crease. In terms of the size of the search spaces explored, we see that AOBF(i) typically expands the smallest number of nodes, as expected. RBFAOO(i) expands more nodes than AOBF(i), due to re-expansions, but in many cases it expands significantly fewer nodes than AOBB(i) which translates into important time savings. We also notice that RBFAOO(i) and AOBB(i) have a relatively small overhead per node expansion. On the other hand, the computational overhead of AOBF(i) is much larger. It is caused primarily by maintaining an extremely large search space in memory and, secondly, because the node values are typically updated all the way up to the root. Most notably, RBFAOO(i) was the only algorithm that could solve the most difficult instances in these benchmarks (eg, pedigrees 7, 13, 19 and 41, as well as grid 75-26-5). This demonstrates the benefit of expanding nodes in best-first rather than depth-first manner as well as using efficiently a bounded amount of memory, thus overcoming the most critical limitation of AOBF(i). Finally, the results on the protein networks show a similar pattern, namely RBFAOO(i) improves considerably over both AOBB(i) and AOBF(i) for relatively small i -bounds. This is important because, unlike the pedigrees and grids, these problems have very large domains (81 val-

ues) and therefore the mini-bucket heuristics could only be compiled for small i -bounds. Figure 5 which plots the normalized total CPU time as a function of the i -bound summarizes the running time profile of the competing algorithms across the benchmarks we considered.

In Table 3 we report on five additional very difficult genetic linkage analysis networks. The mini-bucket i -bound was set to 20 in this case. We see again that RBFAOO is the best performing algorithm closing all instances within the 100 hour time limit. In contrast, AOBB could solve only one instance while AOBF ran out of memory. For example, on the type4-120-17 instance, RBFAOO was nearly 3 orders of magnitude faster than AOBB, while expanding 3 orders of magnitude fewer nodes.

We summarize next the most important additional factors that could help improve RBFAOO(i)’s performance.

Impact of caching: Table 4 shows the average performance of algorithm RBFAOO(i) (as CPU time in seconds, number of nodes expanded, and number of problem instances solved) as a function of available memory, across all three benchmarks. The columns are indexed by the cache table size used, namely *very small* (10-20MB), *small*

Table 2: CPU time (seconds) and number of nodes expanded for protein networks. Time limit 1 hour. RBFAOO(i) ran with a 10-20GB cache table (134,217,728 entries) and overestimation parameter $\delta = 1$.

(100-200MB), *medium* (1-2GB) and *large* (10-20GB), respectively. We see that, as expected, as more memory is available, the performance improves considerably, namely more problem instances are solved while the running time and size of the search space decrease significantly. The best results were obtained with the 10-20GB cache.

Impact of overestimation: Figure 6 plots the CPU time, node re-expansion rate (as the ratio of the number of nodes re-expanded to the total number of expansions) and percentage of problem instances solved by RBFAOO(i) as a function of the overestimation rate δ , across all bench-

marks. We see that RBFAOO(i) without overestimation (ie, $\delta = 0$) performed rather poorly and was outperformed considerably by AOBB(i) and AOBF(i), respectively. This was due to a relatively large number of node re-expansions. On grids, for example, more than 78% of the nodes were actually re-expanded for $\delta = 0$ compared to only 11% re-expansions for $\delta = 1.2$. However, as δ increases the re-expansion rate decreases but the CPU time starts to increase due to explorations of unpromising search spaces. Therefore, we obtained the overall best performance for $\delta = 1$.

Impact of heuristics quality: Based on our empirical evaluation we noticed that RBFAOO(i) was superior to its competitors especially for relatively inaccurate heuristics (which are typically obtained for smaller i -bounds) and on the hardest problem instances. This is important because it is likely that for these types of problems it may only be possible to compute rather weak heuristics given limited resources (eg, *type4* instances in Table 3).

5 RELATED WORK

Algorithms based on proof and disproof numbers (Allis et al., 1994) have been dominating AND/OR search techniques and successfully applied to many game domains (eg, (Nagai, 2002; Kishimoto and Müller, 2005; Schaeffer et al., 2007)). See (Kishimoto et al., 2012) for a comprehensive literature review.

Table 4: Average CPU time (seconds), number of nodes expanded and number of problem instances solved by RBFAOO(i) with different cache sizes. Time limit 1 hour. $i = 10$ for grids and pedigrees, $i = 4$ for protein networks.

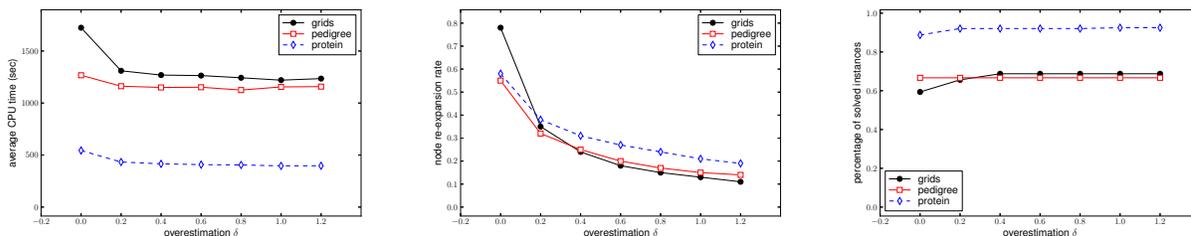

Figure 6: Average CPU time (seconds), node re-expansion rate and percentage of instances solved by RBFAOO(i) as a function of the overestimation rate δ . Time limit 1 hour. $i = 10$ for grids and pedigrees, $i = 4$ for protein networks.

A proof/disproof number estimates the difficulty of proving that the first/second player wins in a partially built tree. The proof number of node n is defined as the minimum number of leaf nodes that must be expanded to prove that the first player wins at n . A node with a smaller proof number is assumed to be easier to prove a win for the first player. In contrast, the disproof number of n is the minimum number of leaf nodes that must be expanded to prove that the second player wins at n . A node with a smaller disproof number is assumed to be easier to prove a win for the second player.

Depth-First Proof-Number Search (df-pn) (Nagai, 2002) is a depth-first reformulation of Best-First Proof-Number Search (PNS) (Allis et al., 1994) enhanced with a so-called transposition table (TT), a cache table preserving the search effort for the expanded nodes. While preserving PNS’ leaf selection strategy, df-pn empirically re-expands fewer internal nodes than PNS that always restarts from the root the procedure of finding a promising leaf to expand. Besides, df-pn runs using a small amount of space limited by the TT size in practice, although whether df-pn is complete or not with a limited amount of TT still remains an open question. As in RBFS (Korf, 1993), df-pn introduces thresholds to limit the search depth of depth-first search. Df-pn updates the thresholds of a node by taking into account when the search tree rooted at that node contains none of the most promising leaf nodes chosen by PNS’ best-first strategy. The df-pn⁺ algorithm (Nagai, 2002) generalizes df-pn by introducing evaluation functions to heuristically initialize proof and disproof numbers and a weight in each edge to decrease the overhead of node re-expansions (Kishimoto and Müller, 2005).

Other related work includes MAO* (Chakrabati et al., 1989), memory-limited AO*. Although MAO* can run under a similar memory limit to RBFAOO, it needs a spe-

cific strategy to discard examined nodes from memory. In contrast, RBFAOO can leverage arbitrary TT replacement strategies including SmallTreeGC (Nagai, 1999), which is empirically most effective in solving games. Additionally, by incorporating ideas behind RBFS and the overestimation technique, RBFAOO has much smaller overhead to update node values than MAO* and AO*.

6 CONCLUSION

The paper presents RBFAOO, a limited memory best-first AND/OR search algorithm for solving combinatorial optimization defined over graphical models. RBFAOO belongs to the Recursive Best-First Search family of algorithms and therefore uses a threshold controlling mechanism to guide the search in a depth-first like manner. It also employs a flexible caching scheme to reuse partial search results as well as an overestimation mechanism to further reduce the internal node re-expansions. We prove correctness and completeness of the algorithm. We evaluate RBFAOO empirically on a variety of benchmarks used during the PASCAL2 Inference Challenge. Our results show that RBFAOO is often superior to current state-of-the-art solvers based on AND/OR search, especially on the most difficult problem instances.

For future work we plan to extend RBFAOO to use dynamic variable orderings, an initial upper bound obtained via local search and soft arc-consistency based heuristics. One possibility we are currently investigating is to implement RBFAOO on top of the `toulbar` solver (de Givry et al., 2005). Since many interesting real-world problems are still too hard to solve exactly, we also plan to convert the algorithm into an anytime best-first search scheme.

Abstract

The implication problem for saturated conditional independence statements is studied in the presence of fixed and undetermined sets of incomplete random variables. Here, random variables are termed incomplete since they admit missing data. Two different notions of implication arise. In the classic notion of V -implication, a statement is implied jointly by a set of statements and a fixed set V of random variables. In the alternative notion of pure implication, a statement is implied by a given set of statements alone, leaving the set of random variables undetermined. A first axiomatization for V -implication is established that distinguishes purely implied from V -implied statements. Axiomatic, algorithmic and logical characterizations of pure implication are established. Pure implication appeals to applications in which the existence of random variables is uncertain, for example, when independence statements are integrated from different sources, when random variables are unknown or shall remain hidden.

