |W|$, which is worse than Theorem 1 if $b_W > 1$. This is the case, for instance, for matroid span constraints, cardinality constraints, trees and multiset covers.

Pruning. The final piece of the puzzle is the pruning step, where we reduce the set $\hat{X}_{\theta} \in \widehat{\mathcal{C}}$ to a final solution $\hat{Y}_{\theta} \subseteq \hat{X}_{\theta}$ that is feasible: $\hat{Y}_{\theta} \in \mathcal{C}$. This is important when the true constraints \mathcal{C} are not up-monotone, as is the case for cuts and paths. Since we have assumed that the function f is

monotone, pruning can only reduce the objective value. The pruning step means finding *any* subset of \hat{X}_θ that is in \mathcal{C} , which is often not hard. We propose the following heuristic for this: if \mathcal{C} admits (approximate) linear optimization, as is the case for all the constraints considered here, then we may improve over a given rounded subset by assigning additive weights: $w(i) = \infty$ if $i \notin \hat{X}_\theta$, and otherwise use either uniform ($w(i) = 1$) or non-uniform ($w(i) = 1 - \hat{x}(i)$) weights. We then solve $\hat{Y}_\theta \in \operatorname{argmin}_{Y \in \mathcal{C}} \sum_{i \in Y} w(i)$. Uniform weights lead to the solution with minimum cardinality, and non-uniform weights will give a bias towards elements with higher certainty in the continuous solution. Truncation via optimization works well for paths, cuts, matchings or matroid constraints. In the extended version [26], we discuss how to handle non-monotone submodular functions and down-monotone constraints.

To demonstrate the utility of Theorem 1, we apply it to a variety of problems. We state only the results, all proofs are in [26]. Many of the constraints below are based on a graph $G = (\mathcal{V}, \mathcal{E})$, and in that case the ground set is the set \mathcal{E} of graph edges. When the context is clear, we overload notation and refer to $n = |\mathcal{V}|$ and $m = |\mathcal{E}|$. Results are summarized in Table 2.

3.2.1 MATROID CONSTRAINTS

An important class of constraints are matroid span or base constraints, with cardinality constraints (uniform matroids) and spanning trees (graphic or cycle matroids) as special cases. A matroid $\mathcal{M} = (\mathcal{I}_\mathcal{M}, r_\mathcal{M})$ is defined by its down-monotone family of independent sets $\mathcal{I}_\mathcal{M}$ or its rank function $r_\mathcal{M} : 2^V \rightarrow \mathbb{R}$. A set Y is a *spanning set* if its rank is that of V : $r_\mathcal{M}(Y) = r_\mathcal{M}(V)$. It is a *base* if $|Y| = r_\mathcal{M}(Y) = r_\mathcal{M}(V)$. Hence, the family of all spanning sets is the up-monotone closure of the family of all bases (e.g., supersets of spanning trees of a graph in the case of a graphic matroid). See [44] for more details on matroids. Let $\mathcal{S}_\mathcal{M}$ denote the spanning sets of matroid \mathcal{M} , and set $k = r_\mathcal{M}(V)$. It is then easy to see that with $\mathcal{C} = \mathcal{S}_\mathcal{M}$, the polytope $\mathcal{P}_\mathcal{C}$ is the matroid span polytope, which can be described as $\mathcal{P}_\mathcal{C} = \{x \in [0, 1]^n, x(S) \geq r_\mathcal{M}(V) - r_\mathcal{M}(V \setminus S), \forall S \subseteq V\}$ [44]. This is clearly in the form of Eqn. 4. Although this polytope is described via an exponential number of inequalities, it can be projected onto efficiently via submodular minimization [15].

Corollary 1. *Let \hat{Y}_θ be the rounded and pruned solution obtained from minimizing the Lovász extension over the span polytope. Then $f(\hat{Y}_\theta) \leq (n - k + 1)f(X^*)$. The integrality gap is also $n - k + 1$.*

In general, the rounding step will only provide an \hat{X}_θ that is a spanning set, but not a base. We can prune it to a base by greedily finding a maximum weight base among the elements of \hat{X}_θ . The worst-case approximation factor

of $n - k + 1$ complements other known results for this problem [25, 18]. The semi-gradient framework of [25] guarantees a bound of k , while more complex (and less practical) approximations [18] yield factors of $O(\sqrt{n})$. The factor k of [25] is the best for small k , while our continuous relaxation works well when k is large.

Cardinality Constraints. This is a special class of a matroid, called the uniform matroid. Since it suffices to analyze monotone submodular functions, the constraint of interest is $\mathcal{C} = \{X : |X| = k\}$. In this case, the corresponding polytope takes a very simple form: $\mathcal{P}_\mathcal{C} = \{x \in [0, 1]^n : \sum_i x_i = k\}$. Furthermore, the rounding step in this context is very intuitive. It corresponds to choosing the elements with the k largest entries in \hat{x} .

Spanning Trees. Here, the ground set $V = \mathcal{E}$ is the edge set in a graph and \mathcal{C} is the set of all spanning trees. The corresponding polytope $\mathcal{P}_\mathcal{C}$ is then the spanning tree polytope. Our bound in this setting is $m - n + 1$. The discrete algorithms of [25, 17] achieve a complementary bound of $|\mathcal{V}| = n$. For dense graphs, the discrete algorithms admit better worst case guarantees, while for sparse graphs (e.g., embeddable into r -regular graphs for small r), our guarantees are better.

3.2.2 SET COVERS

A fundamental family of constraints are set covers. Given a universe \mathcal{U} , and a family of sets $\{S_i\}_{i \in V}$, the task is to find a subset $X \subseteq V$ that covers the universe, i.e., $\bigcup_{i \in X} S_i = \mathcal{U}$, and has minimum cost as measured by a submodular function $f : 2^S \rightarrow \mathbb{R}$. The set cover polytope is up-monotone, constitutes the set of fractional covers, and is easily represented by Eqn. (4) as $\mathcal{P}_\mathcal{C} = \{x \in [0, 1]^{|V|} \mid \sum_{i:u \in S_i} x(i) \geq 1, \forall u \in \mathcal{U}\}$. The following holds for minimum submodular set cover:

Corollary 2. *The approximation factor of our algorithm, and the integrality gap for the minimum submodular set cover problem, is $\gamma = \max_{u \in \mathcal{U}} |\{i : u \in S_i\}|$.*

The approximation factor in Corollary 2 (without the integrality gap) was first shown in [20]. The quantity γ corresponds to the maximum frequency of the elements in \mathcal{U} .

A generalization of set cover is the multi-set cover problem [43], where every element u is to be covered multiple (c_u) times. The multi-cover constraints can be formalized as $\mathcal{P}_\mathcal{C} = \{x \in [0, 1]^{|S|} \mid \sum_{i:u \in S_i} x(i) \geq c_u, \forall u \in \mathcal{U}\}$.

Corollary 3. *The approximation factor and integrality gap of the multi-set cover problem is $\max_{u \in \mathcal{U}} |\{i : u \in S_i\}| - c_u + 1$.*

This result also implies the bound for set cover (with $c_u = 1$). Since the rounding procedure above yields a solution that is already a set cover (or a multi set cover), a subsequent pruning step is not necessary.

²These results were shown in [17, 20, 47]

	Matroid Constraints		Set Covers		Paths, Cuts and Matchings		
	Cardinality	Trees	Vertex Covers	Edge Covers	Cuts	Paths	Matchings
CR.	$n - k + 1$	$m - n + 1$	2	$\deg(G) \leq n$	$P_{max} \leq n$	$C_{max} \leq m$	$\deg(G) \leq n$
SG	k	n	$ VC \leq n$	$ EC \leq n$	$C_{max} \leq m$	$P_{max} \leq n$	$ M \leq n$
EA	\sqrt{n}	\sqrt{m}	\sqrt{n}	\sqrt{m}	\sqrt{m}	\sqrt{m}	\sqrt{m}
Integrality Gaps	$\Omega(n - k + 1)$	$\Omega(m - n + 1)$	2	$\Omega(n)$	$\Omega(n)$	$\Omega(m)$	$\Omega(n)$
Hardness ²	$\Omega(\sqrt{n})$	$\Omega(n)$	$2 - \epsilon$	$\Omega(n)$	$\Omega(\sqrt{m})$	$\Omega(n^{2/3})$	$\Omega(n)$

Table 2: Comparison of the results of our framework (CR) with the semigradient framework of [25] (SG), the Ellipsoidal Approximation (EA) algorithm of [18], hardness [17, 20, 47], and the integrality gaps of the corresponding constrained submodular minimization problems. Note the complementarity between CR and SG.

Vertex Cover. A vertex cover is a special case of a set cover, where \mathcal{U} is the set of edges in a graph, V is the set of vertices, and S_v is the set of all edges incident to $v \in V$. Corollary 2 implies a 2-approximation for submodular vertex cover, which matches the integrality gap and the lower bound in [17]. The 2-approximation for vertex cover was also shown in [17, 20].

Edge Cover. In the Edge Cover problem, \mathcal{U} is the set of vertices in a graph, V is the set of edges and S_v contains the two vertices comprising edge v . We aim to find a subset of edges such that every vertex is covered by some edge in the subset. It is not hard to see that the approximation factor we obtain is the maximum degree of the graph $\deg(G)$, which is upper bounded by $|\mathcal{V}|$, but is often much smaller. The algorithm in [25] has an approximation factor of the size of the edge cover $|EC|$, which is also upper bounded by $O(|\mathcal{V}|)$. These factors match the lower bound shown in [17].

3.2.3 CUTS, PATHS AND MATCHINGS

Even though Eqn. (4) is in the form of covering constraints, it can help solve problems with apparently very different types of constraints. The covering generalization works if we relax \mathcal{C} to its up-monotone closure: $\hat{\mathcal{C}}$ demands that a feasible set must contain (or “cover”) a set in \mathcal{C} . To go from $\hat{\mathcal{C}}$ back to \mathcal{C} , we prune in the end.

Cuts and Paths. Here, we aim to find an edge set $X \subseteq \mathcal{E}$ that forms an s-t path (or an s-t cut), and that minimizes the submodular function f . Both the s-t path and s-t cut polytopes are hard to characterize. However, their up-monotone extension $\hat{\mathcal{P}}_{\mathcal{C}}$ can be easily described. Furthermore, both these polytopes are intimately related to each other as a blocking pair of polyhedra (see [44]). The extended polytope for s-t paths can be described as a *cut-cover* [44] (i.e., any path must hit every cut at least once): $\hat{\mathcal{P}}_{\mathcal{C}} = \{x \in [0, 1]^{|\mathcal{E}|} \mid \sum_{e \in C} x(e) \geq 1, \text{ for every s-t cut } C \subseteq \mathcal{E}\}$. The closure of the s-t path constraint (or the cut-cover) is also called s-t connectors [44]. Conversely, the extended s-t cut polytope can be described as a *path-cover* [44, 27]: $\hat{\mathcal{P}}_{\mathcal{C}} = \{x \in [0, 1]^{|\mathcal{E}|} \mid \sum_{e \in P} x(e) \geq 1, \text{ for every s-t path } P \subseteq \mathcal{E}\}$.

Corollary 4. *The relaxation algorithm yields an approximation factor of $P_{max} \leq |\mathcal{V}|$ and $C_{max} \leq |\mathcal{E}|$ for minimum submodular s-t path and s-t cut respectively (P_{max} and*

C_{max} refer to the maximum size simple s-t path and s-t cut respectively). These match the integrality gaps for both problems.

While the description of the constraints as covers reveals approximation bounds, it does not lead to tractable algorithms for minimizing the Lovász extension. However, the extended cut and the extended path polytopes can be described exactly by a linear number of inequalities [42, 44]. The pruning step for paths and covers becomes a shortest path or minimum cut problem, respectively. As in the other cases, the approximations obtained from relaxations complement the bounds of P_{max} for paths and C_{max} for cuts shown in [25].

Perfect Matchings. Given a graph $G = (\mathcal{V}, \mathcal{E})$, the goal is to find a set of edges $X \subseteq \mathcal{E}$, such that X is a perfect matching in G and minimizes the submodular function f . For a bipartite graph, the polytope $\hat{\mathcal{P}}_{\mathcal{C}}$ can be characterized as $\mathcal{P}_{\mathcal{C}} = \{x \in [0, 1]^{|\mathcal{E}|} \mid \sum_{e \in \delta(v)} x(e) = 1 \text{ for all } v \in \mathcal{V}\}$, where $\delta(v)$ denotes the set of edges incident to v . Similar to the case of Edge Cover, Theorem 1 implies an approximation factor of $\deg(G) \leq |\mathcal{V}|$, which matches the lower bound shown in [17, 24].

4 SUBMODULAR MAXIMIZATION

To relax submodular maximization, we use the multilinear extension. We first show that this extension can be efficiently computed for a large subclass of submodular functions (deferring detailed derivations to [26]). As above, \mathcal{C} denotes the family of feasible sets, and $\mathcal{P}_{\mathcal{C}}$ the polytope corresponding to \mathcal{C} . For maximization, it makes sense to consider \mathcal{C} to be down-monotone (particularly when the function is monotone). Such a down-monotone \mathcal{C} could represent for example, matroid independence constraints, or upper bounds on the cardinality $\mathcal{C} = \{X : |X| \leq k\}$. Analogous to the case of minimization [26], an approximation algorithm for down-monotone constraints can be extended to up-monotone constraints, by using $f'(X) = f(V \setminus X)$.

The relaxation algorithms use the multilinear extension (Eqn. (2)) which in general requires repeated sampling and can be very expensive to compute. In the below, we show how this can be computed efficiently and exactly for many

practical and useful submodular functions.

Weighted Matroid Rank functions. A common class of submodular functions are sums of weighted matroid rank functions, defined as: $f(X) = \sum_i \max\{w_i(A) | A \subseteq X, A \in \mathcal{I}_i\}$, for linear weights $w_i(j)$. These functions form a rich class of coverage functions for summarization tasks [34]. The multilinear extension can be efficiently computed for a number of specific instances of this function. One such special case is the facility location objective [34]: $f(X) = \sum_{i \in V} \max_{j \in X} s_{ij}$, for pairwise similarities s_{ij} . The facility location function admits a nice representation of the multilinear extension (the full derivation is in [26]): $\tilde{f}(x) = \sum_{i \in V} \sum_{l=1}^n s_{ij_l^i} x_{ij_l^i} \prod_{m=1}^l (1 - x_{ij_m^i})$, where for each $i \in V$, the indices $j_1^i, j_2^i, \dots, j_n^i$ denote in sorted order the elements closest to i (in terms of similarity s_{ij}). We can similarly obtain closed form expressions with other forms of matroids, including uniform matroids or partition matroids. Due to limited space, detailed derivations are all given in [26].

Set Cover function: This is another important function, capturing notions of coverage [34]. Given a set of sets $\{\mathcal{S}_1, \dots, \mathcal{S}_n\}$ and the universe $\mathcal{U} = \cup_i \mathcal{S}_i$, define $f(X) = w(\cup_{i \in X} \mathcal{S}_i)$, where w_j denotes the weight of item $j \in \mathcal{U}$. This setup can alternatively be expressed via a neighborhood function $\Gamma : 2^V \rightarrow 2^{\mathcal{U}}$ such that $\Gamma(X) = \cup_{i \in X} \mathcal{S}_i$. Then $f(X) = w(\Gamma(X))$. Let $\Gamma^{-1}(j) = \{i \in V : j \in \Gamma(i)\}$. Then the multilinear extension has a simple form: $\tilde{f}(x) = \sum_{j \in \mathcal{U}} w_j [1 - \prod_{i \in \Gamma^{-1}(j)} (1 - x_i)]$. Again, for full derivations see [26].

Probabilistic Coverage Functions. This is a generalization of the set cover function above, and has been used in a number of models for summarization problems [11]. This provides a probabilistic notion to the set cover function, and can be defined as $f(X) = \sum_{i \in \mathcal{U}} w_i [1 - \prod_{j \in X} (1 - p_{ij})]$. We get back the set cover function, when p_{ij} is a binary vector (either i covers j or not). This function also has an efficiently computable multilinear extension [26]: $\tilde{f}(x) = \sum_{i \in \mathcal{U}} w_i [1 - \prod_{j \in V} (1 - p_{ij} x_j)]$.

Graph Cut related functions Graph cuts are a widely used class of functions. Their multilinear extension also admits closed form representation. The function and its multilinear extension can be written as: $f(X) = \sum_{i \in X, j \notin X} s_{ij}$, $\tilde{f}(x) = \sum_{i,j \in V} s_{ij} x_i (1 - x_j)$. A related function is a similarity penalizing function: $f(X) = -\sum_{i,j \in X} s_{ij}$. This function has been used for encouraging diversity [35, 34]. Its multilinear extension is $\tilde{f}(x) = -\sum_{i,j \in V} s_{ij} x_i x_j$. The detailed derivations of both these expressions are in [26].

Sparse Pseudo-Boolean functions. For graphical models, in particular in computer vision, set functions are often

written as polynomials [19]. Any set function can be written as a polynomial, $p_f(x) = \sum_{T \subseteq V} \alpha_T \prod_{i \in T} x_i$, where $x \in \{0, 1\}^n$ is the characteristic vector of a set. In other words, $f(S) = \sum_{T \subseteq S} \alpha_T$. Submodular functions are a subclass of these polynomials. This representation directly gives the multilinear extension as the same polynomial, $\tilde{f}(x) = \sum_{T \subseteq V} \alpha_T \prod_{i \in T} x_i$, and is efficiently computable if the polynomial is *sparse*, i.e., has few nonzero coefficients α_T [26]. This is the case for graph cut like functions above and for the functions considered in [46, 19]. We have been unable to find the above result elsewhere in the literature, so we formalize it as follows:

Proposition 1. *The polynomial representation is the multilinear extension: $\tilde{f}(x) = p_f(x)$*

Spectral functions. Diversity can also be encouraged via spectral regularizers [8]. Given a positive definite matrix $S \in \mathbb{R}^{n \times n}$, define S_X to be the $|X| \times |X|$ sub-matrix of the rows and columns indexed by X . Any scalar function ψ whose derivative is operator-antitone defines a submodular function, $f(X) = \sum_{i=1}^{|X|} \psi(\lambda_i(S_X))$, by applying it to the eigenvalues of S_X [14]. The resulting class of submodular functions includes the log determinants occurring in DPP inference [16], and, more generally, a smoothed log-determinant function $f(X) = \log \det(S_X + \delta I_X) = \sum_{i=1}^{|X|} \log(\lambda_i(S_X) + \delta)$. It is monotone for $\delta \geq 1$, and has an efficiently computable soft-max extension that is similar to the multilinear extension [16]. A related function that encourages diversity is $f(X) = -\sum_{i=1}^{|X|} (\lambda_i(S_X) - 1)^2$ [8]. It has a surprisingly simple multilinear extension: $\tilde{f}(x) = -\sum_{i,j \in V} s_{ij}^2 x_i x_j + \sum_{i \in V} (2s_{ii} + 1)$. For the detailed derivation of this, see [26].

Given expressions for the functions above, we can also handle weighted combinations $f(X) = \sum_i \lambda_i f_i(X)$, since its multilinear extension is $\tilde{f}(x) = \sum_i \lambda_i \tilde{f}_i(x)$. In the following sections, we briefly describe relaxation algorithms and rounding schemes for maximization.

4.1 MONOTONE MAXIMIZATION

We first investigate monotone submodular maximization subject to matroid independence constraints \mathcal{I} . The technique for maximizing the multilinear extension is the continuous greedy algorithm [50], which is a slight modification of the Frank-Wolfe algorithm [13], with a fixed step size. In each iteration, the algorithm takes a step $x^{t+1} = x^t + \delta h^t$ (with step size $\delta = 1/n^2$) in the direction $h^t = \operatorname{argmax}_{h' \in \mathcal{P}_c} \langle h', \nabla^a \tilde{f}(x^t) \rangle$ best aligned with the alternate gradient. This *continuous greedy* procedure terminates in $O(n^2)$ iterations, after which we are guaranteed to obtain a point x such that $\tilde{f}(x) \geq (1 - 1/e) \tilde{f}(x^*)$ [5, 49]. Moreover, using the pipage rounding technique (in particular, the deterministic variant [50]) ensures that we can round the continuous solution to a set in $O(n^2)$ function calls.

³This extends to top- k facility location as well.

⁴This is for soft-max extension [16].

	Fac. Location ³	Set Cover	Graph Cuts	Diversity I/ II	Concave over card.	log-Det ⁴
Multilinear Closed form	$O(n^3)$	$O(n^2)$	$O(n^2)$	$O(n^2)$	$O(n^2)$	$O(n^3)$
Multilinear Sampling	$O(n^r \log n)$	$O(n^6)$	$O(n^r)$	$O(n^r)$	$O(n^6)$	$O(n^8)$
Gradient Closed form	$O(n^3)$	$O(n^2)$	$O(n^2)$	$O(n^2)$	$O(n^2)$	$O(n^3)$
Gradient Sampling	$O(n^r \log n)$	$O(n^r)$	$O(n^8)$	$O(n^8)$	$O(n^r)$	$O(n^9)$

Table 3: Complexity of evaluating the multilinear extensions and their gradients for both the optimized closed forms given in this paper and for sampling at high accuracy.

Unfortunately, naïve computation of the multilinear extension or its gradient takes exponential time. To compute these in polynomial time, we can apply sampling techniques. To obtain an accuracy better than $1/n^2$, we need $O(n^5)$ samples for the multilinear extension or for each coordinate of its gradient [50, 49]. This implies a complexity of $O(n^6)$ function evaluations for the gradient and $O(n^5)$ function evaluations for the extension itself, thus implying the algorithm’s complexity as $O(n^8 T_{\nabla f})$, where $T_{\nabla f}$ is the time of evaluating the gain of f . For facility location, this means a running time of $O(n^9 \log n)$, and for set cover functions $O(n^9)$.