1 INTRODUCTION

The concept of conditional independence (CI) is important for capturing structural aspects of probability distributions, for dealing with knowledge and uncertainty in artificial intelligence, and for learning and reasoning in intelligent systems [Darwiche (2009); Dawid (1979); Pearl (1988)]. Application areas include natural language processing, speech processing, computer vision, robotics, computational biology, and error-control coding [Darwiche (2009); Halpern (2005); Niepert et al. (2013)]. Central to these applications is the implication problem, which is to decide for an arbitrary set V of random variables, and an arbitrary set $\Sigma \cup \{\varphi\}$ of CI statements over V , whether every probability model that satisfies every element in Σ also sat-

isfies φ . Indeed, non-implied CI statements represent new opportunities to construct complex probability models with polynomially many parameters and to efficiently organize distributed probability computations [Geiger and Pearl (1993)]. An algorithm for deciding the implication problem can also test the consistency of independence and dependence statements collected from different sources; which is particularly important as these statements often introduce non-linear constraints resulting in unfeasible CSP instances [Geiger and Pearl (1993); Niepert et al. (2013)]. While the decidability of the implication problem for CI statements relative to discrete probability measures remains open, it is not axiomatizable by a finite set of Horn rules [Studený (1992)] and already coNP-complete for stable CI statements [Niepert, Van Gucht, and Gyssens (2010)]. An important subclass are therefore saturated CI (SCI) statements, in which all given random variables occur. In fact, graph separation and SCI statements enjoy the same axioms [Geiger and Pearl (1993)], and the implication problem of SCI statements is decidable in almost linear time [Galil (1982)]. These results contribute to the success story of Bayesian networks in AI and machine learning [Darwiche (2009); Geiger and Pearl (1993)], and have recently been carried over to the presence of missing data [Link (2013a)]. Here, independence is not judged on conditions that carry missing data. The findings complement a long line of AI research on the recognized need to reveal missing data and to explain where they come from, e.g. [Chickering and Heckerman (1997); Dempster, Laird, and Rubin (1977); Friedman (1997); Lauritzen (1995); Marlin et al. (2011); Saar-Tsechansky and Provost (2007); Singh (1997); Zhu et al. (2007)]. It is important to realize that implication problems of SCI statements in the presence of missing data differ from implication problems in the absence of data. For an illustration, consider a simplified burglary example. A r (obbery) sets off an a (larm) causing s (heldon) or b (atman) to call security. The independence between sb and r , given a , can be stated as the SCI statement $I(sb, r|a)$ over $V = \{b, a, r, s\}$. In the absence of missing data, $I(s, b|ar)$ and $I(sb, r|a)$ together do V -imply $I(s, br|a)$. With missing data present, however, $I(s, b|ar)$

and $I(sb, r|a)$ together do not V -imply $I(s, br|a)$:

r	a	b	s	P
–	true	true	true	0.5
–	true	false	false	0.5

Here, $I(s, b|ar)$ is satisfied as the assignments on the condition ar involve missing data, represented by –.

Most of the literature on the implication problem for SCI statements have focused on the notion of implication in which the underlying set V of random variables is assumed to be fixed. However, the assumption that V is fixed may not be practical: for example, the fact that not all random variables are known yet should not prevent us from declaring some independence statements; or even if we know all random variables, we may not want to disclose all of them; or when independence statements are integrated from different sources. Instead, we may want to state that given a , sb is independent from the set of remaining random variables, no matter what they are. This statement could be written as $I(sb|a)$. The intriguing point here is the difference between declaring $I(sb|a)$ and declaring $I(r|a)$ when V is left undetermined. In fact, the probability model

r	a	b	s	e	P
true	true	–	–	true	0.5
false	true	–	–	false	0.5

satisfies $I(sb|a)$, but does not satisfy $I(r|a)$. We conclude that $I(sb|a)$ implies $I(r|a)$ for the fixed set V , but $I(sb|a)$ does not imply $I(r|a)$ when the set of random variables is left undetermined.

The example illustrates the need to distinguish between different notions of semantic implication. The first notion is that of V -implication. For example, Link (2013a) established an axiomatization \mathcal{U}_V for the V -implication problem of SCI statements in the presence of missing data. The alternative, stronger notion of pure implication leaves the set of random variables undetermined: the pure implication problem is to decide for every given set $\Sigma \cup \{\varphi\}$ of SCI statements, whether for every probability model π that involves at least all the random variables in $\Sigma \cup \{\varphi\}$ and that satisfies Σ , π also satisfies φ . Pure implication allows us to use independence statements without knowing all the random variables. This lowers barriers for their use and makes them applicable in demanding frameworks where some variables shall remain unknown for some users and where we still want to know how complex probability distributions can be organized efficiently. That is, pure implication enables us to reason under uncertainty about the random variables, while V -implication does not. For illustration, suppose we want to keep the random variable r hidden. Then it is impossible to reason about SCI statements under the notion of V -implication. With pure implication we can still state $I(sb|a)$ and $I(b|a)$, and our results show that we can even conclude $I(s|a)$ from that.

Contribution. In Section 2 we show that the only existing finite axiomatization \mathcal{U}_V for the V -implication of SCI statements cannot distinguish between purely implied and V -implied SCI statements. That is, there are purely implied SCI statements for which every inference by \mathcal{U}_V applies the V -symmetry rule; giving incorrectly the impression that the pure implication of an SCI statement depends on V . In Section 3 we establish a finite axiomatization \mathcal{C}_V such that every purely implied SCI statement can be inferred without any application of the V -symmetry rule; every V -implied SCI statement can be inferred with only a single application of the V -symmetry rule, and this application is done in the last step of the inference. In Section 4 we establish a finite axiomatization \mathcal{C} for the pure implication of SCI statements. As \mathcal{C} results from \mathcal{C}_V by removal of the symmetry rule, the results show that the symmetry rule is only necessary to infer those SCI statements that are V -implied but not implied. In Section 5, pure implication is characterized by V -implication where V involves random variables that do not occur in any of the given SCI statements. In Sections 6, 7 and 8 this result is exploited to characterize the pure implication problem i) logically by a propositional fragment under interpretations by Levesque’s situations, ii) by multivalued database dependencies involving missing data, and iii) by an algorithm that decides pure implication in almost linear time. Related work is discussed in Section 9. We conclude in Section 10.

2 IMPLICATION UNDER FIXED SETS OF RANDOM VARIABLES

We summarize the semantics of CI statements in the presence of missing data from Link (2013a). A definition is given that embodies the ability of an axiomatization to separate V -implied from purely implied SCI statements. It is shown that the existing axiomatization \mathcal{U}_V for V -implication from Link (2013a) does not have this ability.

We denote by \mathfrak{V} a countably infinite set of distinct symbols $\{v_1, v_2, \dots\}$ of *random variables*. A *domain mapping* is a mapping that associates a set, $dom(v_i)$, with each random variable v_i of a finite set $V \subseteq \mathfrak{V}$. This set is called the *domain* of v_i and each of its elements is a *data value* of v_i . We assume that each domain $dom(v_i)$ contains the element –, which we call the *marker*. Although we use the element – like any other data value, we prefer to think of – as a marker, denoting that no information is currently available about the data value of v_i . The interpretation of this marker as no information means that a data value does either not exist (known as a structural zero in statistics, and the null marker inapplicable in databases), or a data value exists but is currently unknown (known as a sampling zero in statistics, and the null marker applicable in databases). The disadvantage of using this interpretation is a loss in knowledge when representing data values known to not

exist, or known to exist but currently unknown. This interpretation overcomes the computational difficulties when more expressive interpretations of missing data are used. As another key advantage one can represent missing data values, even if it is unknown whether they do not exist, or exist but are currently unknown. Strictly speaking, we shall call such random variables *incomplete* as their data values may be missing. For simplicity, we continue to speak off random variables for the remainder of this paper, although we really do mean incomplete random variables. For $X = \{v_1, \dots, v_k\} \subseteq V$ we say that \mathbf{a} is an assignment of X , if $\mathbf{a} \in \text{dom}(v_1) \times \dots \times \text{dom}(v_k)$. For an assignment \mathbf{a} of X we write $\mathbf{a}(y)$ for the projection of \mathbf{a} onto $Y \subseteq X$. We say that $\mathbf{a} = (\mathbf{a}_1, \dots, \mathbf{a}_k)$ is *X-complete*, if $\mathbf{a}_i \neq -$ for all $i = 1, \dots, k$.

A *probability model* over a finite set $V = \{v_1, \dots, v_n\}$ of random variables is a pair (dom, P) where dom is a domain mapping that maps each v_i to a finite domain $\text{dom}(v_i)$, and $P : \text{dom}(v_1) \times \dots \times \text{dom}(v_n) \rightarrow [0, 1]$ is a probability distribution having the Cartesian product of these domains as its sample space.

The expression $I(Y, Z|X)$ where X, Y and Z are disjoint subsets of V is called a *conditional independence (CI) statement* over V . The set X is called the *condition* of $I(Y, Z|X)$. If $XYZ = V$, we call $I(Y, Z|X)$ a *saturated CI (SCI) statement*. Let (dom, P) be a probability model over V . Following Link (2013a), a CI statement $I(Y, Z|X)$ is said to *hold for* (dom, P) if for every complete assignment \mathbf{x} of X , and for every assignment \mathbf{y}, \mathbf{z} of Y and Z , respectively,

$$P(\mathbf{x}, \mathbf{y}, \mathbf{z}) \cdot P(\mathbf{x}) = P(\mathbf{x}, \mathbf{y}) \cdot P(\mathbf{x}, \mathbf{z}). \quad (1)$$

Equivalently, (dom, P) is said to *satisfy* $I(Y, Z|X)$.

The satisfaction of $I(Y, Z|X)$ requires Equation 1 to hold for *complete* assignments \mathbf{x} of X only. The reason is that the independence between an assignment \mathbf{y} and an assignment \mathbf{z} is conditional on the assignment \mathbf{x} . Indeed, in case there is *no information* about the assignment \mathbf{x} , then there should not be any requirement on the independence between \mathbf{y} and \mathbf{z} .

SCI statements interact with one another, and these interactions have been formalized by the following notion of semantic implication. Let $\Sigma \cup \{\varphi\}$ be a set of SCI statements over V . We say that Σ *V-implies* φ , denoted by $\Sigma \models_V \varphi$, if every probability model over V that satisfies every SCI statement $\sigma \in \Sigma$ also satisfies φ . The *V-implication problem* is the following problem.

PROBLEM:	<i>V-implication problem</i>
INPUT:	Set V of random variables Set $\Sigma \cup \{\varphi\}$ of SCI statements over V
OUTPUT:	Yes, if $\Sigma \models_V \varphi$; No, otherwise

For Σ we let $\Sigma_V^* = \{\varphi \mid \Sigma \models_V \varphi\}$ be the *semantic closure*

Table 1: Axiomatization \mathfrak{U} under Incomplete RVs

$\frac{}{I(V - X, \emptyset X)}$ (triviality, \mathcal{T}')	$\frac{I(Y, Z X)}{I(Z, Y X)}$ (symmetry, \mathcal{S})
$\frac{I(YZ, UW X) \ I(YU, ZW X)}{I(YZU, W X)}$ (algebra, \mathcal{A}')	$\frac{I(Y, ZW X)}{I(Y, Z XW)}$ (weak union, \mathcal{W}')

of Σ , i.e., the set of all SCI statements V -implied by Σ . In order to determine the V -implied SCI statements we use a syntactic approach by applying inference rules. These inference rules have the form

$$\frac{\text{premises}}{\text{conclusion}}$$

and inference rules without any premises are called axioms. An inference rule is called *V-sound*, if the premises of the rule V -imply the conclusion of the rule. We let $\Sigma \vdash_{\mathfrak{R}} \varphi$ denote the *inference* of φ from Σ by the set \mathfrak{R} of inference rules. That is, there is some sequence $\gamma = [\sigma_1, \dots, \sigma_n]$ of SCI statements such that $\sigma_n = \varphi$ and every σ_i is an element of Σ or results from an application of an inference rule in \mathfrak{R} to some elements in $\{\sigma_1, \dots, \sigma_{i-1}\}$. For Σ , let $\Sigma_{\mathfrak{R}}^+ = \{\varphi \mid \Sigma \vdash_{\mathfrak{R}} \varphi\}$ be its *syntactic closure* under inferences by \mathfrak{R} . A set \mathfrak{R} of inference rules is said to be *V-sound (V-complete)* for the V -implication of SCI statements, if for every V and for every set Σ of SCI statements over V , we have $\Sigma_{\mathfrak{R}}^+ \subseteq \Sigma_V^*$ ($\Sigma_V^* \subseteq \Sigma_{\mathfrak{R}}^+$). The (finite) set \mathfrak{R} is said to be a (finite) *axiomatization* for the V -implication of SCI statements if \mathfrak{R} is both V -sound and V -complete.

Table 1 contains the set $\mathfrak{U} = \{\mathcal{T}', \mathcal{S}, \mathcal{A}', \mathcal{W}'\}$ of inference rules that form a finite axiomatization for the V -implication of SCI statements under incomplete random variables, as established in Link (2013a).

Motivated by the introductory remarks we now write $I(Y|X)$ instead of writing $I(V - XY, Y|X)$ for an SCI statement over V . It is first shown that the system $\mathfrak{U}_V = \{\mathcal{T}, \mathcal{S}, \mathcal{A}, \mathcal{W}\}$ from Table 2 forms a finite axiomatization for the V -implication of such SCI statements under incomplete random variables.

Proposition 1 \mathfrak{U}_V is a finite axiomatization for the V -implication of SCI statements under incomplete random variables.

Proof Let $V \subseteq \mathfrak{V}$ be a finite set of random variables. Let $\Sigma = \{I(Y_1|X_1), \dots, I(Y_n|X_n)\}$ and $\varphi = I(Y|X)$ be a (set of) SCI statement(s) over V . We can show by an induction over the inference length that $\Sigma \vdash_{\mathfrak{U}_V} \varphi$ if

Table 2: Axiomatization \mathfrak{U}_V under Incomplete RVs

$\frac{}{I(\emptyset X)}$ (triviality, \mathcal{T})	$\frac{I(Y X)}{I(V - XY X)}$ (V-symmetry, \mathcal{S}_V)
$\frac{I(Y X) \quad I(Z X)}{I(YZ X)}$ (union, \mathcal{U})	$\frac{I(Y X)}{I(Y - Z XZ)}$ (weak union, \mathcal{W})

and only if $\Sigma' = \{I(Y_1, V - X_1 Y_1 | X_1), \dots, I(Y_n, V - X_n Y_n | X_n)\} \vdash_{\mathfrak{U}} I(V - XY, Y | X)$. Hence, the V -soundness (V -completeness) of \mathfrak{U}_V follows from the the V -soundness (V -completeness) of \mathfrak{U} . ■

Example 2 Consider $\Sigma = \{I(sb|a), I(b|a)\}$ and $\varphi = I(s|a)$ as a (set of) SCI statement(s) over $V = \{b, a, r, s\}$. Then $\Sigma \models_V \varphi$ as we can show, for example, by the following inference:

$$\frac{\frac{I(sb|a)}{\mathcal{S}_V : I(r|a)} \quad I(b|a)}{\mathcal{U} : I(rb|a)} \quad .$$

$$\frac{}{\mathcal{S}_V : I(s|a)}$$

However, since the inference applies the V -symmetry rule it is not clear whether φ is implied by Σ alone, that is, whether it is true that for all V' that include at least a, s, b it holds that $\Sigma \models_{V'} \varphi$. In fact, if we were to find an inference of φ from Σ by \mathfrak{U}_V that never applies the V -symmetry rule \mathcal{S}_V , then we would know that φ is not only V -implied by Σ but even implied by Σ alone.

The last example motivates the following definition. It addresses the property of an inference system to first infer all those SCI statements implied by a set of SCI statements alone, without any application of the symmetry rule, and, subsequently, apply the V -symmetry rule once to some of these SCI statements to infer all V -implied SCI statements that do depend on the underlying set V of random variables.

Definition 3 Let \mathfrak{S}_V denote a set of inference rules that is V -sound for the V -implication of SCI statements, and in which the V -symmetry rule \mathcal{S}_V is the only inference rule that is dependent on V . We say that \mathfrak{S}_V is conscious of pure implication, if for every V , and every set $\Sigma \cup \{\varphi\}$ of SCI statements over V such that φ is V -implied by Σ there is some inference of φ from Σ by \mathfrak{S}_V such that the V -symmetry rule \mathcal{S}_V is applied at most once, and, if it is applied, then it is applied in the last step of the inference only.

Example 2 and Definition 3 motivate the question if \mathfrak{U}_V is conscious of pure implication.

Theorem 4 \mathfrak{U}_V is not conscious of pure implication.

Proof Let $V = \{b, a, r, s\}$ and $\Sigma = \{I(b|a), I(bs|a)\}$. One can show that $I(s|a) \notin \Sigma_{\{\mathcal{T}, \mathcal{W}, \mathcal{U}\}}^+$. Moreover, for all Y such that $r \in Y$, $I(Y|a) \notin \Sigma_{\{\mathcal{T}, \mathcal{W}, \mathcal{U}\}}^+$, see Lemma 10 from Section 4. However, $I(s|a) \in \Sigma_{\mathfrak{U}_V}^+$ as shown in Example 2. Consequently, in any inference of $I(s|a)$ from Σ by \mathfrak{U}_V the V -symmetry rule \mathcal{S}_V must be applied at least once, but is not just applied in the last step as $r \in V - \{b, a, s\}$. ■

In view of Theorem 4 it is natural to ask whether there is any axiomatization that is conscious of pure implication.