But these high complexities are for using a sampling approximation of the generic expression for the multilinear extension (Eqn. (2)). The specialized expressions in Section 4 lead to algorithms that run several orders of magnitude faster. With $O(n^2)$ iterations, the time becomes $O(n^2 T_{\nabla \tilde{f}})$, where $\nabla \tilde{f}$ is the time to compute the gradient of \tilde{f} . Table 3 compares the function evaluation times for some useful submodular functions. Moreover, we can also use mixtures of these submodular functions, each with efficiently computable multilinear extensions, and compute the resulting multilinear extension also efficiently. While this is still slower than the accelerated greedy [38], it gains power for more complex constraints, such as matroid independence constraints, where the discrete greedy algorithm only achieves an approximation factor of $1/2$, whereas the continuous greedy obtains at least a $1 - 1/e$ factor. Similarly, the continuous greedy algorithm achieves a $1 - 1/e$ approximation guarantee for multiple knapsack constraints [33], while the discrete greedy techniques do not have such guarantees. Hence, the formulations above make it possible to use the optimal theoretical results with a more manageable running time.

4.2 NON-MONOTONE MAXIMIZATION

In the non-monotone setting, we must find a local optimum of the multilinear extension. We could use, for example, a Frank-Wolfe style algorithm [13] and run it until it converges to a local optimum. It is easy to see that at convergence x satisfies $\langle \nabla \tilde{f}(x), y - x \rangle \leq 0, \forall y \in \mathcal{P}_C$ and is a local optimum. Practically, this would mean checking if $\operatorname{argmax}_{y \in \mathcal{P}_C} \langle y, \nabla \tilde{f}(x) \rangle = x$. For simple or no constraints, we could also use a method like L-BFGS. Running this procedure twice, we are guaranteed to obtain a 0.25 approximate solution [6]. This procedure works for any

down-monotone constraint \mathcal{C} . Moreover, this procedure with a slightly different extension has been successfully applied in practice to MAP inference with determinantal point processes [16].

A generic rounding strategy for submodular maximization problems was given by [6], and works for a large class of constraints (including matroid, knapsack constraints, and a combination thereof). Without constraints, this amounts to sampling a set by a distribution based on the continuous solution x — it will satisfy $\mathbf{E}_{X \sim x} f(X) = \tilde{f}(x)$. In practice, however, this may not work well. Since the multilinear extension is linear in any coordinate (holding the other ones fixed), a simpler co-ordinate ascent scheme of choosing the better amongst 0 or 1 for any fractional co-ordinate will guarantee a deterministic procedure of obtaining an integral solution no worse than the continuous one.

The above algorithms and rounding techniques offer a general and optimal framework, even for many complex constraints. Moreover, many of the best algorithms for non-monotone submodular maximization are based on the multilinear extension. For example, the best known algorithm for cardinality constrained non-monotone submodular maximization [4] uses a continuous double greedy algorithm on the multilinear extension. However, the practical utility of those algorithms is heavily impaired by computational complexity. In fact, non-monotone functions even require $O(n^7)$ samples [6]. For DPPs, [16] used an extension that is practical and close to the multilinear extension. Since they do not use the multilinear extension, the above rounding schemes do not imply the same approximation bounds as for the multilinear extension, leaving the worst-case approximation quality unknown. The expressions we show above use the multilinear extension and maintain its benefits, demonstrating that for many functions of practical interest, sampling, and hence extremely high complexity, is not necessary. This observation is a step from theory into practice, and allows for the improved approximations to occur in practice.

4.3 INTEGRALITY GAPS

Surprisingly, the multilinear extension has an integrality gap of 1 for a number of constraints including the matroid and cardinality constraints, since it is easy to round it exactly (using say, the pipage rounding or contention resolution schemes [5, 6]).

5 DIFFERENCE OF SUBMODULAR (DS) FUNCTIONS

Finally, we investigate minimizing the differences between submodular functions. Given submodular functions f and g , we consider the following minimization problem: $\min_{X \in \mathcal{C}} (f(X) - g(X))$. In fact, any set function can be represented as a difference between two non-negative monotone submodular functions [40, 21]. In the unconstrained setting, $\mathcal{C} = 2^V$. A natural continuous relaxation (not necessarily convex) is $\tilde{h}(x) = \check{f}(x) - \check{g}(x)$. The continuous relaxation problem is a DC programming problem, and can be addressed (often very efficiently) using the convex-concave procedure [51]. Moreover, thanks to the special structure of the Lovász extension, there exists a simple rounding scheme for the unconstrained version.

Lemma 3. *Given submodular functions f and g , and a continuous vector x , there exists a $\theta \in (0, 1)$ such that $f(X_\theta) - g(X_\theta) \geq \check{f}(x) - \check{g}(x)$, where $X_\theta = \{x \geq \theta\}$. Moreover, the integrality gap of $h(x)$ (in the unconstrained setting) is equal to 1.*

6 DISCUSSION

We have provided a unifying view to continuous relaxation methods for submodular optimization. For minimization problems with various constraints, we provide a generic rounding strategy with new approximation bounds and matching integrality gaps. For maximization, we provide efficiently computable expressions for many practically interesting submodular functions. This is a useful step towards transferring optimal theoretical results to real-world applications. An interesting question remains whether there exist improved sampling schemes for cases where the multilinear extension is too complex. Also recently, [22] investigated forms of submodular minimization and maximization, with submodular constraints. The proposed algorithms there were all discrete, and it will be interesting if our framework could extend to their setting as well.

Abstract

Given a set of n elements and a corresponding stream of its subsets, we consider the problem of selecting k elements that should appear in at least d such subsets arriving in the “near” future with high probability. For this min- d -occur problem, we present an algorithm that provides a solution with the success probability of at least $1 - O\left(\frac{kd \log n}{D} + \frac{1}{n}\right)$, where D is a known constant. Our empirical observations on two streaming data sets show that this algorithm achieves high precision and recall values. We further present a sliding window adaptation of the proposed algorithm to provide a continuous selection of these elements. In contrast to the existing work on predicting trends based on potential increase in popularity, our work focuses on a setting with provable guarantees.

1 Introduction

Consider a set S_n of n elements. When different sets $S^t \subseteq S_n$ are being observed at time t and may not be analyzed at a later time, we refer to these sets as *streaming sets*. This formulation of streaming sets is ubiquitous at least in the analysis of network traffic (Edwards et al., 1997), query logs (Golbandi et al., 2013), and social media (Mathioudakis and Koudas, 2010), where these sets arrive rapidly. Analyzing these streaming sets to identify historical patterns and predict future trends has been extensively studied for diverse applications including detection of intrusions (Lee et al., 2000), disease outbreak (Achrekar et al., 2011), and viral content (Weng et al., 2013). These works primarily focus on the recall

*Work done during an internship at Yahoo Labs Bangalore.

and the earliness of these predictions. As a result, they are useful for detecting outliers and arranging for preventive measures (Lamb et al., 2013). However, without any lower bound on the obtained precision values, these approaches are ineffective when the false positives may have significant cost associated with them.

Precise predictions are necessary for several planning applications such as resource allocation. For instance, accurate estimates of future traffic may help optimize routing to reduce network latency (Padmanabhan and Mogul, 1996). Similarly, accurate estimates of search query volume may help advertisers optimize marketing budget while bidding for key phrases on a search engine (Jansen and Mullen, 2008). To this end, we study the problem of making these predictions only when we can guarantee a minimum probability of success before the time horizon Δ . We define this problem formally as follows.

Definition 1. Min- d -occur. *Given a stream of sets $S^t \subseteq S_n$ arriving at time t , min- d -occur(S_n, Δ, k) selects at most k elements $\{y_1, y_2, \dots, y_k\} \in S_n$ at time τ such that each of these y_j appears at least d number of times in $\{S^{\tau+1}, \dots, S^\Delta\}$ with probability close to 1.*

Note that a solution to this problem may select fewer than k elements when the criterion for the probabilistic guarantee is not met. The constant Δ depends on the requirements of the application domain, which can be understood through an illustrative example as follows. Consider a stream of queries issued to a search engine that may be arriving at a rate of one million queries per second. Choosing Δ close to 100K would correspond to making the predictions about occurrences in the next 100 milliseconds. The choice of the parameter d depends on the characteristics of the stream of sets and determines the effectiveness of the solution. For the stream of queries, let us assume that we wish to track a set of 50 popular queries (i.e., $n = 50$), which cover approximately 1% of the incoming stream. In other words, 99% of the stream would be composed of empty sets, making the solution likely to be effective

only when $d \leq 1\%$ of Δ . Since these domain-specific stream characteristics are external to our problem formulation, we ignore the empty sets hereafter.

In the absence of any other assumptions about the stream characteristics, the *min- d -occur* problem is ill-posed. In fact, if there is a sudden drop in the frequency of the queries from the set S_n in the query stream (in the above example), there may not exist a solution set for an algorithm to predict. Using an appropriate selection of the set S_n and an assumption about the continuity of the stream statistics in the given time horizon Δ , it might be fair to assume that at least k queries will appear at least $D = 100$ times in the next 100 milliseconds. Under this additional assumption, the above *min- d -occur* problem becomes more useful for $d \leq D$. Using this constant integer D , we define a constrained variant as follows.

Definition 2. Constrained-min- d -occur. *Given that there exist at least k elements in S_n that appear D number of times in $\{S^1, \dots, S^\Delta\}$, constrained-min- d -occur(S_n, D, Δ, k) solves min- d -occur(S_n, Δ, k).*

Below we present a randomized algorithm for the constrained-min- d -occur problem. We show that the probability of a successful prediction from this algorithm is high when $d < \frac{D}{3 \log n}$ and $k = o(n/\log n)$. This theoretical result is further validated using experiments on two streaming data sets: search query logs and hash-tags in tweets. In both of these data sets, this algorithm achieved high precision and recall values for predictions. Interestingly, this algorithm is empirically effective for larger values of d even when a corresponding lower-bound is not computed. We also present a sliding-window based adaptation of our algorithm to accommodate a practical setting where the predictions need to be updated only at regular intervals of time.

Contributions. There are two main theoretical contributions in this paper. First, we present a novel problem formulation – *constrained min- d -occur* – for making guaranteed predictions of future occurrences in streaming data. Second, we present a randomized algorithm for making predictions under this formulation and derive an effective lower-bound on its performance. These theoretical contributions are supported by empirical observations on two real, streaming data sets i.e., Twitter hash-tags and query logs of a search engine.

2 Related Work

Our problem formulation is related to online coverage problems. In the online set cover problem, Alon et al. (2009) assume that a collection of sets is known be-

forehand but they arrive in an online fashion. An algorithm then selects k sets from this collection that solves the max-cover problem for the sets that are already observed. Whereas our setup requires predictions to be made for the sets arriving in future. Another related coverage problem is set-streaming maximum coverage proposed by Saha and Getoor (2009). They assume an orthogonal set up where the collection of sets remain static but their elements are streaming. Their algorithm is not applicable in our setting because we need to choose the elements that are present in maximum number of sets, and *not* the sets that cover maximum number of elements. Another similar problem formulation has appeared in the operating systems literature. Awerbuch et al. (1996) studied the problem of allocating jobs to workstations to ensure a timely, successful completion of the given jobs. They presented an algorithm that performs a sequential prediction of these allocations and allows at most one job to be running at any time. That is, the second job is allocated only after the completion (*not* allocation) of the first job. It is non-trivial to adapt their algorithm to perform k simultaneous allocations, although we have borrowed useful concepts from their lower-bound analysis in the development of our solution.

There exists significant literature on statistical trend prediction in streaming data, most notably for the Twitter data. There has also been some work on tracking topics and events in these streams (Ardon et al., 2013) through an appropriate adaptation of statistical topic models (AlSumait et al., 2008), and for detecting bursts or spikes in topics (Diao et al., 2012). Goorha and Ungar (2010) study the spiking behavior of elements in an input set of elements. Their algorithm can only handle a small set of elements, thereby limiting its utility in a general practical setting. Cataldi et al. (2010) modeled the streaming elements as a graph, and employed page-rank algorithm along with an aging theory to predict the spiking elements. Mathioudakis and Koudas (2010) analyzed the sudden change in frequency patterns of these elements in conjunction with a reputation model for the origin of the streaming elements to make these predictions. Becker et al. (2011) discussed an online setting to identify events and the related tweets, but they did not make predictions for future. Similarly, there has also some work on analyzing trends in user comments (Jain and Galbrun, 2013)

Most of these algorithms are optimized for a specific application, and require significant modification to be applicable to a different setting. These algorithms are evaluated empirically using measures such as the perplexity, recall, and earliness of the predictions. Since these approaches do not formally specify the (implicit) assumptions made about the stream character-

S_n	set of elements $\{e_1, \dots, e_n\}$
n	number of possible elements in the global set
k	number of elements to choose
x_e^t	Score of the element e at time t
y^t	Solution set constructed at time t
N	window size
w_e^t	window data structure for element e at time t

Table 1: Notation used in this paper

istics, it is challenging to assess their utility across different related settings, e.g., our current formulation. Also, lower-bound analyses for the prediction accuracy even for the original problem settings do not exist. In this work, we address both of these issues. We formally stated the assumptions of our prediction setting in the previous section. In the next section, we present a randomized algorithm to obtain a solution for this setting. A lower-bound analysis of the performance of this algorithm is described in the subsequent section.

3 Algorithm

Here we present a randomized algorithm that provides the constrained-min- d -occur (as defined above). In other words, this algorithm selects k elements (from S_n) that are likely to appear at least d number of times in the given future Δ occurrences. As we show below, the probability of a successful prediction from this algorithm is high when: $D > 3d \log n$ and $k = o(n/\log n)$. Later, in Section 6, we demonstrate that these assumptions hold in several practical settings for streaming data.

Algorithm 1 describes the different steps of our approach. We maintain a score x_e^t for each element $e \in S_n$ at every time t . At time t , a new set S^t is presented to the algorithm. For each element e present in the S^t that has already not been selected, we toss a coin with probability of getting heads $= \frac{3x_e^t - 2}{d}$. If a head is observed, we add e to the selection set y . We update the score x_e^t and continue till k elements have been selected. The set y represents the selected k elements.

4 Analysis

Here we prove that each of the k elements $\{y_1, y_2, \dots, y_k\}$ selected by our algorithm has a high probability of occurring at least d times in future (governed by the horizon Δ). We show this probability to be greater than $1 - O(\frac{kd \log n}{D})$.

We approach this proof by constructing a subspace

Algorithm 1 k Min- d -occur Prediction

Require: set of elements S_n , integer k , stream $\{S^1, \dots, S^\Delta\}$

- 1: $n \leftarrow |S_n|$.
- 2: $\forall e \in S_n, x_e^0 \leftarrow 0$.
- 3: $y \leftarrow \{\phi\}$.
- 4: $j = 1$
- 5: **for** $t = 1$ to Δ **do**
- 6: $\beta^t \leftarrow S^t \setminus y$
- 7: **for** $e \in \beta^t$ **do**
- 8: $x_e^t \leftarrow x_e^{t-1} + 1$.
- 9: choose $u \sim \text{Bernoulli}\left(\frac{n(3x_e^t - 2D)/D}{d}\right)$.
- 10: **if** $u = 1$ **then**
- 11: $y_j \leftarrow e$.
- 12: $j \leftarrow j + 1$.
- 13: **if** $j > k$ **then**
- 14: **return** y .
- 15: **end if**
- 16: **end if**
- 17: **end for**
- 18: **end for**

S_u of probabilistic outcomes of coin-toss experiments (as illustrated in Figure 1). In this subspace, 0 denotes the absence of an element in the set arriving at a given time. Whereas the presence of a particular element is denoted by the probabilistic outcome, i.e., the toss of the coin as H (head) or T (tail). In other words, there will be one coin toss for each pair (t, i) if and only if $e_i \in S^t \setminus y^t$. The element e_{i^*} is selected as the j^{th} prediction at time t^* if and only if:

- (t^*, i^*) toss is H ,
- for $t < t^*$ and $e_i \notin y^t$, (t, i) toss is T ,
- for $t = t^*$ and $i < i^*$, (t, i) toss is T .

Let $S_o \subseteq S_u$ be the subspace where each of the k selected elements occur in d sets after choosing them. We refer to this subspace as the solution space. In this subspace, one H appears in each of the k different values of i (in different columns) and there are at least d such sets. Each element would appear in at least d sets after their respective coin tosses are heads.

To show that $Pr[S_o]$ is close to 1, we first choose an intermediate subspace $S_i \subseteq S$ for which the corresponding probability, i.e., $Pr[S_i]$, is close to 1. This intermediate subspace is selected such that we can construct a useful injection from S_i to S_o . To this end, we define S_i to consist of sample points for which there are at least k heads for different elements and for which the first d flips for each element are tails.

(c) Solution space S_o

Figure 1: Illustration of the probabilistic subspace for $n = 7$. Each row represents a set α , where the absence of an element is denoted by 0; the outcome of the coin-toss for each of the other elements is shown as a tuple $(1, H)$ or $(1, T)$.

From the columns of S_u , only those elements are kept for which the first d tosses are tails to form the subspace S_i . The mapping from S_i to S_o has also been shown where the $(x_e^t - d)^{th}$ and x_e^t outcomes of coin toss are flipped depending upon the factors explained later. We start by proving a basic result about the universal space S_u .

Lemma 1. *The probability of getting tails for all coin tosses in $S_u \leq e^{-n/2}$.*

Proof. The probability of getting tails for all elements is the product of probability of getting tails for each element. The latter probability is less than the probability of getting tails for an element that is present in at least D sets. This upper bound probability is the same as the probability that there are no heads among the last d flips for the element that is available for D steps, which is at most

$$\left(1 - \frac{n^{\frac{3(D-d)}{D}-2}}{d}\right)^d \leq \left(1 - \frac{n}{2d}\right)^d \leq e^{-n/2} \quad (1)$$

because $D \geq 3d \log n$. \square

The probabilistic subspace S_i consists of observation sets such that there are at least k heads for different elements and for which the first d flips for each element are tails. Now we lower bound the probability associated with this subspace.

Lemma 2. $Pr[S_i] \geq 1 - O(1/n)$.

Proof. We found the probability of the complement of S_i , denoted by \bar{S}_i , to be easier to compute than for the subspace S_i . This probability is decomposed as a sum of two terms P_1 and P_2 defined below. The term P_1 denotes the probability of getting a head among the first (at most) $d \times n$ flips for each $x_i^t \leq d$. Since the

probability of observing an H is at most $\frac{n^{\frac{3d}{D}-2}}{d}$,

$$P_1 \leq dn \left(\frac{n^{\frac{3d}{D}-2}}{d}\right) \leq 2/n. \quad (2)$$

Let P_2 denote the probability of observing at most $k-1$ heads, i.e.,

$$P_2 = \sum_{i=0}^{k-1} Pr_i[H], \quad (3)$$

where $Pr_i[H]$ is the probability of observing a total i occurrences of H . Assuming i.i.d. observations for coin-tosses, we have

$$P_2 = \sum_{i=0}^{k-1} \binom{n}{i} Pr_1[H]^i Pr_1[T]^{n-i} \quad (4)$$

$$\leq \sum_{i=0}^{k-1} \binom{n}{i} Pr_1[T]^{n-i}, \quad (5)$$

since $Pr_1[H] \leq 1$. Keeping only those elements for which we get tails and they appear in at least D sets, we have

$$P_2 \leq \sum_{i=0}^{k-1} \binom{n}{i} Pr_1[T]^{k-i} \quad (6)$$

$$\leq k \times \max \left(\binom{n}{i} \times (e^{-n/2})^{k-i} \right). \quad (7)$$

For $k < n/2$, $\binom{n}{i} \times (e^{-n/2})^{k-i}$ is an increasing function with respect to i ; the maximum value is obtained for $i = k-1$. Therefore

$$P_2 \leq k \binom{n}{k-1} \times (e^{-n/2})^{k-(k-1)} \quad (8)$$

$$= k \left(\binom{n}{k-1} \times e^{-n/2} \right). \quad (9)$$

Also, since $\binom{n}{k} \leq n^k$,

$$P_2 \leq k \times n^{k-1} e^{-n/2} \leq 1/n, \quad (10)$$

if $k \leq \left(\frac{n}{2 \log n} - 1\right)$. Finally, combining Equation 2 and 10

$$\Pr[S_i] = 1 - (P_1 + P_2) \quad (11)$$

$$= 1 - (O(2/n) + O(1/n)) \quad (12)$$

$$= 1 - O(1/n). \quad (13)$$

□

For each of the members of the above intermediate subspace, we construct a member of the solution space. We ensure that the probabilities of occurrences of both of these instances are similar. The next lemma provides the similarity in the probabilities of these two subspaces.

Lemma 3. $\Pr[S_o] \geq (1 - O(\frac{kd \log n}{D})) \Pr[S_i]$.

Proof. We construct an injection $f : S_i \rightarrow S_o$ such that $\forall s' \in S_i$,

$$\Pr[f(s')] \geq \left(1 - O\left(\frac{kd \log n}{D}\right)\right) \Pr[s']. \quad (14)$$

Consider an instance $s' \in S_i$. Let $\{e_{i_1}, e_{i_2}, \dots, e_{i_k}\}$ be the elements for which the flips are the first heads in s' . Let x_{i_j} denote the number of sets in which e_{i_j} has been present and includes the set where the j^{th} heads occurred for $j \in \{1, 2, \dots, k\}$. By definition of S_i , $x_{i_j} > d$. Let us define

$$z'_{i_j} = n^{\frac{3x_{i_j}}{D} - 2} / d \quad (15)$$

and

$$z_{i_j} = \frac{n^{\frac{3(x_{i_j} - d)}{D} - 2}}{d} = n^{\frac{-3d}{D}} z'_{i_j} \quad (16)$$

$$= \left(1 - O\left(\frac{d \log n}{D}\right)\right) z'_{i_j}. \quad (17)$$

Let p refers to the sets considered in a sample space. Using these notation, we define the injection $f(s')$ as follows. If $z'_{i_j} \geq 1/2$ then all of the (p, i_j) pairs of $f(s')$ are made identical to the respective (p, i_j) of s' . Next, the $(x_{i_j} - d)^{\text{th}}$ flip of e_{i_j} is changed from tails to heads.

If $z'_{i_j} \leq 1/2$ then all of the (p, i_j) pairs of $f(s')$ are similar to (p, i_j) of s' except that the $(x_{i_j} - d)^{\text{th}}$ flip of e_{i_j} is changed from tails to heads and $x_{i_j}^{\text{th}}$ flip of e_{i_j} is changed from heads to tails.

The above process generates $f(s') \in S_o$. Without loss of generality, let us assume that for $j \in \{1, 2, \dots, r\}$ the value of $z'_{i_j} \geq 1/2$. For $j \in \{r+1, r+2, \dots, k\}$, let us assume $z'_{i_j} \leq 1/2$ where r is an integer $1 \leq r \leq k$.

Using this notation, the ratios of probabilities in the two subspaces is given by:

$$\frac{\Pr[f(s')]}{\Pr[s']} = \prod_{i_j=1}^r \frac{z_{i_j}}{1 - z_{i_j}} \cdot \prod_{i_j=r+1}^k \frac{z_{i_j}}{1 - z_{i_j}} \frac{1 - z'_{i_j}}{z'_{i_j}} \quad (18)$$

For $z'_{i_j} \geq 1/2$, using Equation 17, we get

$$\frac{z_{i_j}}{1 - z_{i_j}} = \frac{\left(1 - O\left(\frac{d \log n}{D}\right)\right) z'_{i_j}}{1 - \left(1 - O\left(\frac{d \log n}{D}\right)\right) z'_{i_j}} \quad (19)$$

$$\geq \frac{1/2 - O\left(\frac{d \log n}{D}\right)}{1/2 + O\left(\frac{d \log n}{D}\right)} \quad (20)$$

$$= 1 - O\left(\frac{d \log n}{D}\right). \quad (21)$$

For $z'_{i_j} \leq 1/2$, using Equation 17, we get

$$\left(\frac{z_{i_j}}{1 - z_{i_j}}\right) \left(\frac{1 - z'_{i_j}}{z'_{i_j}}\right) \quad (22)$$

$$\geq \left(1 - O\left(\frac{d \log n}{D}\right)\right) \frac{1 - z'_{i_j}}{1 - z'_{i_j} + O\left(\frac{d \log n}{D} z'_{i_j}\right)}$$

$$\geq 1 - O\left(\frac{d \log n}{D}\right). \quad (23)$$

Using Equation 21 and Equation 23, the Equation 18 reduces to the following.

$$\frac{\Pr[f(s')]}{\Pr[s']} \geq \prod_{i_j=1}^k \left(1 - O\left(\frac{d \log n}{D}\right)\right) \quad (24)$$

$$\geq 1 - O\left(\frac{kd \log n}{D}\right). \quad (25)$$

□

Theorem 3. $\Pr[S_o] \geq 1 - O\left(\frac{kd \log n}{D} + \frac{1}{n}\right)$.

Proof. Using Lemma 2 and Lemma 3. □

Corollary 4. For $k = 1$, we obtain a $2/3$ approximation, i.e., $\Pr[S_o] \geq 2/3$ since $D > 3d \log n$.

5 Sliding Window Approach

In a practical setting, the predictions about future occurrences are made continuously as the streaming sets continue to arrive. Alternatively, the predictions are updated at regular intervals of time using the sets arriving within a sliding time window of size W . The algorithm described above would require a re-computation of the frequency counts of the elements

as the window is updated. To reduce the computational cost of this update, we employ a data structure proposed by Datar et al. (2002) that maintains count statistics for a stream using buckets of different sizes. Using the binary representation for the presence of an element in a streaming set, we use this data structure to calculate the approximate number of 1’s in a given window. For each of these buckets, the time-stamp of the most recent 1 and the total count of 1’s appearing in that bucket are maintained. As a new binary element arrives the following steps are taken.

- The time stamp of each bucket is increased by one.
- If the time stamp of a bucket exceeds the window size, the bucket is dropped.
- If the arriving element is 0, we proceed to the next element.
- If the arriving element is 1, then we create a new bucket with size 1 (this operation is referred to as `add_bucket` operation).
- if there exists $m/2 + 2$ buckets of same size, the oldest two buckets are merged. Here m is a pre-defined integer that is inversely proportional to the maximum permissible relative error ϵ , i.e., $m = \lceil 1/\epsilon \rceil$.

In this data structure, the total number of elements in each bucket is equal to the number of 1’s in the window (referred to as `window_score`). Datar et al. (2002) show that this data structure gives an estimate of the number of 1’s in the window of size W with a relative error of at most ϵ using at most $(\frac{m}{2} + 1) (\log(\frac{2W}{m} + 1) + 1)$ buckets. $\log W + \log \log W$ bits are used per bucket and each new element is processed in $O(\log W)$ worst case time. At each instant, this data structure provides a count estimate in $O(1)$ time.

Algorithm 2 use `add_bucket` and `window_score` to present the sliding window adaptation of Algorithm 1. In our problem formulation, sets $\{S^1, S^2, \dots, S^W\}$ arrive in the window W . Let there be x elements in the union of these sets, then the input stream for the above data structure would be a permutation of x 1’s and $(n - x)$ 0’s. For this stream, we create n buckets at the beginning of the stream and update them as above when a new element arrives.

6 Experiments

The above analysis ensures a high probability of successful predictions from our algorithm. To understand

its effectiveness in practical settings, we performed experiments on two real-world collections of streaming data: query logs from a commercial search engine and hash-tags appearing in tweets.

A naïve approach based on selecting the most frequent elements could be considered as a baseline approach. However, such comparisons would be unfair to the baseline approaches because they would not be directly optimizing the criterion our problem setup mandates. More importantly, such comparisons would risk the clarity in the distinction of the proposed problem formulation and the traditional setup for statistical trend prediction. That said, the results for a naïve approach were indeed empirically inferior to ours.

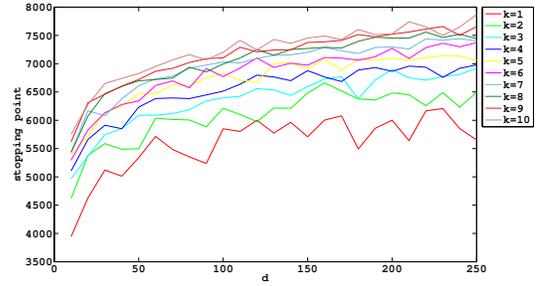

6.1 Search queries

We considered a data set comprising of one month of anonymized search logs that is made public under the Yahoo Webscope program¹. We only consider the anonymized query identifiers in our experiments, ignoring other information – i.e., document identifiers, relevance judgments, etc. – present in this data set. We randomly sample 100K queries and use their respective timestamp to simulate the arrival of these queries as a stream. Each of these queries corresponds to a singleton, streaming set in our formulation. Figure 3 shows the frequency distribution of the resulting 603 unique queries in this data set. We select all of these unique queries to construct the set S_n (i.e.,

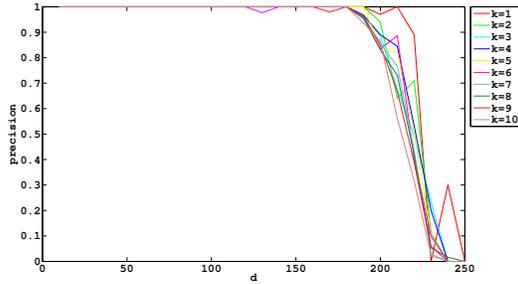

¹The L18 data set available from <http://webscope.sandbox.yahoo.com>

(b) Number of streaming subsets observed before making a prediction

(c) Precision

(d) Recall

Figure 2: *Results on search queries.* Each of the four plots show different evaluation metrics for different values of k and d and $D = 200$. These metrics are averaged over 200 iterations of our algorithm on random sub-streams of the original data stream. (Best seen in color).

$n = 603$). There are 140 queries that appear at least 200 times in the entire stream, therefore the assumption required for the constrained-min- d -occur problem clearly holds for $D = 200$ and $k \leq 10$. We ran our algorithm for different values of d and report our observations in Figure 2. Even though we do not have a valid lower-bound on the prediction accuracy for $d > D$, we examine if the algorithm is still able to make predict queries with larger number of future occurrences.

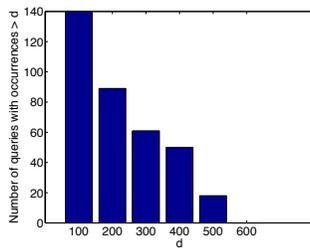

Figure 3: *Frequency distribution of search queries.*

The precision and recall metrics shown in these plots are computed by comparing the set of predicted queries against the queries that actually occur d times in the stream remaining after the prediction is made. For $d = 150$, the predicted queries were 100% accu-

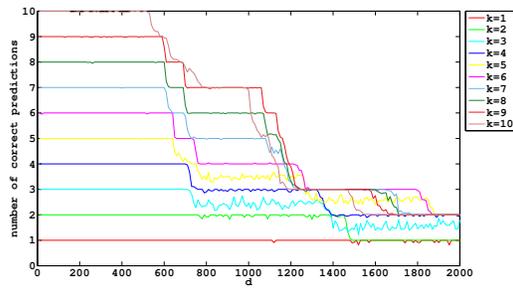

rate for $k \leq 10$. On average, the algorithm was able to make predictions for $k = 10$ after observing about 7500 queries. In the remaining stream, about 60 unique queries appeared more that 150 times. Therefore, the recall of our algorithm is around 0.16.

As we increase d , the probability of observing heads in a coin-toss decreases (see Section 4), making the algorithm take longer to make the predictions. Outside the provably correct range $d < \frac{D}{3 \log n}$, the precision is also observed to be adversely affected in a similar manner. For larger values of k , the algorithm takes more time to make predictions, and the performance degrades outside the provably correct range. In the provably correct range, the recall values for $k = 2$ is nearly twice the value for $k = 1$, because the number of predictions made are twice in the former case and all of the predictions are accurate; the minor deviation is attributed to the difference in the stopping point in the two experiments.

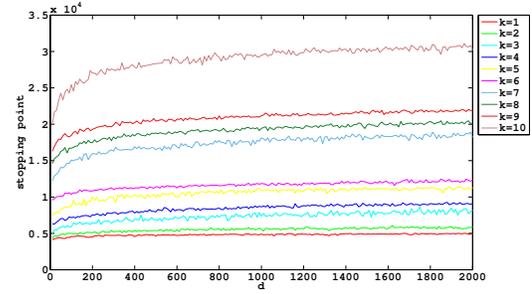

6.2 Twitter hash tags

We used the Twitter’s public REST API² to obtain 150K tweets from the month of November 2013. We

(b) $D=400$

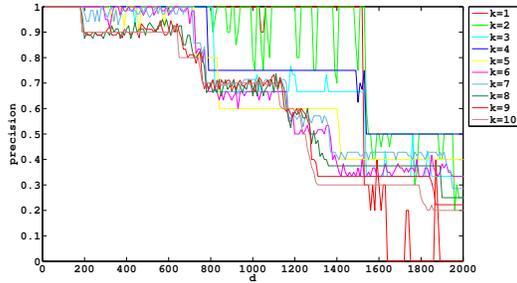

Figure 6: *Comparison of precision curves for different choices of D on Twitter hash-tags.*

consider all of the hash-tags appearing in each of these tweets to compose the respective streaming set. We selected the 1K most frequent hash-tags in this collection to construct S_n . Figure 4 shows the frequency distribution of the unique hash-tags in this data set. Considering the skew in this distribution, we selected a larger value of $D = 200$ for this data set.

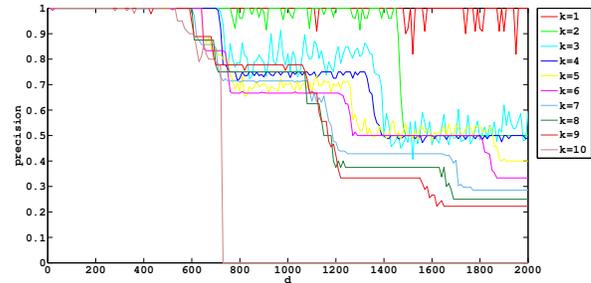

The overall observations for this data sets are similar to those for the previous data set. However, the drop in performance is gradual over a bigger range of values of d . For $k = 1$, the algorithm continued to make almost

accurate predictions till $d = 10 * D = 2000$. For $k = 10$, around 70% precision was observed while predicting 1000 future occurrences. The algorithm only observed 30K tweets to make these predictions. Assuming an estimated arrival rate of 150K tweets per minute, our algorithm can start predicting these ten tags with 70% accuracy in less than a minute.

The parameter D has a trade-off associated with it. On one hand, a larger value of D reduces the time taken to make a prediction and increases the provably useful range of values of d . On the other hand,

(a) $D=100$

(b) $D=200$

Figure 7: Results for the sliding-window approach on Twitter hash-tags. The window size is set of $20K$. The average number of correct predictions(Accuracy) made for $D = 100$ and 200 for different values of k and d .

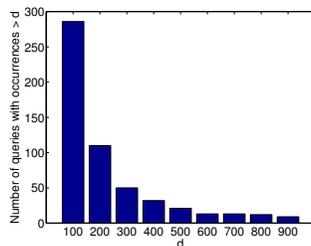

Figure 4: Frequency distribution of unique hash-tags

we may have to increase the size of the stream to ensure that the related assumption for constrained- \min - d -occur holds. Figure 6 shows a comparison of the observed precision values for two different choices of $D = \{200, 400\}$. In both of these plots for most values of k , the precision is close to 1 for almost identical range of d , but the precision drops faster for smaller value of D . Also, the graphs for $D = 400$ are noisy, which suggests a large variance to be associated with their precision estimates. For this reason, we postulate that useful conclusions could not be derived for $D > 400$ in this data set.

6.3 Sliding window

Figure 7 shows the precision curves obtained using the sliding window adaptation of our algorithm (described in Section 5) with window size $W = 20K$. For $D = 200$, the graphs validate two hypothesis about the correctness of our window-based algorithm. First, for $k = 10$, the stopping point (see Figure 5) is greater than the window size. Therefore, the window-based algorithm should fail to make predictions for most values of d . Second, the stopping points for $k < 10$ are less than the window size for almost all of the values of d . Hence, the window-based algorithm should obtain similar performance as the original algorithm without the window. Similar observations were made when a

window size $W = 10K$ was considered. Similar observations were made for $D = 100$. The relative difference between the performances for $D = 100$ and $D = 200$ can be explained similar to the discussion for Figure 6. These observations confirm that sliding window adaptation of the original algorithm well approximates the desired solution. This approximate algorithm is better suited for a practical setting where predictions need to be made at regular intervals of time.

7 Discussion

We presented a new problem formulation, *constrained min-d-occur*, for studying algorithms that guarantee a minimum number of future occurrences in streaming data. For this formulation, we presented a randomized algorithm and derive a lower-bound on the probability of successful predictions obtained from this algorithm. To our knowledge, any prior theoretical results for this problem does not exist. The theoretical result is further validated using experiments on two real-world data sets: search query logs and hash-tags in tweets. In both of these data sets, the proposed algorithm achieved high precision and recall values for predictions. We studied the performance of this algorithm for different choices of parameters. We also presented a sliding-window based adaptation of our algorithm to accommodate a practical setting where the predictions need to be updated only at regular intervals of time. Interestingly, these algorithms were found to be effective for larger values of d for which a useful lower-bound is not computed. Studying the tightness of our current lower-bound would be a useful extension of this work.

Instance Label Prediction by Dirichlet Process Multiple Instance Learning

Abstract

We propose a generative Bayesian model that predicts instance labels from weak (bag-level) supervision. We solve this problem by simultaneously modeling class distributions by Gaussian mixture models and inferring the class labels of positive bag instances that satisfy the multiple instance constraints. We employ Dirichlet process priors on mixture weights to automate model selection, and efficiently infer model parameters and positive bag instances by a constrained variational Bayes procedure. Our method improves on the state-of-the-art of instance classification from weak supervision on 20 benchmark text categorization data sets and one histopathology cancer diagnosis data set.

1 INTRODUCTION

Automated data acquisition has reached unprecedented scales. However, annotation of ground-truth labels is still manual in many applications, lagging behind the massive increase in observed data. This fact makes learning from partially labeled data emerge as a key problem in machine learning. Multiple instance learning (MIL) tackles this problem by learning from labels available only for instance groups, called *bags* [7]. A negatively labeled bag indicates that all instances have negative labels. In a positively labeled bag, there is at least one positively labeled instance; however, which of the instances are positive is not specified. We refer to these bag labeling rules as *multiple instance constraints*. A positive bag instance with a positive label is called a *witness*, and one with a negative label a *non-witness*.

The classical MIL setup involves both bag-level training and bag-level prediction. The mainstream MIL algorithms are developed and evaluated under this classical setup. The harder problem of *instance-level* prediction from *bag-level*

training has been addressed in a comparatively smaller volume of studies [16, 17, 32]. A group of existing models, such as Key Instance SVM (KI-SVM) [16] and CkNN-ROI [32] aim to identify a single positive instance from each positive bag, the so called *key instance*, that determines the bag label, and discard the other instances. In a recent work, Liu et al. [17] generalize this approach by a voting framework (VF) that learns an arbitrary number of key instances from each positive bag. While KI-SVM extends the MI-SVM formulation [2] with binary variables indicating key instances, CkNN-ROI and VF are built on the Citation k-NN method [26].

1.1 Contribution

Our central assumption is that all instances belonging to the same Gaussian / cluster share the same class label. By performing simultaneous assignment of instances to one class or the other and clustering instances within each class, our method effectively captures non-witnesses within the positive bags from their clustering relationships to other instances. Figure 1 illustrates this idea.

We discover the latent positive bag instance labels by non-parametrically modeling the distributions of both classes, while simultaneously assigning the positive bag instances to the most appropriate class. To capture almost arbitrarily complex data distributions, we model the class distributions as mixture of a potentially very large (determined by data and the Dirichlet process prior) number of Gaussians with full covariance. The Dirichlet process prior on the mixture weights addresses the model selection problem, which is in our context the question of how many clusters to use.

We infer the class distribution parameters and positive bag instance labels by an efficient constrained variational inference procedure. For a fixed configuration of positive bag instance labels, we update class distribution parameters as in variational inference of standard Dirichlet process mixtures of Gaussians. Then keeping class distribution parameters fixed, we assign each positive bag instance to the class that maximizes the total variational lower bound of

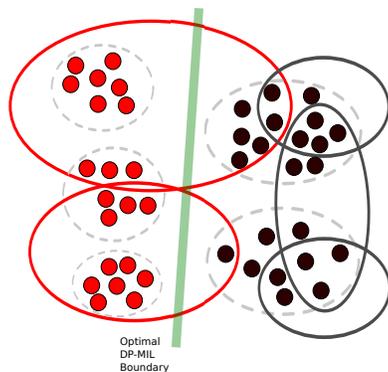

Figure 1: Dots, solid ellipses, and dashed ellipses indicate instances, bags, and clusters in a two dimensional feature space, respectively. Positive class is shown as red and negative class as black. DPMIL infers the label of a positive bag instance based on the class of the cluster that explains it best.

class distributions. This way, an increase in lower bound is guaranteed for all coordinate ascent updates, providing fast convergence.

We evaluate our method on 20 benchmark text categorization data sets, and on a novel application: finding Barrett’s cancer tumors in histopathology tissue images from bag labels. Our method improves the state-of-the-art in both of these applications in terms of instance-level prediction performance. Furthermore, differently from many existing MIL methods, the inferred data modes and cluster weights of our method enable enhanced interpretability. The source code of our method is publicly available ¹.

2 PRIOR ART

There exist several strategies for learning from weak supervision. One is *semi-supervised learning*, which suggests using large volumes of unlabeled data along with the limited labeled data to improve supervised learning performance [6]. *Active learning* is an alternative strategy that proposes learning from the smallest possible set of training samples selected by the model itself [24]. Another strategy is *self-taught learning* where abundant unlabeled data are available from a different but related task than the actual learning problem to be solved [20].

Multiple instance learning also aims to solve the weakly supervised learning problem by allowing supervision only for *groups of instances*. This learning setup has been first introduced by Dietterich et al. [7]. The authors propose detecting witnesses from the assumption that they lie in a

¹<http://hci.iwr.uni-heidelberg.de/Staff/mkandemi/>

single axis parallel rectangle (APR) in the feature space.

MIL methods are built upon different heuristics. A group of methods iteratively choose one instance from each bag as a representative, and infer model parameters from this selected instance set. Based on the new model parameters, a new representative set is selected in the next iteration. Seminal examples of this approach are EMDD [30] and MI-SVM [2]. While the former learns a Gaussian density kernel on the representative instances, the latter trains a support vector machine (SVM) on them.

Another group of MIL methods calculate similarities between bag pairs by bag-level kernels, and train standard kernel learners, such as SVM, based on these bag similarities. MI Kernel [10] and mi-Graph [31] are seminal examples of this approach. The common property of these models is that they assume non-i.i.d. relationships between instances belonging to the same bag. There have been recent attempts to exploit within-bag correlations in more elaborate ways, such as Ellipsoidal MIL [15] and MIMN [11]. The former method represents each bag as an ellipsoid and learns a max-margin classifier that obeys the multiple instance constraints. The latter models the within-bag relationships by a Markov Random Field whose unary potentials are determined by the output of a linear instance-level classifier and clique (bag) potentials are calculated from the unary potentials subject to the multiple instance constraints. These methods are typically both effective and efficient. However, they are not applicable to instance level prediction due to the central non-i.i.d bag instances assumption.