3 GAINING CONSCIOUSNESS

Theorem 4 has shown that axiomatizations are, in general, not conscious of pure implication. We will now establish a finite conscious axiomatization for the V -implication of SCI statements under incomplete random variables. For this purpose, we consider the *difference rule* \mathcal{D} as a new V -sound inference rule:

$$\frac{I(Y|X) \quad I(Z|X)}{I(Y - Z|X)}$$

The V -soundness of the difference rule \mathcal{D} follows easily from the algebra rule \mathcal{A}' .

Theorem 5 Let Σ be a set of SCI statements over V . For every inference γ from Σ by the system $\mathfrak{U}_V = \{\mathcal{T}, \mathcal{S}_V, \mathcal{U}, \mathcal{W}\}$ there is an inference ξ from Σ by the system $\mathfrak{C}_V = \{\mathcal{T}, \mathcal{S}_V, \mathcal{U}, \mathcal{W}, \mathcal{D}\}$ such that

1. γ and ξ infer the same SCI statement,
2. \mathcal{S}_V is applied at most once in ξ ,
3. if \mathcal{S}_V is applied in ξ , then as the last rule.

Proof The proof is done by induction on the length l of γ . For $l = 1$, the statement $\xi := \gamma$ has the desired properties. Suppose for the remainder of the proof that $l > 1$, and let $\gamma = [\sigma_1, \dots, \sigma_l]$ be an inference of σ_l from Σ by \mathfrak{U}_V . We distinguish between four different cases according to how σ_l is obtained from $[\sigma_1, \dots, \sigma_{l-1}]$.

Case 1. σ_l is obtained from the triviality axiom \mathcal{T} , or is an element of Σ . In this case, $\xi := [\sigma_l]$ has the desired properties.

Case 2. We obtain σ_l by an application of the weak union rule \mathcal{W} to a premise σ_i with $i < l$. Let ξ_i be obtained by applying the induction hypothesis to $\gamma_i = [\sigma_1, \dots, \sigma_i]$. Consider the inference $\xi := [\xi_i, \sigma_l]$. If in ξ_i the V -symmetry rule \mathcal{S}_V is not applied, then ξ has the desired properties. If in ξ_i the \mathcal{S}_V is applied as the last rule, then the last two steps in ξ are of the following form:

$$\frac{\frac{I(Y|X)}{\mathcal{S}_V : I(V - XY|X)}}{\mathcal{W} : I(V - XYZ|XZ)}$$

However, these steps can be replaced as follows:

$$\frac{\frac{I(Y|X)}{W : I(Y - Z|XZ)}}{S_V : I(V - XYZ|XZ)} .$$

The resulting inference has the desired properties.

Case 3. We obtain σ_l by an application of the union rule \mathcal{U} to premises σ_i and σ_j with $i, j < l$. Let ξ_i and ξ_j be obtained by applying the induction hypothesis to $\gamma_i = [\sigma_1, \dots, \sigma_i]$ and $\gamma_j = [\sigma_1, \dots, \sigma_j]$, respectively. Consider the inference $\xi := [\xi_i, \xi_j, \sigma_l]$. We distinguish between four cases according to the occurrence of the V -symmetry rule S_V in ξ_i and ξ_j .

Case 3.1. If S_V does not occur in ξ_i nor in ξ_j , then ξ has the desired properties.

Case 3.2. If S_V occurs in ξ_i as the last rule but does not occur in ξ_j , then the last step of ξ_i and the last step of ξ are of the following form:

$$\frac{\frac{I(Y|X)}{S_V : I(V - XY|X)} \quad I(Z|X)}{\mathcal{U} : I((V - XY)Z|X)} .$$

However, these steps can be replaced as follows:

$$\frac{\frac{I(Y|X) \quad I(Z|X)}{\mathcal{D} : I(Y - Z|X)}}{S_V : I(\underbrace{V - ((Y - Z)X)}_{=(V - XY)Z}|X)} .$$

The resulting inference has the desired properties.

Case 3.3. If S_V occurs in ξ_j as the last rule but does not occur in ξ_i , then the last step of ξ_j and the last step of ξ are of the following form:

$$\frac{\frac{I(Z|X)}{S_V : I(V - XZ|X)} \quad I(Y|X)}{\mathcal{U} : I((V - XZ)Y|X)} .$$

However, these steps can be replaced as follows:

$$\frac{\frac{I(Z|X) \quad I(Y|X)}{\mathcal{D} : I(Z - Y|X)}}{S_V : I(\underbrace{V - ((Z - Y)X)}_{=(V - XZ)Y}|X)} .$$

The resulting inference has the desired properties.

Case 3.4. If S_V occurs in ξ_i as the last rule and occurs in ξ_j as the last rule, then the last steps of ξ_i and ξ_j and the last step of ξ are of the following form:

$$\frac{\frac{I(Y|X)}{S_V : I(V - XY|X)} \quad \frac{I(Z|X)}{S_V : I(V - XZ|X)}}{\mathcal{U} : I((V - XY)(V - XZ)|X)} .$$

However, these steps can be replaced as follows:

$$\frac{\frac{I(Y|X) \quad I(Z|X)}{\mathcal{D} : \frac{I(Y - Z|X)}{I(Y - (Y - Z)|X)}}}{S_V : \frac{I(\underbrace{V - ((Y \cap Z)X)}_{=(V - XY)(V - XZ)}|X)}}{=Y \cap Z}$$

The resulting inference has the desired properties.

Case 4. We obtain σ_l by an application of the V -symmetry rule S_V to a premise σ_i with $i < l$. Let ξ_i be obtained by applying the induction hypothesis to $\gamma_i = [\sigma_1, \dots, \sigma_i]$. Consider the inference $\xi := [\xi_i, \sigma_l]$. If in ξ_i the V -symmetry rule S_V is not applied, then ξ has the desired properties. If in ξ_i the V -symmetry rule S_V is applied as the last rule, then the last two steps in ξ are of the following form.

$$\frac{\frac{I(Y|X)}{S_V : I(V - XY|X)}}{S_V : I(\underbrace{V - (V - XY)X}_{=Y}|X)}$$

The inference obtained from deleting these steps has the desired properties. ■

Example 6 Recall Example 2 where $V = \{b, a, r, s\}$, $\Sigma = \{I(sb|a), I(b|a)\}$ and $\varphi = I(s|a)$. While the inference of φ from Σ using \mathcal{U}_V in Example 2 showed that $\Sigma \models_V \varphi$ holds, it did leave open the question whether Σ purely implies φ . Indeed, no inference of φ from Σ by \mathcal{U}_V can provide this insight by Theorem 4. However, using \mathcal{C}_V we can obtain the following inference of φ from Σ :

$$\frac{I(sb|a) \quad I(b|a)}{\mathcal{D} : I(s|a)} .$$

Indeed, the V -symmetry rule S_V is unnecessary to infer φ from Σ .

Examples 2 and 6 indicate that the implication of $I(s|a)$ by $\Sigma = \{I(sb|a), I(b|a)\}$ does not depend on the fixed set V of random variables. In what follows we will formalize the stronger notion of pure implication as motivated in the introduction. Theorem 5 shows that the set $\mathcal{C} := \mathcal{C}_V - \{S_V\}$ of inference rules is nearly V -complete for the V -implication of SCI statements under incomplete random variables.

Theorem 7 Let $\Sigma \cup \{I(Y|X)\}$ be a set of SCI statements over the set V of incomplete random variables. Then $I(Y|X) \in \Sigma_{\mathcal{C}_V}^+$ if and only if $I(Y|X) \in \Sigma_{\mathcal{C}}^+$ or $I(V - XY|X) \in \Sigma_{\mathcal{C}}^+$. ■

Theorem 7 indicates that \mathcal{C} can infer every implied SCI statement that is independent from the set V of incomplete

random variables. Another interpretation of Theorem 7 is the following. In using \mathfrak{C} to infer V -implied statements, the fixation of V can be deferred until the last step of an inference.

4 PURE IMPLICATION

In this section we formalize the notion of pure implication as motivated in the introduction. It is shown that the set \mathfrak{C} of inference rules forms a finite axiomatization for pure implication. On the one hand, this allows us to distinguish between V -implied and purely implied statements. On the other hand, the notion of pure implication can be applied whenever this notion of implication is more convenient to use, for examples, when there is uncertainty about additional random variables that may be required in the future, when some variables are unknown, or when some variables are meant to remain hidden.