MIL as semi-supervised learning. MIL can be formulated as a semi-supervised learning problem by assigning latent variables to positive bag instances and inferring them subject to the multiple instance constraints [8]. mi-SVM [2] applies this principle to the SVM formulation. GPMIL [14] and Bayesian Multiple Instance RVM [21] apply it to the Gaussian process classifier and the relevance vector machine, respectively, by adapting the likelihood function to MIL.

Generative MIL models. The semi-supervised learning approach has also been adopted by some generative methods that model the class distributions and infer the label of each positive bag instance based on which of these two distributions explain that instance with higher likelihood [1, 8]. Foulds et al. [8] model each class distribution by a Gaussian density with isotropic or diagonal covariance, and learn the latent positive bag instances without employing the multiple instance constraints on the training data. Adel et al. [1], on the other hand, provide a generic framework that enforces the multiple instance constraint in the hard assignment of instances to classes. They model class distributions by a Gaussian density and Gaussian copula. We fol-

low this line of research, and extend the existing work by i) using a richer family of distributions (potentially infinite mixtures of Gaussians with full covariance), while ii) keeping the multiple instance constraints and also providing an efficient variational inference procedure, and iii) making instance rather than bag level predictions.

Applications. Recent applications of MIL include diabetic retinopathy screening [19], visual saliency estimation [27] as well as content-based object detection and tracking [23]. MIL is also useful in drug activity prediction where each molecule constitutes a bag, each configuration of a molecule an instance, and binding of any of these configurations to the desired target is treated as a positive label, as first introduced by Dietterich et al. [7]. More recent applications of MIL to this problem include finding the interaction of proteins with Calmodulin molecules [18], and finding bioactive conformers [9]. Xu et al. [28, 29] apply MIL to tissue core (bag) level diagnosis of prostate cancer from histopathology images, where they combine multi-instance boosting [25] and clustering. There does not exist any prior work that focuses on locating tumors from tissue core level supervision, which we do in this paper as a case study.

Instance-level MIL prediction. There exist few studies focusing on instance prediction within the MIL setting. The first principled attempt towards this direction has been made by Zhou et al. [32]. The authors introduce a variant of Citation k-NN, called CkNN-ROI. This method chooses one instance from each positive bag as the *key instance* that determines the bag label based on how well it predicts the training bag labels by nearest neighbor matching, and ignores the other instances. Li et al. [16] detect key instances by a large margin method called KI-SVM. This method extends MI-SVM by binary latent variables assigned to each positive bag instance, which identify strictly one key instance per positive bag, and filter other instances out. The authors propose two variants of their method: i) Bag KI-SVM that has one slack variable per negative bag, and ii) Instance KI-SVM that has one slack variable per negative bag *instance*. Liu et al. [17] later propose detecting multiple key instances per positive bag by another variant of Citation kNN that learns a voting function from training bags. These models are shown to be effective in region-of-interest detection in natural scene images and text categorization. In this paper, we target the same learning problem, and empirically show that rich modeling of class distributions leads to better prediction performance.

3 THE MODEL

Let \mathbf{X} be a data set consisting of B bags $\mathbf{X} = [\mathbf{X}_1, \dots, \mathbf{X}_B]$ indexed by b , and $\mathbf{y} = [y_1, \dots, y_B]$ be the vector of the corresponding binary bag labels $y_b \in$

$\{-1, +1\}$. Each bag $\mathbf{X}_b = [\mathbf{x}_{b1}, \dots, \mathbf{x}_{bN_b}]$ consists of N_b instances. We assume that each instance is associated with a binary latent variable $r_{bn} \in \{-1, +1\}$ representing the label of the instance. We further assume that the positive instances in the data set ($r_{bn} = +1$) come from distribution $p(\mathbf{x}_{bn}|\boldsymbol{\theta}_{+1})$, and the negative instances ($r_{bn} = -1$) come from distribution $p(\mathbf{x}_{bn}|\boldsymbol{\theta}_{-1})$, parameterized by $\boldsymbol{\theta}_{+1}$ and $\boldsymbol{\theta}_{-1}$, respectively. Both of these two distributions are Gaussian mixture models with full covariance and with Dirichlet process priors on mixture weights. The generative process of our model is

$$\begin{aligned}
 p(\mathbf{v}_l) &= \prod_{k=1}^K \text{Beta}(v_{lk}|1, \alpha), & \forall l \\
 p(z_{lbn}|\mathbf{v}_l) &= \text{Mult}(z_{lbn}|\pi_{l1}, \dots, \pi_{lK}), & \forall l, b, n \\
 p(\boldsymbol{\Lambda}_{lk}) &= \mathcal{W}(\boldsymbol{\Lambda}_{lk}|\mathbf{W}_0, \nu_0), & \forall l, k \\
 p(\boldsymbol{\mu}_{lk}|\boldsymbol{\Lambda}_{lk}) &= \mathcal{N}(\boldsymbol{\mu}_{lk}|\mathbf{m}_0, (\beta_0\boldsymbol{\Lambda}_{lk})^{-1}), & \forall l, k, \\
 p(\mathbf{x}_{bn}|\boldsymbol{\mu}, \boldsymbol{\Lambda}, z_{lbn}, r_{bn}) &= \\
 \prod_{l \in \{-1, +1\}} \prod_{k=1}^K \mathcal{N}(\mathbf{x}_{bn}|\boldsymbol{\mu}_{lk}, \boldsymbol{\Lambda}_{lk}^{-1})^{\mathbf{1}(z_{lbn}=k) \cdot \mathbf{1}(r_{bn}=l)}, & \forall b, n, \\
 p(y_b = +1|\mathbf{r}) &= 1 - \prod_{n=1}^{N_b} (1 - \mathbf{1}(r_{bn} = +1)), & \forall b
 \end{aligned}$$

where the hyperparameters of the model are $\{\nu_0, \mathbf{W}_0, \mathbf{m}_0, \beta_0, \alpha\}$. The function $\mathbf{1}(\cdot)$ is the indicator function which returns 1 if its argument is true, and 0 otherwise. $\text{Mult}(\cdot|\cdot \dots \cdot)$, $\text{Beta}(\cdot|\cdot, \cdot)$, $\mathcal{N}(\cdot|\cdot, \cdot)$ and $\mathcal{W}(\cdot|\cdot, \cdot)$ denote the multinomial mass function, and Beta, Gaussian and Wishart distribution densities, respectively. K is the number of clusters, and k is the related index; $l \in \{-1, +1\}$ indexes the two class densities; $\pi_{lk} = v_{lk} \prod_{j=1}^{k-1} (1 - v_{lj})$ is the stick breaking prior over cluster assignments z_{lbn} . The vector \mathbf{Z}_l contains cluster-assignment weights z_{lbn} . The sets $\boldsymbol{\mu} = \{\boldsymbol{\mu}_{-11}, \dots, \boldsymbol{\mu}_{-1K}, \boldsymbol{\mu}_{+11}, \dots, \boldsymbol{\mu}_{+1K}\}$ and $\boldsymbol{\Lambda} = \{\boldsymbol{\Lambda}_{-11}, \dots, \boldsymbol{\Lambda}_{-1K}, \boldsymbol{\Lambda}_{+11}, \dots, \boldsymbol{\Lambda}_{+1K}\}$ contain the mean and inverse covariance of all clusters in the model, respectively. The vector \mathbf{r} has class-assignment variables for all instances in its entries, and $\mathbf{r}_{-r_{bn}}$ has the same for all instances except r_{bn} . The set \mathbf{r}_b has the class-assignment variables of bag b . If $y_b = -1$ is observed, it is also observed that $r_{bn} = -1$ for all instances of bag b . If $y_b = +1$ is observed, r_{bn} for bag instances of b are latent, hence are inferred from data. We refer to this model as *Dirichlet process multiple instance learning (DPMIL)*. Figure 2 illustrates the model in plate notation.

3.1 Inference

Following the probabilistic paradigm, for inference of the model above, we aim to maximize the marginal likelihood $p(\mathbf{X}, \mathbf{y}|\mathbf{z})$ with respect to the class assignments \mathbf{z} subject

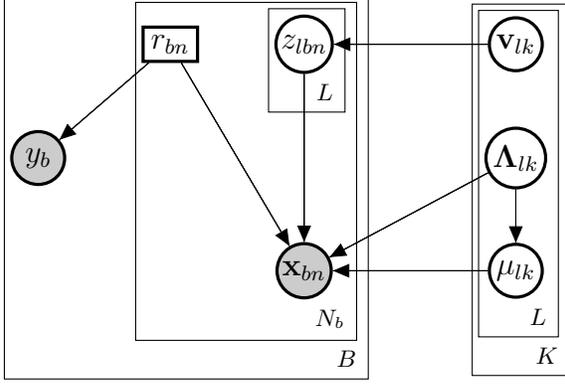

Figure 2: The generative process of DPMIL in plate notation. Shaded nodes denote observed, and unshaded nodes denote latent variables that are inferred by constrained variational Bayes. Note that r_{bn} is a discrete binary latent variable without a prior. Hence it is denoted by a rectangle.

to the multiple instance constraints

$$\begin{aligned} & \underset{\mathbf{r}}{\text{maximize}} && p(\mathbf{X}, \mathbf{y}|\mathbf{r}) \\ & \text{s.t.} && \max(\mathbf{r}_b) = y_b, \quad \forall b. \end{aligned} \quad (1)$$

Let \mathbf{r}_* be a solution to the optimization problem (1), we can define the divergence from the optimal configuration \mathbf{r}_* as

$$D(\mathbf{r}) = \log p(\mathbf{X}, \mathbf{y}|\mathbf{r}_*) - \log p(\mathbf{X}, \mathbf{y}|\mathbf{r}).$$

It is easy to see that $D(\mathbf{r}) \geq 0$ for any \mathbf{r} and $D(\mathbf{r}) = 0$ if $\mathbf{r} = \mathbf{r}_*$.

For a given configuration \mathbf{r} , calculating $p(\mathbf{X}, \mathbf{y}|\mathbf{r})$ is intractable. Hence, we approximate the posterior p a factorized distribution q

$$\begin{aligned} & p(\mathbf{Z}, \boldsymbol{\mu}, \boldsymbol{\Lambda}, \mathbf{v}_{-1}, \mathbf{v}_{+1}|\mathbf{X}, \mathbf{r}) \\ &= \left(\prod_{l \in \{-1, +1\}} \prod_{b=1}^B \prod_{n=1}^{N_b} q(z_{lbn}|\mathbf{r}) \right) \\ & \times \left(\prod_{l \in \{-1, +1\}} \prod_{k=1}^K q(\boldsymbol{\mu}_{lk}, \boldsymbol{\Lambda}_{lk}|\mathbf{r}) q(\mathbf{v}_{lk}|\mathbf{r}) \right). \end{aligned}$$

Let $\boldsymbol{\theta} = \boldsymbol{\theta}_{-1} \cup \boldsymbol{\theta}_{+1}$ denote the set of all parameters and latent variables of both class distributions. Following the standard variational Bayes formulation we can decompose $p(\mathbf{X}, \mathbf{y}|\mathbf{r})$ as

$$\log p(\mathbf{X}, \mathbf{y}|\mathbf{r}) = \mathcal{L}(\boldsymbol{\theta}|\mathbf{r}) + KL(q||p)$$

where

$$\mathcal{L}(\boldsymbol{\theta}|\mathbf{r}) = \mathbb{E}_q[\log p(\mathbf{X}, \mathbf{y}, \boldsymbol{\theta}|\mathbf{r})] - \mathbb{E}_q[\log q(\boldsymbol{\theta}|\mathbf{r})]$$

is the variational lower bound and $KL(\cdot||\cdot)$ is the Kullback-Leibler divergence between the true posterior p and the approximate posterior q . Similarly to above, $KL(q||p) \geq 0$

for all q and $KL(q||p) = 0$ if and only if $q = p$. Combining these two facts, we have

$$\log p(\mathbf{X}, \mathbf{y}|\mathbf{r}_*) = \mathcal{L}(\boldsymbol{\theta}|\mathbf{r}) + \underbrace{KL(q||p) + D(\mathbf{r})}_{E(q, \mathbf{r})}$$

where the divergence term $E(q, \mathbf{r})$ approaches 0 as q and \mathbf{r} approach optimal values. Hence, we can perform inference by

$$\begin{aligned} & \underset{\mathbf{r}, \boldsymbol{\theta}}{\text{maximize}} && \mathcal{L}(\boldsymbol{\theta}|\mathbf{r}) \\ & \text{s.t.} && \max(\mathbf{r}_b) = y_b, \quad \forall b. \end{aligned}$$

which has the same global optimum as the optimization problem (1). This problem can be solved by coordinate ascent. Keeping \mathbf{r} fixed, model parameters $\boldsymbol{\theta}$ can be updated as in standard variational Bayes. Let $\boldsymbol{\psi}_j \subset \boldsymbol{\theta}$ be a subset of model parameters corresponding to a factor of q , the best possible update for this factor can be calculated by

$$\frac{\partial \mathcal{L}}{\partial q(\boldsymbol{\psi}_j)} = \mathbb{E}_{q(\boldsymbol{\theta}_{-\boldsymbol{\psi}_j})}[\log p(\mathbf{X}, \mathbf{y}, \boldsymbol{\theta}|\mathbf{r})] - \log q(\boldsymbol{\psi}_j) - 1 = 0.$$

Hence, the update rule becomes

$$q(\boldsymbol{\psi}_j) = \exp \left\{ \mathbb{E}_{q(\boldsymbol{\theta}_{-\boldsymbol{\psi}_j})}[\log p(\mathbf{X}, \mathbf{y}, \boldsymbol{\theta}|\mathbf{r})] \right\}. \quad (2)$$

Consequently, keeping $\boldsymbol{\theta}$ fixed, \mathbf{r} can be updated by

$$r_{bn}^{(t+1)} = \underset{l \in \{-1, +1\}}{\text{argmax}} \mathcal{L}(\boldsymbol{\theta}|\mathbf{r}_{-bn}^{(t)}, r_{bn} = l). \quad (3)$$

The cases that violate the multiple instance constraint $\max(\mathbf{r}_b^{(t+1)}) = y_b$ can be resolved by flipping one of the instances of bag b that had a positive label at iteration (t) back to positive. The fact that Equations (2) and (3) both increase \mathcal{L} and that $E(q, \mathbf{r}) \geq 0$ bring out fast convergence to a local maximum in practice, as experimented in Section 4.3. The overall inference procedure is given in Algorithm 1, and the detailed update equations are available in Appendix 1.

3.2 Prediction

For a new bag $\mathbf{X}_b^* = [\mathbf{x}_{b1}^*, \dots, \mathbf{x}_{bN_b}^*]$, instance-level prediction can be done by

$$\hat{r}_{bn} \leftarrow \underset{l \in \{-1, +1\}}{\text{argmax}} p(\mathbf{x}_{bn}^*|\mathbf{X}, \mathbf{y}, \mathbf{r}, y_{bn}^* = l),$$

where

$$p(\mathbf{x}_{bn}^*|\mathbf{X}, \mathbf{y}, \mathbf{r}, y_{bn}^* = l) = \int q(\boldsymbol{\theta}_l|\mathbf{X}, \mathbf{y}, \mathbf{r}) p(\mathbf{x}_{bn}^*|\boldsymbol{\theta}_l) d\boldsymbol{\theta}_l,$$

which corresponds to the standard predictive density for DP Gaussian mixtures as given in [4]. The extended formula of the predictive density for fixed \mathbf{r} is given in Appendix 1.

Algorithm 1 Constrained variational inference for DPMIL

Input: Data $\mathbf{X} = [\mathbf{X}_1, \dots, \mathbf{X}_B]$,
Bag labels $\mathbf{y} = \{y_1, \dots, y_b\}$

repeat
 $\backslash\backslash$ Initialize instance class labels
 $r_{bn} = y_b, \quad \forall b, n$
 $\backslash\backslash$ Update the class distributions given the current \mathbf{r}
 for $\psi_j \in \boldsymbol{\theta}$ **do**
 $q(\psi_j | \mathbf{r}) \leftarrow \exp \left\{ \left(\mathbb{E}_{q(\boldsymbol{\theta}_{-\psi_j})} [\log p(\mathbf{X}, \mathbf{y}, \boldsymbol{\theta} | \mathbf{r})] \right) \right\}$
 end for
 $\backslash\backslash$ Update \mathbf{r} given the class distributions
 for $b \in \{j | y_j = +1\}$ **do**
 for $n = 1$ **to** N_B **do**
 $r_{bn}^{(t+1)} \leftarrow \operatorname{argmax}_{l \in \{-1, +1\}} \mathcal{L}(\boldsymbol{\theta} | \mathbf{r}_{-r_{bn}}^{(t)}, r_{bn} = l)$
 end for
 $\backslash\backslash$ Resolve constraint violation
 if $\max(\mathbf{r}_b) = -1$ **then**
 $r_{bj}^{(t+1)} \leftarrow +1$, for any $j \in \{r_{bj}^{(t)} = +1\}$
 end if
 end for
until *convergence*

3.3 Relationship to existing models

DPMIL has the following connections to some of the existing methods:

- **mi-SVM** [2]: DPMIL and mi-SVM can be viewed as generative-discriminative pairs [12]. The two models find similar labels for positive bag instances when classes are separable. DPMIL additionally finds the clusters of both positive and negative instances.
- **EMDD** [30]: EMDD learns a class-conditional distribution $p(y_b = +1 | \mathbf{X}_b)$ in a *discriminative* manner by applying a *single* Gaussian kernel on the most representative *subset* of training instances. DPMIL explains the *generative* process of *all* training instances by *multiple* Gaussian densities.
- **QDA**: Our method extends Quadratic Discriminant Analysis (QDA) in three aspects: i) DPMIL fits multiple Gaussians on each class distribution, while QDA fits only one. ii) DPMIL employs priors over mean and covariance, while QDA performs maximum likelihood estimation, following the frequentist paradigm. iii) DPMIL explains bag labels keeping the multiple instance constraints, while QDA performs single-instance learning.
- **MIMM** [8]: This model is a special case of DPMIL. In particular, when $K = 1$, uninformative priors are used for mixture coefficients \mathbf{Z} and multiple instance constraints are ignored, DPMIL reduces to MIMM.

Quadratic Discriminant Analysis (QDA) is the single-instance version of MIMM.

4 RESULTS

We evaluate the instance prediction performance of our method on two applications: i) web page categorization, and ii) Barrett’s cancer diagnosis. For both experiments, we set cluster count K to 20 (per class), ν_0 to $D + 1$, where D is the dimensionality of the data, \mathbf{W}_0 to the inverse empirical covariance of the data, \mathbf{m}_0 to the empirical mean of the data, β_0 to 1, and the concentration parameter α to 2, which is chosen as the smallest integer larger than the uninformative case ($\alpha = 1$). This value is not manually tuned. Other choices of α are observed not to affect the outcome significantly. We set maximum iteration count to 100.

We compare DPMIL to three MIL and two key instance detection algorithms: mi-SVM [2], MI-SVM [2], GPMIL [14], Bag KI-SVM [16], and Instance KI-SVM [16]. Models such as mi-Graph [31], iAPR [7], EMDD [30], Citation k-NN [26], MILBoost [25], and MIMM [8] are observed to perform worse than the list above, hence are not reported in detail. For all kernelizable models, the radial basis function (RBF) kernel is used. Hyperparameters of the competing models are learned by cross-validation.

4.1 20 text categorization data sets

As a benchmarking study, we evaluate DPMIL on the public *20 Newsgroups* database that consists of 20 text categorization data sets. Each data set consists of 50 positive and 50 negative bags. Positive bags have on average 3 % of their instances from the target category, and the rest from other categories. Each instance in a bag is the top 200 TF-IDF representation of a post. We reduce the dimensionality to 100 by Kernel Principal Component Analysis (KPCA) with an RBF kernel with a length scale of $\sqrt{100}$, following the heuristic of Chang et al [5]. We evaluate the generalization performance using 10-fold cross validation with the standard data splits. We use Area Under Precision-Recall Curve (AUC-PR) as the performance measure due to its insensitivity to class imbalance. Table 1 lists the performance scores of models in comparison for the 20 data sets. We report average AUC-PR of two comparatively recent methods, VF and VF_r, on the same database from [17] Table 5², for which public source code is not available. Our method gives the highest instance prediction performance in 18 of the 20 data sets, and its average performance throughout the database is 3 percentage points higher than the state-of-the-art VF method.

Table 1: Area Under Precision-Recall Curve (AUC-PR) scores of methods on the *20 Newsgroups* database for instance prediction. DPMIL outperforms the other MIL models in 18 out of 20 data sets. B-KI-SVM and I-KI-SVM stand for Bag KI-SVM and Instance KI-SVM, respectively.