A *probability model* is a triple (V, dom, P) where $V = \{v_1, \dots, v_n\} \subseteq \mathfrak{V}$ is a finite set of incomplete random variables, dom is a domain mapping that maps each v_i to a finite domain $dom(v_i)$, and $P : dom(v_1) \times \dots \times dom(v_n) \rightarrow [0, 1]$ is a probability distribution having the Cartesian product of these domains as its sample space. The expression $I(Y|X)$ where X and Y are finite, disjoint subsets of \mathfrak{V} is called a *saturated conditional independence (SCI) statement*. We say that the SCI statement $I(Y|X)$ *holds for* (V, dom, P) if $XY \subseteq V$ and for every complete assignment \mathbf{x} of X , every assignment \mathbf{y} of Y , and every assignment \mathbf{z} of $V - XY$, respectively,

$$P(\mathbf{x}, \mathbf{y}, \mathbf{z}) \cdot P(\mathbf{x}) = P(\mathbf{x}, \mathbf{y}) \cdot P(\mathbf{x}, \mathbf{z}).$$

Equivalently, (V, dom, P) is said to *satisfy* $I(Y|X)$. For an SCI statement $\sigma = I(Y|X)$ let $V_\sigma := XY$, and for a finite set Σ of SCI statements let $V_\Sigma := \bigcup_{\sigma \in \Sigma} V_\sigma$ denote the random variables that occur in it.

Definition 8 Let $\Sigma \cup \{\varphi\}$ be a finite set of SCI statements. We say that Σ *purely implies* φ , denoted by $\Sigma \models \varphi$, if and only if every probability model (V, dom, P) with $V_{\Sigma \cup \{\varphi\}} \subseteq V$ that satisfies every SCI statement $\sigma \in \Sigma$ also satisfies φ .

In the definition of pure implication the set of incomplete random variables is left undetermined. The only requirement is that the SCI statements must apply to the probability model. The pure implication problem for SCI statements can be stated as follows.

PROBLEM:	Pure Implication Problem
INPUT:	Set $\Sigma \cup \{\varphi\}$ of SCI statements
OUTPUT:	Yes, if $\Sigma \models \varphi$; No, otherwise

Pure implication is stronger than V -implication.

Table 3: Axiomatization \mathfrak{C} for Pure Implication

$\overline{I(\emptyset X)}$ (triviality, \mathcal{T})	$\overline{I(Y X)}$ $\overline{I(Y - Z XZ)}$ (weak union, \mathcal{W})
$\frac{I(Y X) \quad I(Z X)}{I(YZ X)}$ (union, \mathcal{U})	$\frac{I(Y X) \quad I(Z X)}{I(Y - Z X)}$ (difference, \mathcal{D})

Proposition 9 Let $\Sigma \cup \{\varphi\}$ be a finite set of SCI statements, such that $V_{\Sigma \cup \{\varphi\}} \subseteq V$. If $\Sigma \models \varphi$, then $\Sigma \models_V \varphi$, but the other direction may fail.

Proof The first statement follows directly from the definitions of pure and V -implication. For the other direction, let $V = \{b, a, r, s\}$, $\Sigma = \{I(r|a)\}$ and let φ be $I(sb|a)$. Clearly, Σ V -implies φ . However, Σ does not purely imply φ as the example from the introduction shows. ■

Soundness and completeness for pure implication are defined as their corresponding notions in the context of some fixed set V by dropping the reference to V . While triviality axiom \mathcal{T} , weak union rule \mathcal{W} , and union rule \mathcal{U} are all sound, the V -symmetry rule \mathcal{S}_V is V -sound but not sound.

We shall now prove that \mathfrak{C} forms a finite axiomatization for the pure implication of SCI statements. For this purpose, we prove two lemmata in preparation. The correctness of the first lemma can easily be observed by inspecting the inference rules in \mathfrak{C} . For each of the rules, every random variable that occurs on the left-hand side of the bar in the conclusion of the rule, already appears on the left-hand side of the bar in at least one premise of the rule.

Lemma 10 Let $\Sigma = \{I(Y_1|X_1), \dots, I(Y_n|X_n)\}$ be a finite set of SCI statements. If $I(Y|X) \in \Sigma_{\mathfrak{C}}^+$, then $Y \subseteq Y_1 \cup \dots \cup Y_n$. ■

For the next lemma one may notice that the random variables that do not occur in V_Σ can always be introduced in the last step of an inference, by applying the weak union rule \mathcal{W} .

Lemma 11 Let Σ be a finite set of SCI statements. If $I(Y|X) \in \Sigma_{\mathfrak{C}}^+$, then there is an inference $\gamma = [\sigma_1, \dots, \sigma_i]$ of $I(Y|X)$ from Σ by \mathfrak{C} such that every attribute occurring in $\sigma_1, \dots, \sigma_{i-1}$ is an element of V_Σ .

Proof Define $W := V_\Sigma$ and let $\bar{\xi} := [I(V_1|U_1), \dots, I(V_{i-1}|U_{i-1})]$ be an inference of $I(Y|X)$ from Σ by \mathfrak{C} . Consider the sequence

$$\xi := [I(V_1 \cap W|U_1 \cap W), \dots, I(V_{i-1} \cap W|U_{i-1} \cap W)].$$

We claim that ξ is an inference of $I(Y \cap W|X \cap W)$ from Σ by \mathcal{C} . For if $I(V_i|U_i)$ is an element of Σ or was obtained by an application of the triviality axiom \mathcal{T} , then $I(Y \cap W|X \cap W) = I(Y|X)$. One can verify that if $I(V_i|U_i)$ is the result of applying one of the rules $\mathcal{U}, \mathcal{W}, \mathcal{D}$, then $I(V_i \cap W|U_i \cap W)$ is the result of the same rule applied to the corresponding premises in ξ .

Now by Lemma 10 we know that $Y \subseteq W$, hence $Y \cap W = Y$. However, this means that we can infer $I(Y|X)$ from $I(Y \cap W|X \cap W)$ by a single application of the weak union rule \mathcal{W} :

$$\frac{I(Y \cap W|X \cap W)}{I(\underbrace{(Y \cap W) - X}_{=Y} | \underbrace{(X \cap W) \cup X}_{=X})}.$$

Hence, the inference $[\xi, I(Y|X)]$ has the desired properties. ■

We are now prepared to prove the following result.

Theorem 12 *The set $\mathcal{C} = \{\mathcal{T}, \mathcal{W}, \mathcal{U}, \mathcal{D}\}$ forms a finite axiomatization for the pure implication of SCI statements under incomplete random variables.*

Proof Let $\Sigma = \{I(Y_1|X_1), \dots, I(Y_n|X_n)\}$ be a finite set of SCI statements and $I(Y|X)$ an SCI statement. We have to show that

$$I(Y|X) \in \Sigma^* \quad \text{if and only if} \quad I(Y|X) \in \Sigma_{\mathcal{C}}^+.$$

Let $T := X \cup Y \cup V_{\Sigma}$. In order to prove the soundness of \mathcal{C} we assume that $I(Y|X) \in \Sigma_{\mathcal{C}}^+$ holds. Let (V, dom, P) be a probability model that satisfies every element of Σ , and where $T \subseteq V$ holds. We must show that (V, dom, P) also satisfies $I(Y|X)$. According to Lemma 11 there is an inference γ of $I(Y|X)$ from Σ by \mathcal{C} such that $U \cup W \subseteq T \subseteq V$ holds for each SCI statement $I(W|U)$ that occurs in γ . Since each rule in \mathcal{C} is sound we can conclude (by induction) that each SCI statement occurring in γ is satisfied by (V, dom, P) . In particular, (V, dom, P) satisfies $I(Y|X)$.

In order to prove the completeness of \mathcal{C} we assume that $I(Y|X) \notin \Sigma_{\mathcal{C}}^+$. Let $V \subseteq \mathfrak{B}$ be a finite set of random variables such that T is a proper subset of V , i.e., $T \subset V$. Consequently, $V - XY$ is not a subset of T . Hence, by Lemma 10, $I(V - XY|X) \notin \Sigma_{\mathcal{C}}^+$. Now from $I(Y|X) \notin \Sigma_{\mathcal{C}}^+$ and from $I(V - XY|X) \notin \Sigma_{\mathcal{C}}^+$ we conclude that $I(Y|X) \notin \Sigma_{\mathcal{C}_V}^+$ by Theorem 7. Since \mathcal{C}_V is V -complete for the V -implication of SCI statements it follows that Σ does not V -imply $I(Y|X)$. Hence, Σ does not purely imply $I(Y|X)$ by Proposition 9. ■

Example 13 *Recall Example 6 where $V = \{b, a, r, s\}$, and Σ consists of the two SCI statements $I(bs|a)$ and $I(b|a)$. The inference of $I(s|a)$ from Σ by \mathcal{C}_V in Example 6 is actually an inference by \mathcal{C} . Hence, $I(s|a)$ is purely implied by Σ , as one would expect intuitively.*

5 PURE AND V -IMPLICATION

Instances $\Sigma \models \varphi$ of the pure implication problem can be characterized by the instance $\Sigma \models_V \varphi$ of the V -implication problem for any set V of incomplete random variables that properly contains $V_{\Sigma \cup \{\varphi\}}$.