4.2 Barrett’s cancer diagnosis

Biopsy imaging is a widely used cancer diagnosis technique in clinical pathology [22]. A sample is taken from the suspicious tissue, stained with hematoxylin & eosin, which dyes nuclei, stroma, lumen, and cytoplasm to different colours. Afterwards, the tissue is photographed under a microscope, and a pathologist examines the resultant image for diagnosis. In many cases, diagnosis of one patient requires careful scanning of several tissue slides of extensive

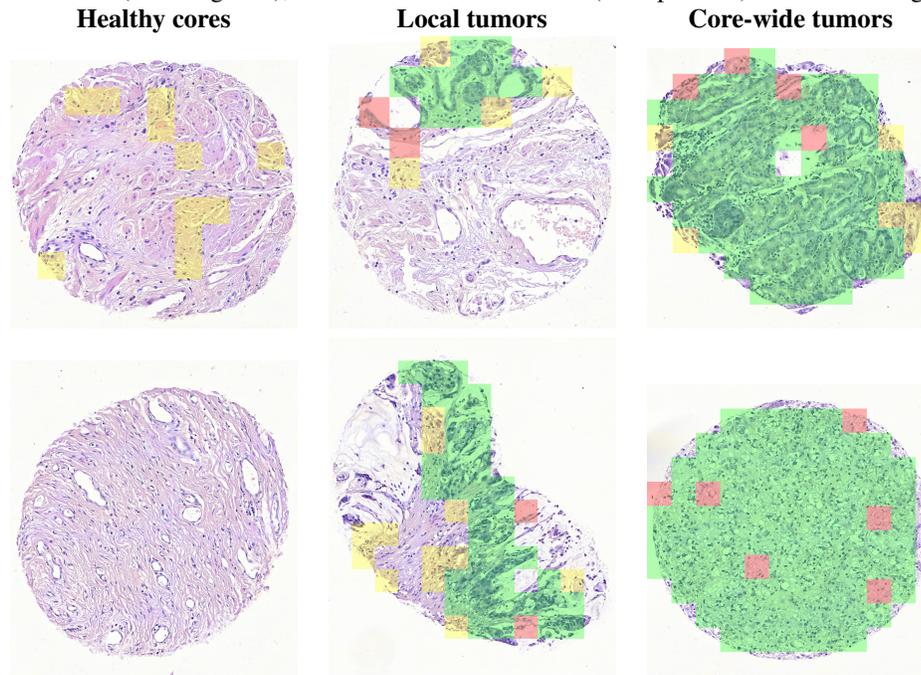

sizes. Considerable time could be saved by an algorithm that finds the tumors and leads the pathologist to tumorous regions.

We evaluate DPMIL in the task of finding Barrett’s cancer tumors in human esophagus tissue images from image-level supervision. Our data consists of 210 tissue core images (143 cancer and 67 healthy) taken from 97 Barrett’s cancer patients. We treat tumor regions drawn by expert pathologists as ground truth. We split each tissue core (with average size of 2179x1970 pixels) into a grid of 200x200 pixel patches. We represent each patch by a 738-dimensional feature vector of SIFT descriptors, local binary patterns with 20×20 -pixel cells, intensity histogram of 26 bins for each of the RGB channels, and the mean of the features described in [13] for cells lying in that patch. The data set includes 14303 instances, 53.4% of which are cancerous. We treat each image as a bag and each patch belonging to that image as an instance. A bag is labeled as positive if it includes tumor, and negative otherwise. Similarly to above, we reduce the data dimensionality to 30 by KPCA with an RBF kernel having a length scale of $\sqrt{30}$. We evaluate generalization performance by 4-fold cross-validation over bags. We repeated this procedure 5 times.

The patch-level diagnosis performance comparison of models is given in Table 2. Prediction performance of DPMIL lies in the middle of the chance level of 53.4% and the upper bound of 83.5% which is reached by patch-level

² Liu et al. [17] report 0.42 AUC-PR for KI-SVM and 0.41 AUC-PR for mi-SVM in Table 5.

Figure 3: Patch prediction results on sample tissue core images. **Green:** correctly detected cancer (true positive), **Red:** Missed detection of cancer (false negative), **Yellow:** False cancer alarm (false positive). **Rest:** True negative.

training of an SVM with RBF kernel. DPMIL clearly outperforms existing models both in prediction accuracy and F1 score (harmonic mean of precision and recall). Figure 3 shows prediction results of DPMIL on six sample tissue cores (bags) with different proportions of tumor. DPMIL produces few false positives for the healthy tissues (left-most column), detects local tumors with reasonable accuracy (middle columns), and produces few false negatives for tissue cores covered entirely by tumor (right-most column).

Figure 4 shows the mixture weights of the clusters for the class distributions averaged over data splits. The *healthy* class is dominated by a single cluster due to the relatively uniform structure of a healthy esophagus tissue. On the other hand, for the *cancer* class, the weights are more evenly distributed among five clusters. This result is consistent with the fact that the data set includes images from various grades of cancer. Each grade of cancer causes a different visual pattern in the tissue, resulting in a multimodal distribution of tumor patches. As shown in Figure 5, clusters capture meaningful visual structures. Patches in the first row correspond to a stage of Barrett’s cancer where cells form circular structures called *glands* which do not exist in a healthy esophagus tissue. The second row illustrates samples of cells with faded color, and in the third row the tissue is covered by an overly high population of poorly differentiated cells.

4.3 Learning rate and computational time

Weak supervision often emerges as a necessity for analyzing big data. Hence, computational efficiency of an MIL model is of key importance for feasibility for real-world scenarios. To this end, we provide an empirical analysis of the learning rate and the training time of DPMIL. As shown in Figure 6, the variational lower bound $\log \mathcal{L}(\theta|\mathbf{r})$ exhibits a sharp increase in the first few iterations, and saturates within 50 iterations.

Figure 6: Evolution of the variational lower bound $\log \mathcal{L}(\theta|\mathbf{r})$ throughout training iterations for the Barrett’s cancer data set. DPMIL exhibits a steep learning curve and converges in less than 50 iterations.

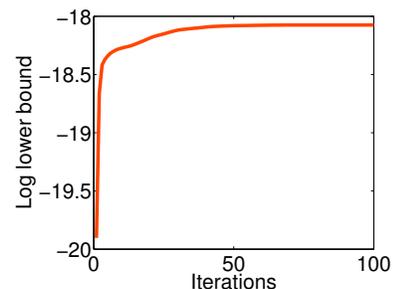

Table 3 shows the average training times of the models in comparison for one data split. Thanks to its Bayesian nonparametric nature, DPMIL does not require a cross-validation stage for model selection, unlike the other mod-

Figure 4: Cluster mixture coefficients for *cancer* ($y_b = +1$) and *healthy* ($y_b = -1$) in the Barrett’s cancer data set. The healthy class distribution is dominated by a single mode unlike the cancer class distribution, supporting that a healthy tissue has a more even look than the cancer class which includes images belonging to various levels of cancer.

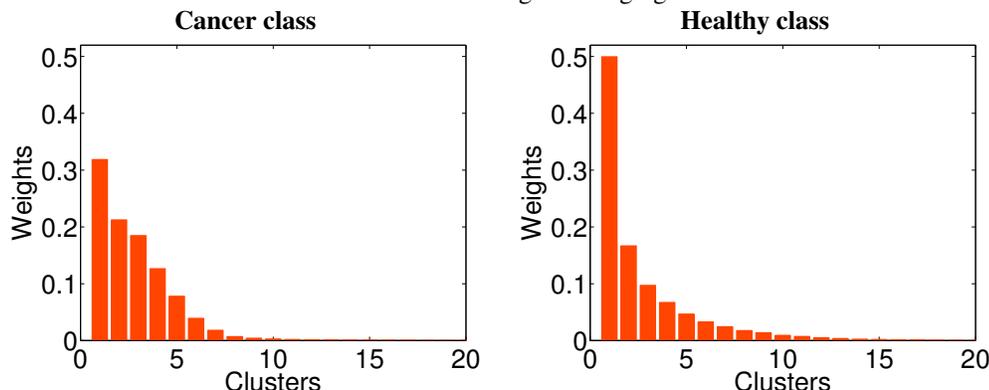

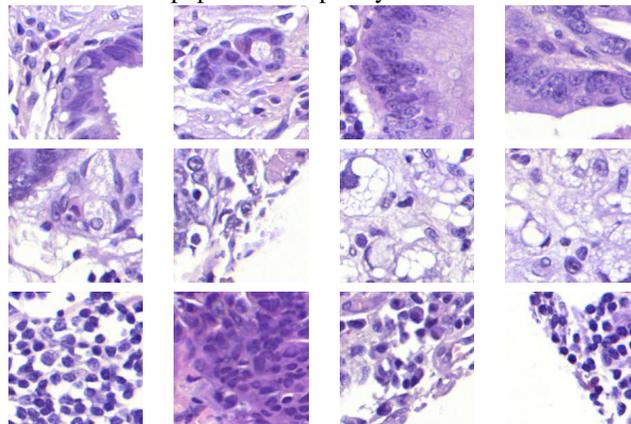

Figure 5: Sample patches from three different clusters (one in each row) of the *cancer* class. Each patch belongs to a different image. First cluster shows glandular formations of cancer cells, second cluster contains single cancer cells with faded color, and third cluster shows increased population of poorly differentiated cancer cells.

els. To avoid variability due to the desired level of detail in hyperparameter tuning (grid resolution and number of validation splits) which could lead to unfair comparison, we excluded the cross-validation time for the competing models. As a result of its steep learning rate, DPMIL provides reasonable training time, ranking as the most efficient model in text categorization and third in Barrett’s cancer diagnosis.

5 DISCUSSION

Multiple instance learning methods have long been developed and evaluated for bag label prediction. In this paper, we focus on the harder problem of instance level prediction from bag level training. We approach the problem from a semi-supervised learning perspective, and attempt to discover the unknown labels of positive bag instances by rich modeling of class distributions in a generative manner. We model these distributions by Gaussian mixture models with full covariance to handle complex multimodal cases. To

Table 3: Training times (in seconds) of models in comparison for one data split. Thanks to the efficient variational inference procedure, DPMIL can be trained in reasonable time.

Model name	Text categorization	Barrett’s cancer
DPMIL	2.9	44.7
KISVM-B	11.0	107.7
mi-SVM	12.2	126.6
KISVM-I	10.1	15.3
GPMIL	90.5	1491.7
MISVM	4.1	10.8

avoid the model selection problem (i.e. predetermination of the number of data modes), we apply Dirichlet process priors over mixture coefficients.

As experimented in a large set of benchmark data sets and one cancer diagnosis application, our method clearly improves the state-of-the-art in instance classification from

weak labels. We attribute this improvement to the effectiveness of the *let the data speak* attitude in semi-supervised learning: The model discovers the unknown positive bag instance labels by assigning them to the class that explains the data generation process better (i.e. the class that increases the variational lower bound more). Of the other methods in our comparison, mi-SVM, VF, and KISVM are ignorant about the class distributions. The remaining methods are tailored for predicting bag, but not instance labels.

Generative modeling of data is commonly undesirable in standard pattern classification tasks, as a result of Vapnik's razor principle³. However, our results imply that generative data distribution modeling turns out to be an effective strategy when weak supervision is an additional source of uncertainty.

Modeling class distributions with mixture models brings enhanced interpretability as a by-product. Analysis of inferred clusters may provide additional information, or may support further modeling decisions. Even though we restrict our analysis to binary classification for illustrative purposes, extension of our method to multiclass cases is simply a matter of increasing the number of Gaussian mixture models from two to a desired number of classes.

Appendix 1: Variational update equations and predictive density

Variational update equations of the approximate posterior q correspond to those of the Gaussian mixture model as described in [3] where the Dirichlet prior on mixture weights are replaced by a Dirichlet process prior and instances are assigned to the appropriate distribution by indicator functions $\mathbf{1}(\cdot)$.

For $q(\nu_{lk}) = \text{Beta}(\gamma_{lk}^1, \gamma_{lk}^2)$,

$$\gamma_{lk}^1 = 1 + \sum_{b=1}^B \sum_{n=1}^{N_b} q(z_{lbn} = k) \mathbf{1}(r_{bn} = l),$$

$$\gamma_{lk}^2 = \alpha + \sum_{b=1}^B \sum_{n=1}^{N_b} q(z_{lbn} > k) \mathbf{1}(r_{bn} = l).$$

For $q(z_{lbn} = k) = \text{Mult}(\tau_{lbn}^1, \dots, \tau_{lbn}^K)$,

$$\tau_{lbn}^k \leftarrow \left(\Psi(\gamma_{lk}^1) - \Psi(\gamma_{lk}^1 + \gamma_{lk}^2) + \sum_{j=1}^{k-1} (\Psi(\gamma_{lj}^2) - \Psi(\gamma_{lj}^1 + \gamma_{lj}^2)) \right.$$

$$+ \sum_{i=1}^D \Psi\left(\frac{\nu_{lk} + 1 - i}{2}\right) + D \log(2) + \log |\mathbf{W}_{lk}| - \frac{D}{2} \log(2\pi)$$

$$\left. - \frac{D}{2} \beta_{lk}^{-1} - \frac{1}{2} \nu_{lk} (\mathbf{x}_{bn} - \mathbf{m}_{lk})^T \mathbf{W}_{lk} (\mathbf{x}_{bn} - \mathbf{m}_{lk}) \right) \mathbf{1}(r_{bn} = l).$$

³**Vapnik's razor principle:** When solving a (learning) problem of interest, do not solve a more complex problem as an intermediate step.

For $q(\boldsymbol{\mu}_{lk}, \boldsymbol{\Lambda}_{lk}) = \mathcal{N}(\boldsymbol{\mu}_{lk} | \mathbf{m}_{lk}, (\beta_{lk} \boldsymbol{\Lambda}_{lk}^{-1})) \mathcal{W}(\boldsymbol{\Lambda}_{lk} | \mathbf{W}_{lk}, \nu_{lk})$, where

$$\beta_{lk} = \beta_0 + N_{lk},$$

$$\mathbf{m}_{lk} = \beta_{lk}^{-1} (\beta_0 \mathbf{m}_0 + N_{lk} \bar{\mathbf{x}}_{lk}),$$

$$\mathbf{W}_{lk}^{-1} = \mathbf{W}_0^{-1} + N_{lk} \mathbf{S}_{lk} + \frac{\beta_0 N_{lk}}{\beta_0 + N_{lk}} (\bar{\mathbf{x}}_{lk} - \mathbf{m}_0)(\bar{\mathbf{x}}_{lk} - \mathbf{m}_0)^T,$$

$$\nu_{lk} = \nu_0 + N_{lk} + 1.$$

Here,

$$N_{lk} = \sum_b^B \sum_{n=1}^{N_b} \mathbf{1}(r_{bn} = l) q(z_{lbn} = k),$$

$$\bar{\mathbf{x}}_{lk} = \frac{1}{N_{lk}} \sum_b^B \sum_{n=1}^{N_b} \mathbf{1}(r_{bn} = l) q(z_{lbn} = k) \mathbf{x}_{bn},$$

$$\mathbf{S}_{lk} = \frac{1}{N_{lk}} \sum_{b=1}^B \sum_{n=1}^{N_b} \mathbf{1}(r_{bn} = l) q(z_{lbn} = k) (\mathbf{x}_{bn} - \bar{\mathbf{x}}_{lk})(\mathbf{x}_{bn} - \bar{\mathbf{x}}_{lk})^T.$$

For an inferred configuration $\hat{\mathbf{r}}$, the predictive density of DPMIL is identical to that of a standard Gaussian mixture model as given in [3]

$$p(\mathbf{x}_{bn}^* | \mathbf{X}, \mathbf{y}, \hat{\mathbf{r}}, y_{bn}^* = l) = \int q(\boldsymbol{\theta}_l | \mathbf{X}, \mathbf{y}, \hat{\mathbf{r}}) p(\mathbf{x}_{bn}^* | \boldsymbol{\theta}_l) d\boldsymbol{\theta}_l,$$

$$= \frac{1}{\hat{\pi}_l} \sum_{k=1}^K \pi_{lk} \text{St} \left(\mathbf{x}_{bn}^* \middle| \mathbf{m}_k, \frac{(\nu_k + 1 - D) \beta_k}{1 + \beta_k} \mathbf{W}_k, \nu_k + 1 - D \right),$$

where $\hat{\pi}_{lk} = \sum_{k=1}^K \pi_l$ and $\text{St}(\cdot | \cdot, \cdot, \cdot)$ is the Student's t density function.

Abstract

Zero-sum stochastic games provide a formalism to study competitive sequential interactions between two agents with diametrically opposing goals and evolving state. A solution to such games with discrete state was presented by Littman (Littman, 1994). The continuous state version of this game remains unsolved. In many instances continuous state solutions require non-linear optimisation, a problem for which closed-form solutions are generally unavailable. We present an exact closed-form solution to a subclass of zero-sum continuous stochastic games that can be solved as a parameterised linear program by utilising symbolic dynamic programming. This novel technique is applied to calculate exact solutions to a variety of zero-sum continuous state stochastic games.

1 INTRODUCTION

Modelling competitive sequential interactions between agents has important applications within economic and financial decision-making. Stochastic games (Shapley, 1953) provide a convenient framework to model sequential interactions between non-cooperative agents. In zero-sum stochastic games, participating agents have diametrically opposing goals. A reinforcement learning solution to discrete state zero-sum stochastic games was presented by Littman (Littman, 1994). Closed-form solutions for the continuous state case remain unknown, despite the general importance of this formalism — zero-sum continuous state stochastic games provide a convenient framework with which to model robust sequential optimisation in adversarial settings including domains such as option valuation on derivative markets.

The difficulty of solving zero-sum continuous state stochastic games originates from the need to calculate a

Nash equilibrium for every state, of which there are infinitely many. In this paper we make the following key contributions:

- We characterise a subclass of zero-sum continuous state stochastic games with restricted reward and transition functions that can be solved exactly via parameterised linear optimisation.
- We provide an algorithm that solves this subclass of stochastic games exactly and optimally using Symbolic Dynamic Programming (SDP) (Boutilier *et al.*, 2001; Sanner *et al.*, 2011; Zamani & Sanner, 2012) for arbitrary horizons.

This paper is organised as follows: In Section 2 we describe Markov Decision Processes (MDPs) (Howard, 1960) and value iteration (Bellman, 1957), a widely used dynamic programming method for solving MDPs. In Sections 3 and 4, we present zero-sum stochastic games with discrete and continuous states, respectively, as game-theoretic generalisations of the MDP framework. Following this, in Section 5, we introduce SDP, and show how it can be used to calculate the first known exact solution to a particular subclass of zero-sum continuous state stochastic games. In Section 6 we calculate exact solutions to three empirical domains: a continuous state generalisation of matching pennies, binary option valuation and robust energy production. In Section 7, we survey the related literature. We conclude in Section 8 and identify interesting directions for future research.

2 MARKOV DECISION PROCESSES

A Markov Decision Process (MDP) (Howard, 1960) is defined by the tuple $\langle S, A, T, R, h, \gamma \rangle$. S and A specify a finite set of states and actions, respectively. T is the transition function $T : S \times A \rightarrow S$, which defines the effect of an action on the state. R is the reward function $R : S \times A \rightarrow \mathbb{R}$, which encodes the preferences of the agent. The horizon h represents the number of decision

steps until termination and the discount factor $\gamma \in [0, 1)$ is used to discount future rewards. In general, an agent’s objective is to find a policy, $\pi : S \rightarrow A$, which maximises the expected sum of discounted rewards over horizon h .

Value iteration (VI) (Bellman, 1957) is a general dynamic programming algorithm used to solve MDPs. VI is based on the set of Bellman equations, which mathematically express the optimal solution of an MDP. They provide a recursive expansion to compute: (1) $V^*(s)$, the expected value of following the optimal policy in state s ; and (2) $Q^*(s, a)$, the expected quality of taking a in state s , then following the optimal policy. The key idea of VI is to successively approximate $V^*(s)$ and $Q^*(s, a)$ by $V^h(s)$ and $Q^h(s, a)$, respectively, at each horizon h . These two functions satisfy the following recursive relationship:

$$Q^h(s, a) = R(s, a) + \gamma \cdot \sum_{s' \in S} T(s, a, s') \cdot V^{h-1}(s') \quad (1)$$

$$V^h(s) = \max_{a \in A} \{Q^h(s, a)\} \quad (2)$$

The algorithm can be executed by first initialising $V^0(s)$ to zero or the terminal reward. Then for each h , $V^h(s)$ is calculated from $V^{h-1}(s)$ via Equations (1) and (2), until the intended h -stage-to-go value function is computed. Value iteration converges linearly in the number of iterations to the true values of $Q^*(s, a)$ and $V^*(s)$ (Bertsekas, 1987).

MDPs can be used to model multiagent systems by assuming that other agents are part of the environment and have fixed behaviour. As a result, they ignore the difference between responsive agents and a passive environment (Hu & Wellman, 1998). In the next two sections we present game theoretic frameworks which generalises MDPs to situations with two or more responsive agents.

3 ZERO-SUM DISCRETE STOCHASTIC GAMES

Discrete state stochastic games (DSGs) are formally defined by the tuple $\langle S, A_1, \dots, A_n, T, R_1, \dots, R_n, h, \gamma \rangle$. S is a set of discrete states and A_i is the action set available to agent i . T is a transition function $T : S \times A_1 \times \dots \times A_n \rightarrow \Delta(S)$, where $\Delta(S)$ is the set of probability distributions over the state space S . The reward function $R_i : S \times A_1 \times \dots \times A_n \rightarrow \mathbb{R}$, encodes the individual preferences of agent i . The horizon h represents the number of decision steps until termination and the discount factor $\gamma \in [0, 1)$ is used to discount future rewards. In general, an agent’s objective is to find a policy, $\pi_i : S \rightarrow \sigma_i(A_i)$ which maximises the expected sum of discounted rewards over horizon h . Here $\sigma_i(A_i)$ specifies probability distributions over action set A_i . The optimal policy in a DSG may be stochastic, that is, it may define a mixed strategy for each state.

Zero-sum DSGs are a type of DSG involving two agents with diametrically opposing goals. Under these conditions the reward structure for the game can be represented by a single reward function since an agents reward function is simply the opposite of their opponent’s. The objective of each agent is to maximise its expected discounted future rewards in the minimax sense. That is, each agent views its opponent as acting to minimise the agent’s reward. Zero-sum DSGs can be solved using a technique analogous to value iteration for MDPs (Littman, 1994). The value function, $V^h(s)$, in this setting can be defined as:

$$V^h(s) = \max_{m \in \sigma_1(A_1)} \min_{o \in \sigma_2(A_2)} \sum_{a_1 \in A_1} \sum_{a_2 \in A_2} Q^h(s, a_1, a_2) \cdot m_{a_1} \cdot o_{a_2} \quad (3)$$

where $m \in \mathbb{R}^{|A_1|}$ and $o \in \mathbb{R}^{|A_2|}$ are mixed (stochastic) strategies from $\sigma_1(A_1)$ and $\sigma_2(A_2)$, respectively. $Q^h(s, a_1, a_2)$, the quality of taking action a_1 against action a_2 in state s , is given by:

$$Q^h(s, a_1, a_2) = R(s, a_1, a_2) + \gamma \cdot \sum_{s' \in S} T(s, a_1, a_2, s') \cdot V^{h-1}(s'). \quad (4)$$

Equation (3) can be further simplified by noting that given any m , the optimal minimum strategy is achieved through a deterministic action choice. This observation leads to the following form:

$$V^h(s) = \max_{m \in \sigma_1(A_1)} \min_{a_2 \in A_2} \sum_{a_1 \in A_1} Q^h(s, a_1, a_2) \cdot m_{a_1}. \quad (5)$$

Together Equations (4) and (5) define a recursive method to calculate the optimal solution to zero-sum DSGs. The policy for the opponent can be calculated by applying symmetric reasoning and the Minimax theorem (Neumann, 1928).

3.1 SOLUTION TECHNIQUES

Zero-sum DSGs can be solved via discrete linear optimisation at each horizon h . The value function in Equation (5) can be reformulated as a linear program through the following steps:

1. Define $V^h(s)$ to be the value of the inner minimisation term in Equation (5). This leads to the following linear program for a known state s :

$$\begin{aligned} & \text{maximise } V^h(s) \\ & \text{subject to} \\ & V^h(s) = \min_{a_2 \in A_2} \sum_{a_1 \in A_1} Q^h(s, a_1, a_2) \cdot m_{a_1} \quad (6a) \\ & \sum_{a_1 \in A_1} m_{a_1} = 1; m_{a_1} \geq 0 \quad \forall a_1 \in A_1 \end{aligned}$$

2. Replace the equality (=) in constraint (6a) with \leq by observing that the maximisation of $V^h(s)$ effectively pushes the \leq condition to the = case. This gives:

$$\begin{aligned} & \text{maximise } V^h(s) \\ & \text{subject to} \\ & V^h(s) \leq \min_{a_2 \in A_2} \sum_{a_1 \in A_1} Q^h(s, a_1, a_2) \cdot m_{a_1} \quad (7a) \\ & \sum_{a_1 \in A_1} m_{a_1} = 1; m_{a_1} \geq 0 \quad \forall a_1 \in A_1 \end{aligned}$$

3. Remove the minimisation operator in constraint (7a) by noting that the minimum of a set is less than or equal to the minimum of all elements in the set. This leads to the final form of the discrete linear optimisation problem:

$$\begin{aligned} & \text{maximise } V^h(s) \\ & \text{subject to} \\ & V^h(s) \leq \sum_{a_1 \in A_1} Q^h(s, a_1, a_2) \cdot m_{a_1} \quad \forall a_2 \in A_2 \\ & \sum_{a_1 \in A_1} m_{a_1} = 1; m_{a_1} \geq 0 \quad \forall a_1 \in A_1 \end{aligned}$$

We can now use existing linear programming solvers to compute the optimal solution to this linear program for each $s \in S$ at a given horizon h .

The linear program used to solve zero-sum DSGs cannot be used with continuous state formulations, since there are infinitely many states. A key contribution of this paper is in showing that zero-sum continuous state stochastic games can still be solved exactly through the use of symbolic dynamic programming. In the next section we present the continuous state analogue to zero-sum DSGs.

4 ZERO-SUM CONTINUOUS STOCHASTIC GAMES

Continuous state stochastic games (CSGs) are formally defined by the tuple $\langle \vec{x}, A_1, \dots, A_n, T, R_1, \dots, R_n, h, \gamma \rangle$. In CSGs states are represented by vectors of continuous variables, $\vec{x} = (x_1, \dots, x_m)$, where $x_i \in \mathbb{R}$. The other components of the tuple are as previously defined in Section 3.

Zero-sum CSGs impose the same restrictions on the number of agents and the reward structure as their discrete state counterparts.

The optimal solution to zero-sum CSGs can be calculated via the following recursive functions:

$$Q^h(\vec{x}, a_1, a_2) = R(\vec{x}, a_1, a_2) + \gamma \cdot \int T(\vec{x}, a_1, a_2, \vec{x}') \cdot V^{h-1}(\vec{x}') d\vec{x}' \quad (8)$$

$$V^h(\vec{x}) = \max_{m \in \sigma(A_1)} \min_{a_2 \in A_2} \sum_{a_1 \in A_1} Q^h(\vec{x}, a_1, a_2) \cdot m_{a_1} \quad (9)$$

We can derive Equation (8) from Equation (4) by replacing s, s' and the \sum operator with their continuous state counterparts, \vec{x}, \vec{x}' and \int , respectively. Equation (9) is simply Equation (5) restated.

4.1 SOLUTION TECHNIQUES

Zero-sum CSGs can be solved using a technique analogous to that presented in Section 3.1. Namely, the value function in Equation (9) can be reformulated as the following continuous optimisation problem:

$$\begin{aligned} & \text{maximise } V^h(\vec{x}) \\ & \text{subject to} \\ & V^h(\vec{x}) \leq \sum_{a_1 \in A_1} Q^h(\vec{x}, a_1, a_2) \cdot m_{a_1} \quad \forall a_2 \in A_2 \quad (10a) \\ & \sum_{a_1 \in A_1} m_{a_1} = 1; m_{a_1} \geq 0 \quad \forall a_1 \in A_1 \end{aligned}$$

This optimisation problem cannot be easily solved using existing techniques due to two factors: (1) there are infinitely many states in \vec{x} ; and (2) constraint (10a) is nonlinear in \vec{x} and m_{a_1} for general representations of $Q^h(\vec{x}, a_1, a_2)$. To further illustrate the second limitation consider $Q^h(\vec{x}, a_1, a_2)$ in the form of a linear function in x , for some a_1 and a_2 :

$$Q^h(\vec{x}, a_1, a_2) = \sum_j c_j \cdot x_j \quad (11)$$

Substituting Equation (11) into constraint (10a) yields:

$$V^h(\vec{x}) \leq \sum_{a_1 \in A_1} m_{a_1} \sum_j c_j \cdot x_j \quad \forall a_2 \in A_2. \quad (12)$$

It is clear from Equation (12) that a linear representation of $Q^h(\vec{x}, a_1, a_2)$ leads to a nonlinear constraint where m_{a_1} must be optimal with respect to the free variable \vec{x} . This results in a parameterised nonlinear program, whose optimal solutions are known to be NP-hard (Bennett & Mangasarian, 1993; Petrik & Zilberstein, 2011).

At this point we present the first key insight of this paper: we can transform constraint (10a) from a parameterised nonlinear constraint to a piecewise linear constraint by imposing the following restrictions: (1) restricting the reward function, $R(\vec{x}, a_1, a_2)$, to piecewise constant functions; and (2) restricting the transition function, $T(\vec{x}, a_1, a_2, \vec{x}')$, to piecewise linear functions. As a result, $V^h(\vec{x})$ and $Q^h(\vec{x}, a_1, a_2)$ will be piecewise constant functions, thereby guaranteeing a tractable solution to constraint (10a).

One key challenge still remains, namely, dealing with the infinitely many states in \vec{x} . We know that the $V^h(\vec{x})$ and $Q^h(\vec{x}, a_1, a_2)$ functions have structure, but are unable to derive them. Furthermore, given known structures for $V^h(\vec{x})$ and $Q^h(\vec{x}, a_1, a_2)$ we must determine the restrictions that

guarantee a tractable solution. The SDP framework in conjunction with its closed-form operations provide answers to both of these concerns.

In the next section we show that zero-sum CSGs, with the aforementioned restrictions, can be solved optimally for arbitrary horizons using symbolic dynamic programming.

5 SYMBOLIC DYNAMIC PROGRAMMING

Symbolic dynamic programming (SDP) (Boutilier *et al.*, 2001) is the process of performing dynamic programming via symbolic manipulation. In the following sections we present a brief overview of SDP operations and also show how SDP can be used to solve zero-sum CSGs.

5.1 CASE REPRESENTATION

SDP assumes that all functions can be represented in case statement form (Boutilier *et al.*, 2001) as follows:

$$f = \begin{cases} \phi_1 : f_1 \\ \vdots \\ \phi_k : f_k \end{cases}$$

Here, the ϕ_i are logical formulae defined over the state \vec{x} that can consist of arbitrary logical combinations of boolean variables and linear inequalities ($\geq, >, <, \leq$) over continuous variables. We assume that the set of conditions $\{\phi_1, \dots, \phi_k\}$ disjointly and exhaustively partition \vec{x} such that f is well-defined for all \vec{x} . In general, the f_i may be polynomials of \vec{x} with non-negative exponents. However, in this paper we restrict the f_i to be either constant or linear functions of the state variable \vec{x} . Henceforth, we refer to functions with linear ϕ_i and piecewise constant f_i as linear piecewise constant (LPWC) and functions with linear ϕ_i and piecewise linear f_i as linear piecewise linear (LPWL) functions.

5.2 CASE OPERATIONS

Operations on case statements may be either unary or binary. In this section we present a brief overview of the SDP operations needed to calculate closed form solutions to zero-sum CSGs. All of the operations presented here are closed form for LPWC and LPWL functions. We refer the reader to (Sanner *et al.*, 2011; Zamani & Sanner, 2012) for more thorough expositions of SDP and its operations.

Unary operations on a single case statement f , such as scalar multiplication $c \cdot f$ where $c \in \mathbb{R}$, are applied to each f_i ($1 \leq i \leq k$).

Binary operations such as addition, subtraction and multiplication are executed in two stages. Firstly, the cross-

product of the logical partitions of each case statement is taken, producing paired partitions. Finally, the binary operation is applied to the resulting paired partitions. The ‘‘cross-sum’’ \oplus operation can be performed on two cases in the following manner:

$$\begin{cases} \phi_1 : f_1 \\ \phi_2 : f_2 \end{cases} \oplus \begin{cases} \psi_1 : g_1 \\ \psi_2 : g_2 \end{cases} = \begin{cases} \phi_1 \wedge \psi_1 : f_1 + g_1 \\ \phi_1 \wedge \psi_2 : f_1 + g_2 \\ \phi_2 \wedge \psi_1 : f_2 + g_1 \\ \phi_2 \wedge \psi_2 : f_2 + g_2 \end{cases}$$

‘‘cross-subtraction’’ \ominus and ‘‘cross-multiplication’’ \otimes are defined in a similar manner but with the addition operator replaced by the subtraction and multiplication operators, respectively. Some partitions resulting from case operators may be inconsistent and are thus removed.

Minimisation over cases, known as *casemin*, is defined as:

$$\text{casemin} \left(\begin{cases} \phi_1 : f_1 \\ \phi_2 : f_2 \end{cases}, \begin{cases} \psi_1 : g_1 \\ \psi_2 : g_2 \end{cases} \right) = \begin{cases} \phi_1 \wedge \psi_1 \wedge f_1 < g_1 : f_1 \\ \phi_1 \wedge \psi_1 \wedge f_1 \geq g_1 : g_1 \\ \phi_1 \wedge \psi_2 \wedge f_1 < g_2 : f_1 \\ \phi_1 \wedge \psi_2 \wedge f_1 \geq g_2 : g_2 \\ \vdots \\ \vdots \end{cases}$$

casemin preserves the linearity of the constraints and the constant or linear nature of the f_i and g_i . If the f_i or g_i are quadratic then the expressions $f_i > g_i$ or $f_i \leq g_i$ will be at most univariate quadratic and any such constraint can be linearised into a combination of at most two linear inequalities by completing the square.

Substitution into case statements is performed via a set θ of variables and their substitutions e.g. $\theta = \{x'_1/(x_1 + x_2), x'_2/x_1^2 \exp(x_2)\}$, where the LHS of the $/$ represents the substitution variable and the RHS of the $/$ represents the expression that should be substituted in its place. θ can be applied to both non-case functions f_i and case partitions ϕ_i as $f_i\theta$ and $\phi_i\theta$, respectively. Substitution into case statements can be written as:

$$f\theta = \begin{cases} \phi_1\theta : f_1\theta \\ \vdots \\ \phi_k\theta : f_k\theta \end{cases}$$

Substitution is used when calculating integrals with respect to deterministic δ transitions (Sanner *et al.*, 2011).

A case statement can be maximised with respect to a continuous parameter y as $f_1(\vec{x}, y) = \max_y f_2(\vec{x}, y)$. The continuous maximisation operation is a complex case operation whose explanation is beyond the scope of this paper. We refer the reader to (Zamani & Sanner, 2012) for further details.

Case statements and their operations are implemented using Extended Algebraic Decision Diagrams (XADDs) (Sanner *et al.*, 2011). XADDs provide a compact

data structure with which to maintain compact forms of $Q^h(\vec{x}, a_1, a_2)$ and $V^h(\vec{x})$.

5.3 SDP FOR ZERO-SUM CONTINUOUS STOCHASTIC GAMES

In this section we will show that a subclass of zero-sum continuous stochastic games with (a) piecewise constant rewards; and (b) piecewise linear transition functions can be solved exactly and in closed-form by using SDP.

To calculate the exact solution to zero-sum CSGs we begin by replacing all functions and operations in Equations (8) and (9) by their case statement equivalents. That is, we exchange operations such as $+$, \times and \min , by their symbolic equivalents, \oplus , \otimes and casemin , respectively, and express $R(\vec{x}, a_1, a_2)$, $T(\vec{x}, a_1, a_2, \vec{x}')$, $V^0(\vec{x})$ as case statements. m_{a_1} is also encoded as a trivial case statement representing an uninstantiated symbolic variable:

$$m_{a_1} = \left\{ \top : m_{a_1} \right.$$

The optimal solution to zero-sum CSGs can now be described by the following recursive SDP equations:

$$Q^h(\vec{x}, a_1, a_2) = R(\vec{x}, a_1, a_2) \oplus \gamma \otimes \int T(\vec{x}, a_1, a_2, \vec{x}') \otimes V^{h-1}(\vec{x}') d\vec{x}' \quad (13)$$

$$\tilde{Q}^h(\vec{x}, a_2) = \sum_{a_1 \in A_1} Q^h(\vec{x}, a_1, a_2) \otimes m_{a_1} \quad (14)$$

$$V^h(\vec{x}) = \max_m \text{casemin} \left(\text{casemin}_{a_2 \in A_2} \left(\tilde{Q}^h(\vec{x}, a_2) \right), \mathbb{I} \right) \quad (15)$$

Equation (14) calculates a symbolic Q function weighted by the variable m_{a_1} for each a_1 . In Equation (15) the inner casemin operation is calculated with respect to $\tilde{Q}^h(\vec{x}, a_2)$ instantiated with a particular a_2 . The “indicator” function \mathbb{I} serves as the summation constraint $\sum_{a_1 \in A_1} m_{a_1} = 1$ and ensures that the subsequent \max operation returns legal values for the m_{a_1} . The indicator is defined as follows:

$$\mathbb{I} = \begin{cases} \forall a_1 \in A_1 [(m_{a_1} \geq 0) \wedge (m_{a_1} \leq 1) \wedge (\sum m_{a_1} = 1)] : +\infty \\ \forall a_1 \in A_1 \neg [(m_{a_1} \geq 0) \wedge (m_{a_1} \leq 1) \wedge (\sum m_{a_1} = 1)] : -\infty \end{cases}$$

The function \mathbb{I} returns $+\infty$ when the conjunction of all constraints on each m_{a_1} are satisfied and $-\infty$, otherwise.

In Algorithm 1 we present CSG-VI , a methodology to calculate the optimal h -stage-to-go value function through Equations (13) to (15). In the algorithm we notationally specify the arguments of the Q^h and V^h functions when they are instantiated by an operation. For the base case of $h = 0$, we set $V^0(\vec{x})$, expressed in case statement form, to zero or to the terminal reward. For all $h > 0$ we apply the

previously defined SDP operations in the following steps:

1. Prime the Value Function. In line 6 we set up a substitution $\theta = \{x_1/x'_1, \dots, x_m/x'_m\}$, and obtain $V^{h'} = V^h \theta$, the “next state”.
2. Discount and add Rewards. We assume that the reward function contains primed variables and incorporate it in line 8.
3. Continuous Regression. For the continuous state variables in \vec{x} lines 10 – 11 follow the rules of integration w.r.t. a δ function (Sanner *et al.*, 2011). This yields the following symbolic substitution: $\int f(x'_j) \otimes \delta[x'_j - g(\vec{z})] dx'_j = f(x'_j) \{x'_j/g(\vec{z})\}$, where $g(\vec{z})$ is a case statement and \vec{z} does not contain x'_j . The latter operation indicates that any occurrence of x'_j in $f(x'_j)$ is symbolically substituted with the case statement $g(\vec{z})$.
4. Incorporate Agent 1’s strategy. At this point we have calculated $Q^h(\vec{x}, a_1, a_2)$, as shown in Equation (13). In lines 13 - 14 we weight the strategy for a specific a_1 by m_{a_1} . We note that m_{a_1} is a case statement representing an uninstantiated symbolic variable.
5. Case Minimisation. In lines 16 – 17 we compute the best case for a_2 as a function of all other variables, as shown in Equation (14).
6. Incorporate Constraints. In line 19 we incorporate constraints on the m_{a_1} variable: $\sum_{a_1 \in A_1} m_{a_1} = 1$ and $m_{a_1} \geq 0 \wedge m_{a_1} \leq 1 \quad \forall a_1 \in A_1$. The casemin operator ensures that all case partitions which involve illegal values of m_{a_1} are mapped to $-\infty$.
7. Maximisation. In lines 22 – 23 we compute the best response strategy for every state. We note that this can only be done via symbolic methods since there are infinitely many states. At this point we have calculated $V^h(\vec{x})$ as shown in Equation (15).

It can be proved that all of the SDP operations used in Algorithm 1 are closed form for LPWC or LPWL functions (Sanner *et al.*, 2011; Zamani & Sanner, 2012). Given a LPWC $V^0(\vec{x})$ and that SDP operations are closed form, the resulting $V^{h+1}(\vec{x})$ is also LPWC. Therefore, by induction $V^{h+1}(\vec{x})$ is LPWC for all horizons h .

In the next section we demonstrate how SDP can be used to compute exact solutions to a variety of zero-sum continuous stochastic games.

6 EMPIRICAL RESULTS

In this section we evaluate our novel SDP solution technique for zero-sum CSGs on three continuous domains¹:

¹All of the source code can be found online at <http://code.google.com/p/xadd-inference>.