Theorem 14 *Let $\Sigma \cup \{\varphi\}$ be a set of SCI statements. Then the following are equivalent:*

1. $\Sigma \models \varphi$
2. for some V such that $V_{\Sigma \cup \{\varphi\}} \subset V$, $\Sigma \models_V \varphi$
3. for all V such that $V_{\Sigma \cup \{\varphi\}} \subset V$, $\Sigma \models_V \varphi$

Proof It is clear that 3. entails 2. Let $\varphi = I(Y|X)$, and let V be any finite set of random variables such that $V_{\Sigma \cup \{\varphi\}} \subset V$. If 2. holds, then Theorem 7 and Theorem 12 show that 1. holds or $\Sigma \vdash_{\mathcal{C}} I(V - XY|X)$ holds. However, Lemma 10 shows that the latter condition cannot hold as $V - XY$ contains some random variable that does not occur in V_{Σ} . Hence, 2. entails 1. If 1. holds, then Theorem 7 and Theorem 12 show that 3. holds as well. ■

Example 15 $\Sigma = \{I(bs|a), I(b|a)\}$ purely implies $I(s|a)$ as, for instance, $\Sigma \models_V I(s|a)$ for $V = \{b, a, r, s\}$. $\Sigma' = \{I(bs|a)\}$ does not purely imply $I(r|a)$ as for $V = \{b, e, a, r, s\}$, Σ' does not V -imply $I(r|a)$ as witnessed in the introduction.

In the following we apply Theorem 14 to establish characterizations of pure implication in terms of logical formulae under Levesque's situations, database dependencies, and algorithmic solutions. For a set $\Sigma \cup \{\varphi\}$ of SCI statements we write $V_c = V_{\Sigma \cup \{\varphi\}} \cup \{v_0\}$ for some $v_0 \notin V_{\Sigma \cup \{\varphi\}}$, $\sigma_c = I(V_c - XY, Y|X)$ for $\sigma = I(Y|X) \in \Sigma \cup \{\varphi\}$ and $\Sigma_c = \{\sigma_c \mid \sigma \in \Sigma\}$. In particular, $\Sigma \models \varphi$ if and only if $\Sigma_c \models_{V_c} \varphi_c$.

6 LEVESQUE'S SITUATIONS

We recall the framework for situations from Levesque (1989), and exploit them to establish a logical characterization of the pure implication problem.

For a finite set L of propositional variables, let L^* denote the *propositional language* over L , generated from the unary connective \neg (negation), and the binary connectives \wedge (conjunction) and \vee (disjunction). Elements of L^* are also called formulae of L , and usually denoted by φ', ψ' or their subscripted versions. Sets of formulae are denoted by Σ' . We omit parentheses if this does not cause ambiguity.

Let L^ℓ denote the set of all literals over L , i.e., $L^\ell = L \cup \{\neg v' \mid v' \in L\}$. A *situation* of L is a total function $\omega : L^\ell \rightarrow \{\mathbb{F}, \mathbb{T}\}$ that does not map both a propositional variable $v' \in L$ and its negation $\neg v'$ to \mathbb{F} . That is, we must not have $\omega(v') = \mathbb{F} = \omega(\neg v')$ for any $v' \in L$.

A situation $\omega : L^\ell \rightarrow \{\mathbb{F}, \mathbb{T}\}$ of L can be lifted to a total function $\Omega : L^* \rightarrow \{\mathbb{F}, \mathbb{T}\}$. Assuming φ' is in Negation Normal Form, this lifting is defined by:

- $\Omega(\varphi') = \omega(\varphi')$, if $\varphi' \in L^\ell$,
- $\Omega(\varphi' \vee \psi') = \mathbb{T}$ iff $\Omega(\varphi') = \mathbb{T}$ or $\Omega(\psi') = \mathbb{T}$,
- $\Omega(\varphi' \wedge \psi') = \mathbb{T}$ iff $\Omega(\varphi') = \mathbb{T}$ and $\Omega(\psi') = \mathbb{T}$.

A situation ω is a *model* of a set Σ' of L -formulae if and only if $\Omega(\sigma') = \mathbb{T}$ holds for every $\sigma' \in \Sigma'$. We say that Σ' *implies* an L -formula φ' , denoted by $\Sigma' \models_L \varphi'$, if and only if every situation that is a model of Σ' is also a model of φ' .

Equivalences. Let $\phi : V_c \rightarrow L_c$ denote a bijection between a set V_c of random variables and the set $L_c = \{v' \mid v \in V\}$ of propositional variables. We extend ϕ to a mapping Φ from the set of SCI statements over V_c to the set L_c^* . For an SCI statement $I(Y, Z \mid X)$ over V_c , let $\Phi(I(Y, Z \mid X))$ denote

$$\bigvee_{v \in X} \neg v' \vee \left(\bigwedge_{v \in Y} v' \right) \vee \left(\bigwedge_{v \in Z} v' \right).$$

Disjunctions over zero disjuncts are \mathbb{F} and conjunctions over zero conjuncts are \mathbb{T} . We will denote $\Phi(\varphi_c) = \varphi'_c$ and $\Phi(\Sigma_c) = \{\Phi(\sigma_c) \mid \sigma \in \Sigma_c\} = \Sigma'_c$.

In our example, for $\varphi_c = I(bse, r \mid a)$ we have $\varphi'_c = \neg a' \vee (b' \wedge s' \wedge e') \vee r'$, and for $\Sigma_c = \{I(re, bs \mid a)\}$ we have $\Sigma'_c = \{\neg a' \vee (b' \wedge s') \vee (r' \wedge e')\}$.

It was shown in Link (2013a) that for any set $\Sigma_c \cup \{\varphi_c\}$ of SCI statements over V_c there is a probability model $\pi = (dom, P)$ over V_c that satisfies Σ_c and violates φ_c if and only if there is a situation ω_π over L_c that is a model of Σ'_c but not a model of φ'_c . For arbitrary probability models π it is not obvious how to define the situation ω_π . However, if Σ_c does not V_c -imply φ_c , then there is a special probability model $\pi = (dom, \{\mathbf{a}_1, \mathbf{a}_2\})$ over V_c that i) has two assignments $\mathbf{a}_1, \mathbf{a}_2$ of probability one half each, ii) satisfies all SCI statements in Σ_c and iii) violates φ_c . Given such π , let ω_π denote the following special situation of L_c , taken from Link (2013a):

$$\omega_\pi(v') = \begin{cases} \mathbb{T} & , \text{ if } \mathbf{a}_1(v) = \mathbf{a}_2(v) \\ \mathbb{F} & , \text{ otherwise} \end{cases} \quad , \text{ and}$$

$$\omega_\pi(\neg v') = \begin{cases} \mathbb{T} & , \text{ if } \mathbf{a}_1(v) = \mu = \mathbf{a}_2(v) \text{ or} \\ & \mathbf{a}_1(v) \neq \mathbf{a}_2(v) \\ \mathbb{F} & , \text{ otherwise} \end{cases} .$$

From the results in Link (2013a) and Theorem 14 we obtain the following logical characterization of pure implication.

Theorem 16 *Let $\Sigma \cup \{\varphi\}$ be a finite set of SCI statements and $L_c = \{v' \mid v \in V_{\Sigma \cup \{\varphi\}} \cup \{v_0\}\}$. Then $\Sigma \models \varphi$ if and only if $\Sigma'_c \models_{L_c} \varphi'_c$.*

Proof Theorem 14 shows that $\Sigma \models \varphi$ if and only if

$\Sigma_c \models_{V_c} \varphi_c$ for $V_c = V_{\Sigma \cup \{\varphi\}} \cup \{v_0\}$. By (Link, 2013a, Thm.6), $\Sigma_c \models_{V_c} \varphi_c$ if and only if $\Sigma'_c \models_{L_c} \varphi'_c$. ■

Recall that $\Sigma = \{I(sb \mid a)\}$ does not purely imply $\varphi = I(s, br \mid a)$ as the special probability model π defined by

r	a	b	s	e	P
true	true	–	–	true	0.5
false	true	–	–	false	0.5

satisfies Σ_c , but violates φ_c . Any special situation where $\omega_\pi(b') = \mathbb{T} = \omega_\pi(s')$, $\omega_\pi(\neg a') = \omega_\pi(r') = \omega_\pi(e') = \mathbb{F}$ is a model of $\Sigma'_c = \{\neg a' \vee (b' \wedge s') \vee (r' \wedge e')\}$, but not a model of $\varphi'_c = \neg a' \vee (b' \wedge s' \wedge e') \vee r'$.