Algorithm 1: $\text{CSG-VI}(\text{CSG}, H, \mathbb{I}) \rightarrow (V^h)$

```

(1) continuous stochastic matching pennies; (2) binary option stochastic game; and (3) robust energy production. The results represent the first known exact solutions to these domains.

6.1 CONTINUOUS STOCHASTIC MATCHING PENNIES

Matching pennies is a well known zero-sum game with a mixed strategy Nash Equilibrium (Osborne, 2004). In this paper we extend the standard formulation of the game by incorporating continuous state and sequential decisions while still maintaining the zero-sum nature of the reward.

6.1.1 Domain Description

We define continuous stochastic matching pennies as an extensive form game between two players $p \in \{1, 2\}$. The aim of a player is to maximise its expected discounted pay-off at a fixed horizon H . Our game is played within the interval $[0, 1]$, two fixed variables $c \in [0, 1)$ and $d \in (0, 1]$ with $(c < d)$, are used to partition the interval into three regions $r \in \{1, 2, 3\}$. Each region is associated with its own

zero-sum reward structure. The continuous state variable $x \in [0, 1]$ is used to specify which region the players are competing within.

At each horizon ($h \leq H$) each player executes an action $a_p \in \{\text{heads}_p, \text{tails}_p\}$. Player 1 “wins” if both players choose the same action. Otherwise, Player 2 wins. The joint actions of the players affect the state x as follows:

$$P(x' | x, a_1, a_2) = \delta \left[x' - \begin{cases} (\text{heads}_1) \wedge (\text{heads}_2) \wedge (x \geq k) : & x - k \\ (\text{heads}_1) \wedge (\text{tails}_2) \wedge (x \leq 1) : & x + k \\ (\text{tails}_1) \wedge (\text{heads}_2) \wedge (x \geq k) : & x + k \\ (\text{tails}_1) \wedge (\text{tails}_2) \wedge (x \leq 1) : & x - k \end{cases} \right]$$

The constant $k \in (0, 1)$ is a step size which perturbs the state x . If Player 1 wins, the state moves to the left by k , otherwise it moves to the right by k . The Dirac function $\delta[\cdot]$ ensures that the transitions are valid conditional probability functions that integrate to 1.

We define the rewards obtained by Player 1 in region r as:

$$R_1^r = \begin{cases} (\text{heads}_1) \wedge (\text{heads}_2) : & \alpha_1^r \\ (\text{heads}_1) \wedge (\text{tails}_2) : & \alpha_2^r \\ (\text{tails}_1) \wedge (\text{heads}_2) : & \alpha_3^r \\ (\text{tails}_1) \wedge (\text{tails}_2) : & \alpha_4^r \end{cases}$$

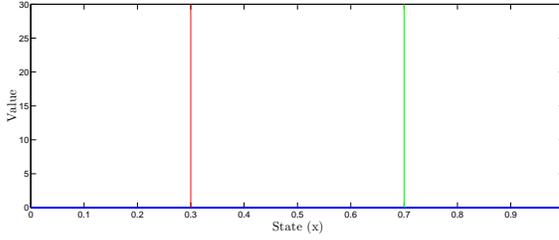

Here we restrict $\alpha_i^r \in \mathbb{R}$. The rewards obtained by Player 2 in the same region are simply $-R_1^r$. Given this reward formulation we specify two different reward structures: symmetric and asymmetric. In a symmetric reward structure $\alpha_1^r = \alpha_4^r$ and $\alpha_2^r = \alpha_3^r$. An example of this reward structure is shown in Table 1. Under a symmetric reward setting the expected reward for each player is the same across all regions r . In an asymmetric reward structure we allow each of the α_i^r to differ in both sign and magnitude. Table 2 shows an example of an asymmetric reward structure. Under an asymmetric setting the expected reward for each player may vary across each region r . This gives a player an incentive to reach regions with a higher expected reward.

Table 1: Symmetric reward structure for Player 1.

	Region 1	Region 2	Region 3
$(\text{heads}_1) \wedge (\text{heads}_2)$	10	5	20
$(\text{heads}_1) \wedge (\text{tails}_2)$	-10	-5	-20
$(\text{tails}_1) \wedge (\text{heads}_2)$	-10	-5	-20
$(\text{tails}_1) \wedge (\text{tails}_2)$	10	5	20

Table 2: Asymmetric reward structure for Player 1.

	Region 1	Region 2	Region 3
$(\text{heads}_1) \wedge (\text{heads}_2)$	1	5	7
$(\text{heads}_1) \wedge (\text{tails}_2)$	-3	-5	-2
$(\text{tails}_1) \wedge (\text{heads}_2)$	0	-5	10
$(\text{tails}_1) \wedge (\text{tails}_2)$	2	5	20

(a) Symmetric rewards.

(b) Asymmetric rewards.

Figure 1: The optimal value functions of the continuous stochastic matching pennies game for Player 1 at horizon 4 under (a) symmetric and (b) asymmetric reward structures. Threshold values are set to $c = 0.3$ and $d = 0.7$ and are highlighted in red and green, respectively. The step size is $k = 0.3$.

6.1.2 Results

We investigate the continuous stochastic matching pennies game under both symmetric and asymmetric rewarded structures. For both experiments the threshold values are set to $c = 0.3$ and $d = 0.7$. The step size is $k = 0.3$.

Figure (1a) shows the results of the continuous stochastic matching pennies game using the symmetric reward structure given in Table 1. The results show that the expected reward for Player 1 remains at zero over all 4 horizons, irrespective of the state x . The symmetric reward structure clearly shows that both players achieve the same expected reward in all regions r . This in turn ensures that both players are indifferent between their pure strategies. Hence, the expected reward for each player is zero in all regions. This result corresponds to the well known solution of the matching pennies game with symmetric rewards and serves as a proof of concept for our novel solution technique.

Figure (1b) shows the effect of the asymmetric reward structure given in Table 2. The figure shows that Player 1 achieves the highest expected reward in Region 3, followed by Region 2 and finally by Region 1. This corresponds to the expected reward within each region of Table 2. The results indicate that the Player 1 is no longer indifferent between its pure strategies in each region and may take short-term losses to reach more favourable regions.

6.2 BINARY OPTION STOCHASTIC GAME

Binary options are financial instruments which allow an investor to bet on the outcome of a yes/no proposition. The proposition typically relates to whether the price of a particular asset that underlies the option will rise above or fall below a specified amount, known as the strike price, $\kappa \in \mathbb{R}$. When the option reaches maturity the investor receives a fixed pay-off if their bet was correct and nothing otherwise.

6.2.1 Domain Description

We analyse the valuation of a binary option as an extensive form zero-sum game between a trader and the market. The aim of the trader is to maximise their expected discounted pay-off at a fixed horizon H through buying and selling options within an adversarial market. The problem has two state variables: the underlying market value of the asset $v \in [0, 100]$ and the trader's inventory of options $i \in \mathbb{N}$.

At each time step the trader can execute one of three actions $a_{trd} \in \{buy_{trd}, sell_{trd}, hold_{trd}\}$, where buy_{trd} refers to a request to buy an option from the market, $sell_{trd}$ refers to a request to sell an option to the market and $hold_{trd}$ is equivalent to taking no action. The market can execute one of two actions: $a_{mkt} \in \{sell_{mkt}, nsel_{mkt}\}$, where $sell_{mkt}$ corresponds to selling an option to the trader and $nsel_{mkt}$ corresponds to not selling to the trader.

The joint actions of the trader and market, a_{trd} and a_{mkt} , respectively, affect both the underlying market value of the asset and the trader's inventory. For the sake of simplicity we assume that the market value may increase or decrease by fixed step sizes, $u \in \mathbb{R}$ for an increase and $d \in \mathbb{R}$ for a decrease.

The trader's option inventory dynamics are given by:

$$P(i'|v, i, a_{trd}, a_{mkt}) = \delta \left[i' - \begin{cases} (buy_{trd}) \wedge (sell_{mkt}) : & i + 1 \\ (sell_{trd}) \wedge (i > 0) : & i - 1 \\ otherwise : & i \end{cases} \right]$$

It should be noted that under this formulation the market will always buy an option from the trader when the trader selects $sell_{trd}$. The market value changes according to:

$$P(v'|v, i, a_{trd}, a_{mkt}) = \delta \left[v' - \begin{cases} (buy_{trd}) \wedge (sell_{mkt}) : & v + u \\ (sell_{trd}) \wedge (i > 0) : & v - d \\ otherwise : & v \end{cases} \right]$$

Assuming that the strike price $\kappa \in [0, 100]$, the rewards obtained by the trader are given by:

$$R_{trader} = \begin{cases} (sell_{trd}) \wedge (i > 0) \wedge (v > \kappa) : & 1 \\ otherwise : & 0 \end{cases}$$

The market's reward is simply the additive inverse of the trader's reward. Hence, the binary option game is zero-sum.

6.2.2 Results

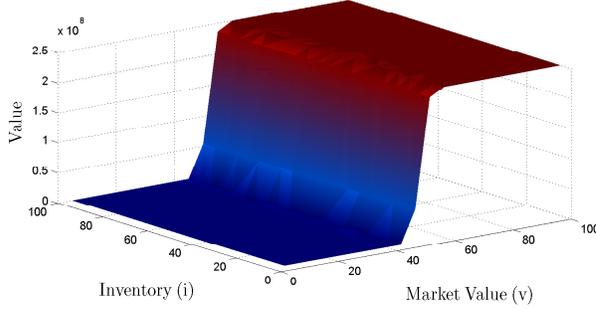

Figure 2: The optimal value function of the binary option stochastic game for the trader at horizon 20. The strike price is set to $\kappa = 45.0$ and the increment and decrement values are set to $u = 1.0$ and $d = 1.0$, respectively. Under the domain specification the value function is invariant to the inventory i .

In Figure (2) we show the optimal value function for the binary option game at horizon 20. The strike price is set to $\kappa = 45.0$ and the increment and decrement values, u and d are both set to 1.0. The value function clearly shows that under this formulation the trader achieves the most reward by selling options as soon $v > \kappa$. Selling an option causes the underlying value to decrease. Once the value falls beneath the strike price, the trader will buy options, which increases the underlying value. This leads to the continual cycling of buying and selling of the option at values close to the strike price κ . In essence the trader behaves like a market maker in that they take both sides of the transaction at values near κ . We note that while Figure (2) is invariant to the inventory of options i , its inclusion is critical for the correct formalisation of the domain.

6.3 ROBUST ENERGY PRODUCTION

The provision of energy resources is an integral component of any economy. Energy providers must be able to produce energy in response to changes in energy demand. In situations where demand exceeds supply, an energy crisis may occur. In this paper we investigate energy production from the viewpoint of an energy provider responsible for supplying energy in an adversarial environment.

6.3.1 Domain Description

We define our energy production domain as an extensive form zero-sum game between an energy provider and nature. The aim of the energy provider is to maximise its

expected discounted reward at a fixed horizon H by changing production levels in response to changes in demand. The domain has two state variables: the production level $p \in \mathbb{R}^+$ and the energy demand $d \in \mathbb{R}^+$.

At each time step the energy provider can execute one of two actions $a_{prd} \in \{inc_{prd}, dec_{prd}\}$, where inc_{prd} refers to increasing energy production and dec_{prd} refers to decreasing energy production. Nature can also execute one of two actions $a_{nat} \in \{inc_{dem}, dec_{dem}\}$, where inc_{dem} refers to increasing energy demand and dec_{dem} refers to decreasing energy demand. We specify the increase in the amount of energy produced or demanded by $prd_u, nat_u \in \mathbb{R}^+$ and a corresponding decrease by $prd_d, nat_d \in \mathbb{R}^+$.

The joint actions of the energy provider and nature, a_{prd} and a_{nat} , respectively, affect the production level as follows:

$$P(p'|d, p, a_{prd}, a_{nat}) = \delta \left[p' - \begin{cases} (inc_{prd}) : & p + prd_u \\ (dec_{prd}) \wedge (p > prd_d) : & p - prd_d \\ otherwise : & p \end{cases} \right]$$

The energy demand changes according to:

$$P(d'|d, p, a_{prd}, a_{nat}) = \delta \left[d' - \begin{cases} (inc_{dem}) : & d + nat_u \\ (dec_{dem}) \wedge (d > nat_d) : & d - nat_d \\ otherwise : & d \end{cases} \right]$$

The reward obtained by the energy provider are specified as:

$$R_{prd} = \begin{cases} (p < d) : & -100 \\ otherwise : & 0 \end{cases}$$

We note that under this reward structure failure to meet energy demand is heavily penalised, whereas meeting or even exceeding demand are given the same reward. Nature's reward is simply the additive inverse of the energy provider's reward.

6.3.2 Results

In Figure (3) we show the optimal value function for the robust energy production game at horizon 8. The production and demand increase and decrease variables were set to $prd_u = prd_d = 1.0$ and $nat_u = nat_d = 0.5$, respectively. The value function shows that the energy provider achieves the highest value when the energy provided meets or exceeds demand. The value function is lowest when the demand exceeds supply, which is in accordance with the reward structure. The value function clearly decreases in

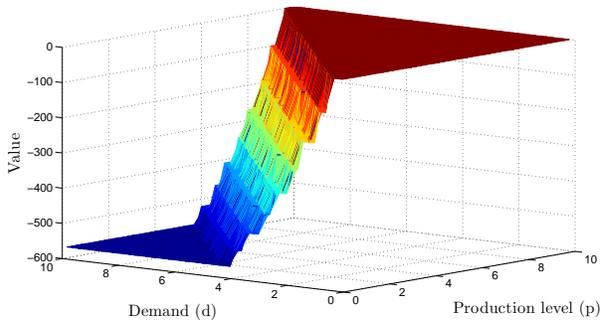

Figure 3: The optimal value function of the robust energy production game for the producer at horizon 8. The production and demand increase and decrease variables were set to $prd_u = prd_d = 1.0$ and $nat_u = nat_d = 0.5$, respectively.

a step-wise manner from the point where the production level meets demand, indicating that production levels just beneath demand have a higher value than those well below demand.

7 RELATED WORK

Solutions to stochastic games have been proposed from within both game theory and reinforcement learning. The first algorithm, game theoretic or otherwise, for finding a solution to a stochastic game was given by Shapley (Shapley, 1953). Shapley’s algorithm calculates a value function $V(s)$ over discrete states which converges to an optimal value function $V^*(s)$. $V^*(s)$ represents the expected discounted future reward if both players in the game follow the game’s Nash equilibrium. The algorithm is in essence an extension of the Value Iteration algorithm to stochastic games.

A partially implementable solution, based on reinforcement learning, for a subclass of stochastic games was first introduced by (Littman, 1994). Littman’s algorithm, Minimax-Q, extends the traditional Q-learning algorithm for MDPs to zero-sum discrete stochastic games. The algorithm converges to the stochastic game’s equilibrium solution. Hu and Wellman (Hu & Wellman, 1998) extended Minimax-Q to general-sum games and proved that it converges to a Nash equilibrium under certain restrictive conditions. Although both reinforcement learning based algorithms are able to calculate equilibrium solutions they are limited to discrete state formulations of stochastic games. In this paper we provide the first known exact closed-form solution to a subclass of continuous state zero-sum stochastic games defined by piecewise constant reward and piecewise linear transition functions.

Several techniques have been put forward to tackle contin-

uous state spaces in MDPs. Li and Littman (Li & Littman, 2005) describe a method for approximate solutions to continuous state MDPs. In their work, Li and Littman only allow for rectilinearly aligned constraints in their reward and transition functions, not arbitrary linear constraints, and cannot handle general linear transition models without approximation. Our SDP method provides exact solutions without these restrictions, which makes SDP strictly more general. Also, Li and Littman did not consider game-theoretic extensions of their work or the parameterised optimisation problem that these extensions entail.

Symbolic dynamic programming techniques have been previously used to calculate exact solutions to single agent MDPs with both continuous state and actions in a variety of non-game theoretic domains (Sanner *et al.*, 2011; Zamani & Sanner, 2012). In this paper we build on this work and present the first application of SDP to stochastic games with concurrently acting agents.

8 CONCLUSIONS

In this paper we have characterised a subclass of zero-sum continuous stochastic games that can be solved exactly via parameterised linear optimisation. We have also presented a novel symbolic dynamic programming algorithm that can be used to calculate exact solutions to this subclass of games for arbitrary horizons. The algorithm was used to calculate the first known exact solutions to a variety of continuous stochastic games with piecewise constant reward and piecewise linear transitions.

There are a number of avenues for future research. Firstly, it is important to examine more general representations of the reward and transition functions while still guaranteeing exact solutions. Another direction of research lies within improving the scalability of the algorithm by either extending techniques for Algebraic Decision Diagrams (Bahar *et al.*, 1993) from APRICODD (St-Aubin *et al.*, 2000) under the current restrictions on the reward and transition functions, bounded error compression for XADDs (Vianna *et al.*, 2013) for more expressive representations, or lazy approximation of value functions as piecewise linear XADDs (Li & Littman, 2005). Search based approaches such as RTDP (Barto *et al.*, 1995) and HAO* (Meuleau *et al.*, 2009) are also readily adaptable to SDP. These extensions may then be used to model sequential decision making in more complex financial and economic domains. Finally, SDP can be used to calculate exact solutions to general sum stochastic games. The advances made within this paper open up a number of potential novel research paths which may be used to progress solutions to sequential game theoretic domains with continuous state.

Recursive Best-First AND/OR Search for Optimization in Graphical Models

Akihiro Kishimoto and Radu Marinescu
IBM Research – Ireland
{akihirok, radu.marinescu}@ie.ibm.com

Abstract

The paper presents and evaluates the power of limited memory best-first search over AND/OR spaces for optimization tasks in graphical models. We propose *Recursive Best-First AND/OR Search with Overestimation* (RBFAOO), a new algorithm that explores the search space in a best-first manner while operating with restricted memory. We enhance RBFAOO with a simple overestimation technique aimed at minimizing the overhead associated with re-expanding internal nodes and prove correctness and completeness of RBFAOO. Our experiments show that RBFAOO is often superior to the current state-of-the-art approaches based on AND/OR search, especially on very hard problem instances.

1 INTRODUCTION

Graphical models provide a powerful framework for reasoning with probabilistic information. These models use graphs to capture conditional independencies between variables, allowing a concise knowledge representation and efficient graph-based query processing algorithms. Combinatorial optimization tasks such as MAP or marginal MAP inference arise in many applications and are typically tackled with either search or inference algorithms (Pearl, 1988; Dechter, 2003). The most common search scheme is the *depth-first branch and bound*. Its use for finding exact solutions was studied and evaluated extensively in the context of AND/OR search spaces that are sensitive to the underlying problem structure (Marinescu and Dechter, 2009a,b).

Meanwhile, *best-first* search algorithms, despite their better time efficiency than depth-first search (Dechter and Pearl, 1985), are largely ignored in practice primarily due to their inherently enormous memory requirements (Marinescu and Dechter, 2009b). Furthermore, an important best-first search property, avoiding the exploration of unbounded paths, seems irrelevant to optimization tasks in

graphical models where all solutions are at the same depth (ie, the number of variables).

We aim at inheriting the advantages of both depth-first and best-first search schemes. We introduce RBFAOO, a new algorithm that explores the context minimal AND/OR search graph associated with a graphical model in a *best-first* manner (even with non-monotonic heuristics) while operating within restricted memory. RBFAOO extends Recursive Best-First Search (RBFS) (Korf, 1993) to graphical models and thus uses a threshold controlling technique to drive the search in a depth-first like manner while using the available memory to cache and reuse partial search results. In addition, RBFAOO employs an overestimation method designed to further reduce the high overhead caused by re-expanding internal nodes. RBFAOO is also related to the AND/OR search algorithms based on proof/disproof numbers (Allis et al., 1994) (eg, df-pn and df-pn⁺ (Nagai, 2002)) which are very popular for solving two-player zero-sum games. However, since game solvers ignore the solution cost, they do not come with optimality guarantee. Moreover, while df-pn’s completeness on finding suboptimal solutions assumes that the cache table preserves all search results of nodes previously explored (Kishimoto and Müller, 2008), RBFAOO is proven to be complete with a small cache table. We evaluate empirically RBFAOO on benchmark problems used during the PASCAL2 Inference Challenge. Our results show that RBFAOO is often superior to the state-of-the-art solvers based on AND/OR search, especially on the hardest problem instances.

2 PRELIMINARIES

We consider combinatorial optimization problems defined over graphical models, including Bayesian networks and Markov random fields (Pearl, 1988; Koller and Friedman, 2009). A *graphical model* is a tuple $\mathcal{M} = \langle \mathbf{X}, \mathbf{D}, \mathbf{F}, \otimes \rangle$, where $\mathbf{X} = \{X_1, \dots, X_n\}$ is a set of variables and $\mathbf{D} = \{D_1, \dots, D_n\}$ is the set of their finite domains of values. $\mathbf{F} = \{f_1, \dots, f_r\}$ is a set of positive real-valued functions defined on subsets of variables, called *scopes* (ie,

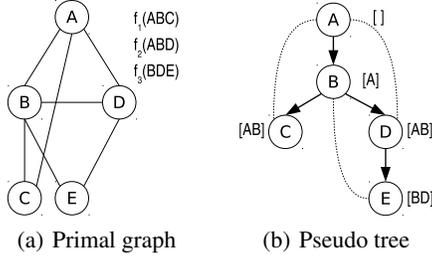

Figure 1: A simple graphical model.

$\forall j f_j : \mathbf{Y}_j \rightarrow \mathbb{R}^+$ and $\mathbf{Y}_j \subseteq \mathbf{X}$). The set of function scopes implies a *primal graph* whose vertices are the variables and which includes an edge connecting any two variables that appear in the scope of the same function. The combination operator $\otimes \in \{\prod, \sum\}$ defines the complete function represented by the graphical model \mathcal{M} as $C(\mathbf{X}) = \otimes_{j=1}^r f_j(\mathbf{Y}_j)$. In this paper, we focus on *min-sum problems*, in which we would like to compute the optimal value C^* and/or its optimizing configuration x^* :

$$C^* = C(x^*) = \min_{\mathbf{X}} \sum_{j=1}^r f_j(\mathbf{Y}_j) \quad (1)$$

Koller and Friedman (2009) convert the MAP task defined by $\max_{\mathbf{X}} \prod_j f_j$ to log-space and solve it as an *energy minimization* (min-sum) problem to avoid numerical issues.

2.1 AND/OR SEARCH SPACES

Dechter and Mateescu (2007) introduce the concept of AND/OR search spaces for graphical models. A *pseudo tree* of the primal graph defines the search space and captures problem decomposition.

Definition 2.1. A pseudo tree of an undirected graph $G = (V, E)$ is a directed rooted tree $\mathcal{T} = (V, E')$, such that every arc of G not included in E' is a back-arc in \mathcal{T} , namely it connects a node in \mathcal{T} to an ancestor in \mathcal{T} . The arcs in E' may not all be included in E .

Given a graphical model $\mathcal{M} = \langle \mathbf{X}, \mathbf{D}, \mathbf{F}, \Sigma \rangle$ with primal graph G and a pseudo tree \mathcal{T} of G , the *AND/OR search tree* $S_{\mathcal{T}}$ based on \mathcal{T} has alternating levels of OR nodes corresponding to the variables and AND nodes corresponding to the values of the OR parent’s variable, with edges weighted according to \mathbf{F} . Identical subproblems, identified by their *context* (the partial instantiation that separates the subproblem from the rest of the problem graph), can be merged, yielding an *AND/OR search graph* (Dechter and Mateescu, 2007). Merging all context-mergeable nodes yields the *context minimal AND/OR search graph*, denoted by $C_{\mathcal{T}}$. The size of the context minimal AND/OR graph is exponential in the induced width of G along a depth-first traversal of \mathcal{T} (Dechter and Mateescu, 2007).

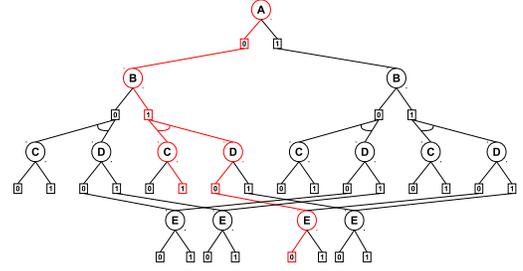

Figure 2: Context minimal AND/OR search graph.

A *solution tree* T of $C_{\mathcal{T}}$ is a subtree such that: (1) it contains the root node of $C_{\mathcal{T}}$; (2) if an internal AND node n is in T then all its children are in T ; (3) if an internal OR node n is in T then exactly one of its children is in T ; (4) every tip node in T (ie, nodes with no children) is a terminal node. The cost of a solution tree is the sum of the weights associated with its arcs.

Each node n in $C_{\mathcal{T}}$ is associated with a *value* $v(n)$ capturing the optimal solution cost of the conditioned subproblem rooted at n . It was shown that $v(n)$ can be computed recursively based on the values of n ’s successors: OR nodes by minimization, AND nodes by summation (see also (Dechter and Mateescu, 2007)).

Example 1. Figure 1(a) shows a simple graphical model with 5 bi-valued variables $\{A, B, C, D, E\}$ and 3 functions $\{f_1(ABC), f_2(ABD), f_3(BDE)\}$, respectively. Figure 2 displays the context minimal AND/OR search graph based on the pseudo tree from Figure 1(b). The contexts of the variables are shown next to the corresponding pseudo tree nodes. A solution tree corresponding to the assignment $(A = 0, B = 1, C = 1, D = 0, E = 0)$ is highlighted.

2.2 AND/OR SEARCH ALGORITHMS

AND/OR Branch and Bound (AOBB) (Marinescu and Dechter, 2009a,b) is a state-of-the-art informed search approach for solving optimization tasks over graphical models. AOBB explores in a *depth-first* manner the context minimal AND/OR search graph associated with the problem and therefore takes advantage of problem decomposition. During search, AOBB keeps track of the value of the best solution found so far (an upper bound on the optimal cost) and uses this value and the heuristic function to prune away portions of the search space that are guaranteed not to contain the optimal solution in a typical branch and bound manner. Most notably, AOBB guided by a class of partitioning based heuristics won the first place in the PASCAL2 competition (Otten et al., 2012).

Best-First AND/OR Search (Marinescu and Dechter, 2009b) (AOBF) is a variant of AO* (Nilsson, 1980) applicable to graphical models that explores the graph in a *best-first* rather than depth-first manner. This enables AOBF to visit a significantly smaller search space than AOBB

which sometimes translates into important time savings. Extensive empirical evaluations (Marinescu and Dechter, 2009b) showed that when given enough memory AOBF is often superior to AOBB. However, in many practical situations AOBF’s overhead of maintaining in memory the explicated portion of the search space is still prohibitively large. AOBB therefore remains the best alternative.

3 RECURSIVE BEST-FIRST AND/OR SEARCH WITH OVERESTIMATION

We introduce RBFAOO, a new algorithm that belongs to the class of recursive best-first search algorithms and employs a local threshold controlling mechanism to explore the context minimal AND/OR search graph in a depth-first like manner (Korf, 1993; Nagai, 2002). It can however use additional memory to cache and reuse partial search results to enhance performance. RBFAOO also leverages an overestimation technique to possibly find a suboptimal solution and then refine it to an optimal one. The latter plays an essential role in enhancing the performance by avoiding a high overhead of re-expanding internal nodes.

Before explaining RBFAOO in detail, we give an overview of the threshold controlling scheme that makes RBFAOO behave similarly to AO*. Assume that the weight from an OR node to an AND node is 1, the weight from an AND node to an OR node is 0, and a heuristic function h returns values as shown in Figure 3. Let $q(n)$, called *q-value*, be a lower bound of the solution cost at node n and $th(n)$ be RBFAOO’s threshold at n . RBFAOO keeps examining the subtree rooted at n until either $q(n) > th(n)$ or the subtree is solved optimally. In Figure 3(a), RBFAOO selects B to expand, because $w(A, B) + q(B) = w(A, B) + h(B) = 3 < w(A, C) + q(C) = w(A, C) + h(C) = 5$. It sets $th(B) = w(A, C) + q(C) - w(A, B) = 4$ to indicate that C becomes the best child (ie, $w(A, B) + q(B) > w(A, C) + q(C)$ holds) if $q(B) > th(B)$. Then, RBFAOO expands B and updates $q(B)$ by using the q -values of B ’s children (Figure 3(b)). Because $q(B) = q(D) + q(E) = h(D) + h(E) = 3$, $q(B) \leq th(B)$ still holds. Hence, RBFAOO examines B ’s descendants with no backtracks to A . Assume that D is chosen to examine. RBFAOO sets $th(D) = th(B) - q(E) = 2$ to indicate that C becomes best if $q(D) > th(D)$ holds, which is equivalent to $q(B) > th(B)$, because $q(B) = q(D) + q(E)$ and $th(B) = th(D) + q(E)$. Next, RBFAOO expands D and updates $q(D) = w(D, F) + h(F) = 4$ (Figure 3(c)). Because $q(D) > th(D)$, the subtree rooted at D contains no best leaf in terms of AO*’s strategy. RBFAOO backtracks to A by updating $q(B) = q(D) + q(E) = 6$ and examines C (Figure 3(d)) with $th(C) = w(A, B) + q(B) - w(A, C) = 6$ to be able to select B when B becomes best.

RBFAOO gradually grows its search space by updating the q -values of internal nodes and re-expanding them. The

overhead of internal node re-expansions is still high, even if RBFAOO does not always propagate back the q -values. For example, assume that an internal OR node n has two children c_1 and c_2 , c_1 is selected to re-expand, and RBFAOO proves that c_2 becomes best to examine after expanding only one leaf that is k -steps away from c_1 . If k is large, RBFAOO need to spend most of time in re-expanding internal nodes without exploring the new search space. The overestimation technique avoids this scenario by increasing the threshold while it verifies solution optimality.

3.1 ALGORITHM DESCRIPTION

Figure 4 shows the pseudo-code of RBFAOO. Let ϵ be a small number and assume $\infty - \epsilon < \infty$. In practice, a finite real number is used to represent ∞ . Let δ be an empirically tuned parameter that determines the amount of overestimation. *HasNoChildren* checks whether a node has no children (ie, terminal leaf or dead-end) or not. *Evaluate* evaluates a terminal leaf/dead-end n and returns a pair of the cost (ie, 0 or ∞) and a Boolean flag indicating whether n is solved or a dead-end. *UnsolvedChild* returns an unsolved child. *SaveInCache* saves in the cache table a q -value and a flag indicating whether a node is solved optimally or not. *RetrieveFromCache* retrieves them from the cache table. *Context* calculates the context of a node.

When RBFAOO starts solving a problem, the threshold of the root node is set to $\infty - \epsilon$. If RBFAOO exceeds this threshold, the problem is proven to have no solution. Otherwise, RBFAOO returns the optimal solution cost to the problem. In addition, RBFAOO can be easily instrumented to recover the assignment corresponding to the optimal solution cost (this extension is omitted for clarity reasons).

Function *RBFS*(n) traverses the subtree rooted at n in a depth-first manner. It calculates either an optimal solution cost or a lower bound by using *BestChild* or *Sum* and checks if the termination condition is satisfied. If the solution optimality is guaranteed at n , $n.solved$ is set to **true**.

At an OR node, *RBFS*(n) may find a suboptimal solution. In this case, $n.solved$ is still set to **false** and *RBFS*(n) continues examining other children until it finds an optimal solution at n . Because the solution cost found so far is an upper bound of the optimal one, *RBFS*(n) uses that solution cost (maintained by *ub*) to prune away unpromising branches and to adjust the threshold.

When *RBFS*(n) selects c_{best} , it examines c_{best} with a new threshold. At OR nodes, $c_{best}.th$ is set to subtracting the weight between n and c_{best} from the minimum of:

1. The current threshold for n .
2. The second smallest lower bound q_2 to solve n ’s child with considering the weight from n to that child among a list of such lower bounds of n ’s children.

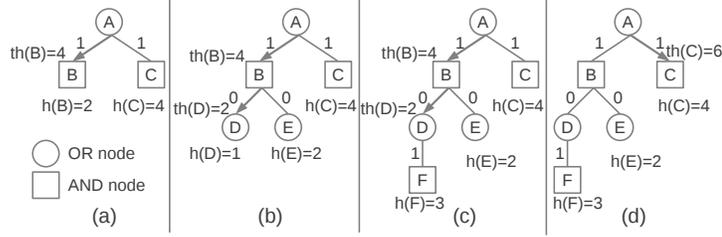

Figure 3: Snapshot of RBFAOO without overestimation.

This indicates when the current second best child becomes the best one. Additionally, a parameter δ called *overestimation rate*, that allows for returning a suboptimal solution cost is added to q_2 to avoid an excessive number of backtracks to n .

3. The upper bound of the optimal solution at n .

At AND nodes, $c_{best}.th$ is set to the sum of c_{best} 's q-value and the gap between $n.th$ and the total q-value of n 's children. If $q(c_{best}) > c_{best}.th$, $q(n) > n.th$ also holds.

Let N be the number of nodes in the search space. If the search space fits into memory, AO* expands $O(N)$ nodes in the worst case. In contrast, due to node re-expansions, RBFAOO's worst-case scenario is $O(N^2)$. However, in practice, by introducing δ , RBFAOO avoids such a high node re-expansion overhead (see Section 4).

3.2 IMPLEMENTATION DETAILS

The cache table is implemented as a hash table with the Zobrist function (Zobrist, 1970) using 96-bit integers. The Zobrist function computes almost uniformly distributed hash keys by XORing precomputed random integers, each of which represents the component of a context and is commonly used in game-playing programs and in planning. Each cache table entry preserves the context of a node to avoid collisions caused by an astronomically small possibility of two different nodes having the same hash key.

When RBFAOO fills up the cache table and tries to store new results there, some cached results must be replaced. We use SmallTreeGC (Nagai, 1999), a batch-based replacement that discards $R\%$ of the table entries with small subtree sizes. We set R to 30.

Due to floating-point errors, RBFAOO is occasionally unable to expand a new leaf. We bypass this by using small error margins when comparing floating-point numbers.

As in full RBFS (Korf, 1993), q-values of children can be increased based on the current q-value of their parent. This technique generates more accurate heuristic information when cache table entries are replaced or non-monotonic heuristic functions are used. We implemented this tech-

nique and observed small performance improvement.

3.3 CORRECTNESS AND COMPLETENESS

We prove that RBFAOO is both correct and complete for solving optimization tasks defined over graphical models even with a small cache table and arbitrary cache table replacement schemes as long as certain table entries are preserved. In contrast, $df-pn^+$ may return suboptimal solutions if the contexts of nodes are used. Additionally, although its completeness on finding either one (possibly suboptimal) or no solution is proven, $df-pn^+$ must preserve all TT entries and the completeness with TT replacement schemes remains an open question (Kishimoto and Müller, 2008). The following theorems hold with/without enhancements described in Section 3.2.

Theorem 3.1 (correctness). *Given a graphical model $\mathcal{M} = \langle \mathbf{X}, \mathbf{D}, \mathbf{F}, \Sigma \rangle$, if RBFAOO solves \mathcal{M} with admissible heuristic function h , its solution is always optimal.*

Proof. Let $v(n)$ be the optimal solution cost for node n . We first prove that for any value q for node n in the cache table, $q \leq v(n)$ holds. Since different nodes with the same context are proven to be equivalent in DAGs (Marinescu and Dechter, 2009b), we denote n as $\text{Context}(n)$ when a search result at node n is saved in the cache table. Additionally, we assume $h(n) = h(n')$ if $\text{Context}(n) = \text{Context}(n')$.

Let Cache_t be the state of the cache table immediately after the t -th save is performed in the cache table. Let $Q_t(n)$ be the value saved in Cache_t for n if that value exists in Cache_t or $h(n)$ if n is not preserved in Cache_t . By induction on t , we prove that all the entries in cache table contain values that do not overestimate optimal ones.

1. Because no result is stored in Cache_0 , the above property holds for $t = 0$.
2. Assume that the above property holds for $t = k$. $Q_{k+1}(n)$, saved in Cache_{k+1} , is then calculated as:
 - If n is a terminal leaf, $\text{Evaluate}(n)$ in the pseudo code always returns $v(n)$. $Q_{k+1}(n) = v(n)$ therefore holds.