7 DATABASE DEPENDENCIES

Database dependencies enforce the semantics of application domains in database systems [Link (2001)]. Let $\mathfrak{A} = \{\hat{v}_1, \hat{v}_2, \dots\}$ be an infinite set of distinct symbols, called attributes. A *relation schema* is a finite non-empty subset R of \mathfrak{A} . Each attribute $\hat{v} \in R$ has an infinite domain $dom(\hat{v})$. In order to encompass missing data values the domain of each attribute contains the null marker $-$. The intention of $-$ is to mean “no information” [Lien (1982)]. A *tuple* over R is a function $t : R \rightarrow \bigcup_{\hat{v} \in R} dom(\hat{v})$ with $t(\hat{v}) \in dom(\hat{v})$ for all $\hat{v} \in R$. For $X \subseteq R$ let $t(X)$ denote the restriction of t to X . A *relation* r over R is a finite set of tuples over R . For a tuple t over R and a set $X \subseteq R$, t is said to be *X-total*, if for all $\hat{v} \in X$, $t(\hat{v}) \neq -$. A relation over R is a *total relation*, if it is R -total. A *multivalued dependency* (MVD) over R is a statement $X \twoheadrightarrow Y$ where X and Y are disjoint subsets of R [Lien (1982)]. The MVD $X \twoheadrightarrow Y$ over R is satisfied by a relation r over R if and only if for all $t_1, t_2 \in r$ the following holds: if t_1 and t_2 are X -total and $t_1(X) = t_2(X)$, then there is some $t \in r$ such that $t(XY) = t_1(XY)$ and $t(X(R - XY)) = t_2(X(R - XY))$. Thus, the relation r satisfies $X \twoheadrightarrow Y$ when every X -total value determines the set of values on Y independently of the set of values on $R - Y$. For a set $\hat{\Sigma} \cup \{\hat{\varphi}\}$ of MVDs over R , $\hat{\Sigma}$ R -implies $\hat{\varphi}$, denoted by $\hat{\Sigma} \models_R \hat{\varphi}$, if and only if every relation over R that satisfies all elements in $\hat{\Sigma}$ also satisfies $\hat{\varphi}$.

For a set $\Sigma_c \cup \{\varphi_c\}$ of SCI statements over V_c one may associate the set $\hat{\Sigma}_c \cup \{\hat{\varphi}_c\}$ of MVDs over $R_c := \{\hat{v} \mid v \in V_c\}$, where $\hat{\sigma}_c = X \twoheadrightarrow Y$ for $\sigma_c = I(Y, Z \mid X)$ and $\hat{\Sigma}_c = \{\hat{\sigma}_c \mid \sigma \in \Sigma_c\}$.

Theorem 17 *Let $\Sigma \cup \{\varphi\}$ be a finite set of SCI statement. Then $\Sigma \models \varphi$ if and only if $\hat{\Sigma}_c \models_{R_c} \hat{\varphi}_c$.*

Proof Theorem 14 shows that $\Sigma \models \varphi$ if and only if $\Sigma_c \models_{V_c} \varphi_c$ for $V_c = V_{\Sigma \cup \{\varphi\}} \cup \{v_0\}$. By (Link, 2013a, Thm.8), $\Sigma_c \models_{V_c} \varphi_c$ if and only if $\hat{\Sigma}_c \models_{R_c} \hat{\varphi}_c$. ■

8 ALGORITHM & COMPLEXITY

(Link, 2013a, Thm. 7) shows that $\Sigma_c \models_{V_c} \varphi_c$ for $\varphi_c = I(Z, Y|X)$ holds if and only if $\Sigma_c[X] \models_{V_c} \varphi_c$ holds classically, that is, when no domain contains the marker. Here, $\Sigma_c[X] := \{I(V, W|U) \mid I(V, W|U) \in \Sigma_c \wedge U \subseteq X\}$. The *independence basis* $IDep_{\Sigma_c[X]}(X)$ consists of the minimal $Y \subseteq V_c - X$ such that $\Sigma_c[X] \models_{V_c} I(Z, Y|X)$. By (Link, 2013a, Thm. 8), $\Sigma \models \varphi$ if and only if $\Sigma_c[X] \models_{R_c} \hat{\varphi}_c$, that is, every total relation over R_c that satisfies $\Sigma_c[X]$ also satisfies $\hat{\varphi}_c$. Galil (1982) gave an efficient algorithmic solution to the latter problem.

Theorem 18 *Using the algorithm in Galil (1982), the pure implication problem $\Sigma \models I(Y|X)$ can be decided in time $\mathcal{O}(|\Sigma_c| + \min\{k_{\Sigma_c[X]}, \log \bar{p}_{\Sigma_c[X]}\} \times |\Sigma_c[X]|)$. Herein, $|\Sigma_c|$ denotes the total number of random variables in Σ_c , $k_{\Sigma_c[X]}$ denotes the cardinality of $\Sigma_c[X]$, and $\bar{p}_{\Sigma_c[X]}$ denotes the number of sets in $IDep_{\Sigma_c[X]}(X)$ that have non-empty intersection with Y . ■*

9 RELATED WORK

Dawid (1979) first investigated fundamental properties of conditional independence, leading to a claim that “rather than just being another useful tool in the statistician’s kitbag, conditional independence offers a new language for the expression of statistical concepts and a framework for their study”. Geiger and Pearl (1993) have systematically investigated the implication problem for fragments of CI statements over different probability models. In particular, they have established an axiomatization of SCI statements by a finite set of Horn rules. Studený (1992) showed that no axiomatization by a finite set of Horn rules exists for general CI statements. Niepert, Van Gucht, and Gyssens (2010) established an axiomatization for stable CI statements, which subsume SCI statements, and showed that their associated implication problem is coNP-complete. Independently, database theory has investigated the concept of embedded multivalued dependencies (MVDs) whose implication problem is undecidable [Herrmann (1995)] and not axiomatizable by a finite set of Horn rules [Stott Parker Jr. and Parsaye-Ghomi (1980)]. Studený (1992) also showed that the implication problem of embedded MVDs and that of CI statements do not coincide. In contrast, the implication problems of MVDs, SCI statements and some fragment of Boolean propositional logic all coincide [Geiger and Pearl (1993); Sagiv et al. (1981); Wong, Butz, and Wu (2000)]. These findings have been established for the notion of implication over fixed sets of variables and the idealized case where all data values are known. Biskup, Hartmann, and Link (2012) differentiated between V -implication and pure implication for SCI statements with complete random variables only, applying ideas from database theory in Biskup (1980) and

Link (2012). In the case of missing data, equivalences between implication problems for MVDs with null markers, SCI statements with incomplete random variables, and a fragment of propositional logic under Levesque’s situations were established recently in Link (2013a) and Hartmann and Link (2012). However, the notion of pure implication for conditional independence statements has not been studied yet in the context of missing data.

10 CONCLUSION

Recently, probabilistic conditional independence statements were studied in the presence of incomplete random variables, which admit missing data values. The associated implication problem for saturated CI statements was characterized axiomatically by a finite set \mathcal{U}_V of Horn rules, logically by a propositional fragment under interpretations by Levesque’s situations, and algorithmically by an equivalence to database dependencies. In this paper it was shown that there is a difference between SCI statements V -implied jointly by a given set of SCI statements and a fixed set V of incomplete random variables, and those purely implied by a given set of SCI statements alone. It was shown that \mathcal{U}_V cannot separate V -implied from purely implied SCI statements. An axiomatization \mathcal{C}_V was then established that can infer any purely implied SCI statement without applications of the V -symmetry rule \mathcal{S}_V , and infer any V -implied SCI statement with a single application of \mathcal{S}_V in the very last step of the inference only. The system \mathcal{C} that results from \mathcal{C}_V by removing \mathcal{S}_V was proven to form a finite axiomatization for the stronger notion of pure implication. The pure implication problem $\Sigma \models \varphi$ was characterized by the V -implication problem $\Sigma \models_V \varphi$ for sets V that properly contain the random variables that occur $\Sigma \cup \{\varphi\}$. This result enabled us to characterize pure implication logically and algorithmically as well. Our results clarify the role of the V -symmetry rule \mathcal{S}_V as a pure means to infer V -implied SCI statements. The notion of pure implication is appealing when the existence of random variables is uncertain, for example, when independence statements are integrated from different sources, when random variables are unknown or when they shall remain hidden. It is future work to extend the findings of this paper to the general case where an arbitrary finite set S of complete random variables can be specified, thereby, covering the current setting by the case where $S = \emptyset$ and the classical setting by the case where every random variable is complete. This would extend the work in Link (2013b) where the notion of pure implication was not considered.

Abstract

A matroid is a notion of independence in combinatorial optimization which is closely related to computational efficiency. In particular, it is well known that the maximum of a constrained modular function can be found greedily if and only if the constraints are associated with a matroid. In this paper, we bring together the ideas of bandits and matroids, and propose a new class of combinatorial bandits, *matroid bandits*. The objective in these problems is to learn how to maximize a modular function on a matroid. This function is stochastic and initially unknown. We propose a practical algorithm for solving our problem, *Optimistic Matroid Maximization (OMM)*; and prove two upper bounds, gap-dependent and gap-free, on its regret. Both bounds are sublinear in time and at most linear in all other quantities of interest. The gap-dependent upper bound is tight and we prove a matching lower bound on a partition matroid bandit. Finally, we evaluate our method on three real-world problems and show that it is practical.