```

// Set up for the root node
double RBFAO(node root) {
    root.th =  $\infty - \epsilon$ ;
    q = RBFS(root);
    return q;
}
// Depth-first search with a threshold
double RBFS(node n) {
    // Terminal leaf/dead-end check
    if (HasNoChildren(n)) {
        // Calculate the probability
        // for a terminal leaf or dead-end
        (q, s) = Evaluate(n);
        // Store search results
        SaveInCache(Context(n), q, s);
        return q;
    }
    GenerateChildren(n);
    // Continue search until satisfying
    // the termination condition
    if (n is an OR node)
        loop {
            (cbest, q, q2, ub) = BestChild(n);
            if (n.th < q || n.solved = true)
                break;
            // Update the threshold
            cbest.th = min(n.th,
                q2 +  $\delta$ ,
                ub) - w(n, cbest);
            RBFS(cbest);
        }
    else
        loop { // AND node
            q = Sum(n);
            if (n.th < q || n.solved = true)
                break;
            (cbest, qcbest) = UnsolvedChild(n);
            // Update the threshold
            cbest.th = n.th - (q - qcbest);
            RBFS(cbest);
        }
    // Store search results
    SaveInCache(Context(n), q, n.solved);
    return q;
}

// Select the best child
double BestChild(node n) {
    q = q2 = ub =  $\infty$ ;
    n.solved = false;
    foreach (n's child ci) {
        ct = Context(ci);
        if (ct is in the cache table)
            (qci, s) = RetrieveFromCache(ct);
        else {
            qci = h(ci);
            s = false;
        }
        qci = w(n, ci) + qci;
        if (s = true) // ci is solved
            ub = min(ub, qci);
        if (qci < q ||
            (qci = q && n.solved = false)) {
            q2 = q;
            n.solved = s;
            q = qci;
            cbest = ci;
        } else if (qci < q2)
            q2 = qci;
    }
    return (cbest, q, q2, ub);
}
// Calculate the total value
double Sum(node n) {
    q = 0;
    n.solved = true;
    foreach (n's child ci) {
        ct = Context(ci);
        if (ct is in the cache table)
            (qci, s) = RetrieveFromCache(ct);
        else {
            qci = h(ci);
            s = false;
        }
        q = q + qci;
        n.solved = n.solved  $\wedge$  s;
    }
    return q;
}

```

Figure 4: Pseudo-code of RBFAO

- If n is an internal OR node, $Q_{k+1}(n) = w(n, c_{best}) + Q_k(c_{best}) = \min_i (w(n, c_i) + Q_k(c_i))$ holds where c_i is n 's child. Additionally, because $Q_k(c_i) \leq v(c_i)$, $Q_{k+1}(n) \leq \min_i (w(n, c_i) + v(c_i)) = v(n)$ holds.
- If n is an internal AND node, $Q_{k+1}(n) = \sum_i Q_k(c_i)$ where c_i is n 's child. Since $Q_k(c_i) \leq v(c_i)$, $Q_{k+1}(n) \leq \sum_i v(c_i) = v(n)$ holds.

Hence, $Q_t(n) \leq v(n)$ holds in case of $t = k + 1$.

Let $Q(\text{root})$ be a value that is about to be saved in the cache table with satisfying the termination condition of

$\text{root.solved} = \text{true}$. $Q(\text{root}) \leq v(\text{root})$ holds from the above. Additionally, because RBFAO has traced a solution tree with the cost of $Q(\text{root})$, $v(\text{root}) \leq Q(\text{root})$ holds. Therefore, $Q(\text{root}) = v(\text{root})$ holds. \square

Theorem 3.2 (completeness). *Let $\mathcal{M} = \langle \mathbf{X}, \mathbf{D}, \mathbf{F}, \Sigma \rangle$ be a graphical model with primal graph G , let \mathcal{T} be a pseudo tree G and let $C_{\mathcal{T}}$ be the context minimal AND/OR search graph based on \mathcal{T} (also a finite DAG). Assume that RBFAO preserves the q -values of the nodes n_1, n_2, \dots, n_k which are on the current search path and the q -values of n_i 's siblings. Then RBFAO eventually returns an optimal solution or proves no solution exists.*

Proof sketch. Let a *marked* node be a node expanded at least once by RBFAOO and an *unmarked* node be a node that has never been expanded. Denote $p_1 \subset p_2$ if the path length of p_2 is longer than that of p_1 and p_2 is identical to p_1 if p_2 is limited to the path with the length of p_1 . Denote $p_1 \not\subset p_2$ unless it holds $p_1 \subset p_2$. Let $s(n, p)$ be the sum of the edge costs from the root to n via path p . Assume that $s(n, p) + q(n) < \infty - \epsilon$ holds for any path p if $q(n) \neq \infty$, which is reasonable in practical settings.

Let $q_{t,p}(n)$ and $th_{t,p}(n)$ be the q-value and threshold for t -th visit to n via path p , respectively. Assume that RBFAOO expands no unmarked nodes after expanding k unmarked nodes. Then, because the search space is finite, there are two unproven marked nodes n and m examined as follows:

1. RBFAOO starts searching downward from n via path p_1 since $q_{t_1,p_1}(n) \leq th_{t_1,p_1}(n)$ holds.
2. RBFAOO reaches m via path p_2 that satisfies $th_{t_2,p_2}(m) < q_{t_2,p_2}(m)$ and $p_1 \subset p_2$.
3. RBFAOO keeps exploring the remaining search space rooted at n via p_1 (and composed of marked nodes) and backtracks to n .
4. Continue steps (1)-(3).

If n is an AND node, satisfying $th_{t',p_3}(c) < q_{t',p_3}(c)$ immediately leads to satisfying $th_{t,p_1}(n) < q_{t,p_1}(n)$ where c is n 's unproven child and $p_1 \subset p_3$. Because backtracking to n 's parent contradicts step (1), n is an OR node. Additionally, $th_{t',p_3}(c) < th_{u,p_3}(c)$ holds for any unproven child $c, t' < u$ and $p_1 \subset p_3$, because the q-values of n 's children are preserved in memory as described in the assumption of the theorem. With similar discussions, there is an infinite sequence $u_1, u_2, \dots, u_k, \dots$ that satisfies $u_i < u_j$ for $i < j$, $th_{u_i,p_2}(m) < th_{u_j,p_2}(m)$ and $th_{u_i,p_2}(m) < q_{u_i,p_2}(m)$. This indicates that m has at least one unproven child o_1 via path r_1 ($p_2 \not\subset r_1$) that contributes to increasing $q_{u_i,p_2}(m)$ and satisfying $th_{u_i,p_2}(m) < q_{u_i,p_2}(m)$ when $q_{u_i,p_2}(m)$ is calculated. Because the search space is DAG, $q(o_1)$ is never affected by $q(m)$. With similar discussions, if no unmarked node is expanded, there is an infinite number of nodes $o_1, o_2, \dots, o_k, \dots$, where o_{j+1} is a child of o_j that contributes to increasing $q(o_j)$ and satisfying $th(o_j) < q(o_j)$. However, this contradicts the assumption of the finite search space. Hence, by eventually examining the whole search space, RBFAOO finds an optimal solution (see Theorem 3.1) or proves no solution. \square

4 EXPERIMENTS

We empirically evaluate our proposed best-first search scheme on the MAP task in graphical models. We compare

RBFAOO against the state-of-the-art depth-first and best-first AND/OR search solvers proposed recently in (Marinescu and Dechter, 2009b) and denoted by AOBB and AOBF, respectively. All competing algorithms use pre-compiled mini-bucket heuristics (Kask and Dechter, 2001; Marinescu and Dechter, 2009b) for guidance and are restricted to a static variable ordering obtained as a depth-first traversal of a minfill pseudo tree (Marinescu and Dechter, 2009a). Since AOBF cannot use an initial upper bound (obtained via local search) we also disabled its use by AOBB and RBFAOO in order to maintain a fair comparison.

Our benchmark problems¹ include three sets of instances from genetic linkage analysis (Fishelson and Geiger, 2002) (denoted pedigree), grid networks and protein side-chain interaction networks (denoted pdb) (Yanover et al., 2008). In total, we evaluated 21 pedigrees, 32 grids and 240 protein networks. The algorithms were implemented in C++ (64-bit) and the experiments were run on a 2.6GHz 8-core processor with 80GB of RAM.

We report the CPU time in seconds and the number of nodes expanded for solving the problems. We also specify the problems parameters such as the number of variables (n), maximum domain size (k), the depth of the pseudo tree (h) and the induced width of the graph (w^*). The best performance points are highlighted. In each table, 'oom' stands for out-of-memory and '-' denotes out-of-time. Note that oom for RBFAOO/AOBB indicates that the mini-bucket heuristic pre-computation procedure uses up the physical memory before search is performed.

Tables 1 and 2 show the results obtained for experiments with pedigree, grid and protein networks. For space reasons and clarity we select a representative subset from the full 293 instances. The columns are indexed by the mini-bucket i -bound which ranged between 6 and 16 for pedigrees and grids, and between 2 and 5 for proteins, respectively. All algorithms were allotted a 1 hour time limit. Algorithm AOBF(i) was allowed a maximum of 80GB of RAM while algorithm RBFAOO(i) used a 10-20GB cache table with 134,217,728 entries pre-allocated before search. The overestimation parameter δ was set to 1.

We observe clearly that RBFAOO(i) improves considerably over its competitors, especially at relatively small i -bounds which yield relatively weak heuristics. For example, on the pedigree30 instance, RBFAOO(6) with the smallest reported i -bound ($i = 6$) was 4 and 41 times faster than AOBF(6) and AOBB(6), respectively. Similarly, RBFAOO(6) solves the 75-23-5 grid in about 30 minutes and expands over 300 million nodes, while both AOBB(6) and AOBF(6) run out of time and memory, respectively. As the i -bound increases and the heuristics become more accurate thus pruning the search space more effectively, the differences in running time between the algorithms de-

¹All instances are available at <http://graphmod.ics.uci.edu>.

Table 1: CPU time (seconds) and number of nodes expanded for pedigree and grid networks. Time limit 1 hour. RBFAOO(i) ran with a 10-20GB cache table (134,217,728 entries) and overestimation parameter $\delta = 1$.