1 Introduction

Combinatorial optimization is a well-established field that has many practical applications, ranging from resource allocation [14] to designing network routing protocols [20]. Modern combinatorial optimization problems are often so massive that even low-order polynomial-time solutions are not practical. Fortunately, many important problems, such as finding a minimum spanning tree, can be solved greedily. Such problems can be often viewed as optimization on a *matroid* [25], a notion of independence in combinatorial optimization which is closely related to computational efficiency. In particular, it is well known that the maximum of a constrained modular function can be found greedily if and only if all feasible solutions to the problem are the in-

dependent sets of a matroid [8]. Matroids are common in practice because they generalize many notions of independence, such as linear independence and forests in graphs.

In this paper, we propose an algorithm for learning how to maximize a stochastic modular function on a matroid. The modular function is represented as the sum of the weights of up to K items, which are chosen from the ground set E of a matroid, which has L items. The weights of the items are stochastic and represented as a vector $\mathbf{w} \in [0, 1]^L$. The vector \mathbf{w} is drawn i.i.d. from a probability distribution P . The distribution P is initially unknown and we learn it by interacting repeatedly with the environment.

Many real-world optimization problems can be formulated in our setting, such as building a spanning tree for network routing [20]. When the delays on the links of the network are stochastic and their distribution is known, this problem can be solved by finding a minimum spanning tree. When the distribution is unknown, it must be learned, perhaps by exploring routing networks that seem initially suboptimal. We return to this problem in our experiments.

This paper makes three main contributions. First, we bring together the concepts of matroids [25] and bandits [15, 3], and propose a new class of combinatorial bandits, *matroid bandits*. On one hand, matroid bandits can be viewed as a new learning framework for a broad and important class of combinatorial optimization problems. On the other hand, matroid bandits are a class of K -step bandit problems that can be solved both computationally and sample efficiently.

Second, we propose a simple greedy algorithm for solving our problem, which explores based on the optimism in the face of uncertainty. We refer to our approach as *Optimistic Matroid Maximization (OMM)*. OMM is both computationally and sample efficient. In particular, the time complexity of OMM is $O(L \log L)$ per episode, comparable to that of sorting L numbers. Moreover, the expected cumulative regret of OMM is sublinear in the number of episodes, and at most linear in the number of items L and the maximum number of chosen items K .

Finally, we evaluate OMM on three real-world problems. In

the first problem, we learn routing networks. In the second problem, we learn a policy for assigning loans in a micro-finance network that maximizes chances that the loans are repaid. In the third problem, we learn a movie recommendation policy. All three problems can be solved efficiently in our framework. This demonstrates that OMM is practical and can solve a wide range of real-world problems.

We adopt the following notation. We write $A + e$ instead of $A \cup \{e\}$, and $A + B$ instead of $A \cup B$. We also write $A - e$ instead of $A \setminus \{e\}$, and $A - B$ instead of $A \setminus B$.

2 Matroids

A *matroid* is a pair $M = (E, \mathcal{I})$, where $E = \{1, \dots, L\}$ is a set of L items, called the *ground set*, and \mathcal{I} is a family of subsets of E , called the *independent sets*. The family \mathcal{I} is defined by the following properties. First, $\emptyset \in \mathcal{I}$. Second, every subset of an independent set is independent. Finally, for any $X \in \mathcal{I}$ and $Y \in \mathcal{I}$ such that $|X| = |Y| + 1$, there must exist an item $e \in X - Y$ such that $Y + e \in \mathcal{I}$. This is known as the *augmentation property*. We denote by:

$$E(X) = \{e : e \in E - X, X + e \in \mathcal{I}\} \quad (1)$$

the set of items that can be added to set X such that the set remains independent.

A set is a *basis* of a matroid if it is a maximal independent set. All bases of a matroid have the same cardinality [25], which is known as the *rank* of a matroid. In this work, we denote the rank by K .

A *weighted matroid* is a matroid associated with a vector of non-negative weights $\mathbf{w} \in (\mathbb{R}^+)^L$. The e -th entry of \mathbf{w} , $\mathbf{w}(e)$, is the weight of item e . We denote by:

$$f(A, \mathbf{w}) = \sum_{e \in A} \mathbf{w}(e) \quad (2)$$

the sum of the weights of all items in set A . The problem of finding a *maximum-weight basis* of a matroid:

$$A^* = \arg \max_{A \in \mathcal{I}} f(A, \mathbf{w}) = \arg \max_{A \in \mathcal{I}} \sum_{e \in A} \mathbf{w}(e) \quad (3)$$

is a well-known combinatorial optimization problem. This problem can be solved greedily (Algorithm 1). The greedy algorithm has two main stages. First, A^* is initialized to \emptyset . Second, all items in the ground set are sorted according to their weights, from the highest to the lowest, and greedily added to A^* in this order. The item is added to the set A^* only if it does not make the set dependent.

3 Matroid Bandits

A *minimum spanning tree* is a maximum-weight basis of a matroid. The ground set E of this matroid are the edges of

Algorithm 1 The greedy method for finding a maximum-weight basis of a matroid [8].

Input: Matroid $M = (E, \mathcal{I})$, weights \mathbf{w}

```

 $A^* \leftarrow \emptyset$ 
Let  $e_1, \dots, e_L$  be an ordering of items such that:
 $\mathbf{w}(e_1) \geq \dots \geq \mathbf{w}(e_L)$ 
for all  $i = 1, \dots, L$  do
  if ( $e_i \in E(A^*)$ ) then
     $A^* \leftarrow A^* + e_i$ 
  end if
end for

```

a graph. A set of edges is considered to be independent if it does not contain a cycle. Each edge e is associated with a weight $\mathbf{w}(e) = u_{\max} - \mathbf{u}(e)$, where $u_{\max} = \max_e \mathbf{u}(e)$ and $\mathbf{u}(e)$ is the weight of edge e in the original graph.

The minimum spanning tree cannot be computed when the weights $\mathbf{w}(e)$ of the edges are unknown. This may happen in practice. For instance, consider the problem of building a routing network, which is represented as a spanning tree, where the expected delays on the links of the network are initially unknown. In this work, we study a variant of maximizing a modular function on a matroid that can address this kind of problems.

3.1 Model

We formalize our learning problem as a matroid bandit. A *matroid bandit* is a pair (M, P) , where M is a matroid and P is a probability distribution over the weights $\mathbf{w} \in \mathbb{R}^L$ of items E in M . The e -th entry of \mathbf{w} , $\mathbf{w}(e)$, is the weight of item e . The weights \mathbf{w} are stochastic and drawn i.i.d. from the distribution P . We denote the expected weights of the items by $\bar{\mathbf{w}} = \mathbb{E}[\mathbf{w}]$ and assume that each of these weights is non-negative, $\bar{\mathbf{w}}(e) \geq 0$ for all $e \in E$.

Each item e is associated with an *arm* and we assume that *multiple arms* can be pulled. A subset of arms $A \subseteq E$ can be pulled if and only if A is an independent set. The return for pulling arms A is $f(A, \mathbf{w})$ (Equation 2), the sum of the weights of all items in A . After the arms A are pulled, we observe the weight of each item in A , $\mathbf{w}(e)$ for all $e \in A$. This model of feedback is known as *semi-bandit* [2].

We assume that the matroid M is known and that the distribution P is unknown. Without loss of generality, we assume that the support of P is a bounded subset of $[0, 1]^L$. We would like to stress that we do not make any structural assumptions on P .

The optimal solution to our problem is a maximum-weight basis in expectation:

$$A^* = \arg \max_{A \in \mathcal{I}} \mathbb{E}_{\mathbf{w}}[f(A, \mathbf{w})] = \arg \max_{A \in \mathcal{I}} \sum_{e \in A} \bar{\mathbf{w}}(e). \quad (4)$$

Algorithm 2 OMM: Optimistic matroid maximization.

Input: Matroid $M = (E, \mathcal{T})$

// Initialization

Observe $\mathbf{w}_0 \sim P$ $\hat{w}_{e,1} \leftarrow \mathbf{w}_0(e) \quad \forall e \in E$ $T_e(0) \leftarrow 1 \quad \forall e \in E$ **for all** $t = 1, \dots, n$ **do**

// Compute UCBs

 $U_t(e) \leftarrow \hat{w}_{e,T_e(t-1)} + c_{t-1,T_e(t-1)} \quad \forall e \in E$ // Find a maximum-weight basis with respect to U_t $A^t \leftarrow \emptyset$ Let e_1^t, \dots, e_L^t be an ordering of items such that: $U_t(e_1^t) \geq \dots \geq U_t(e_L^t)$ **for all** $i = 1, \dots, L$ **do****if** ($e_i^t \in E(A^t)$) **then** $A^t \leftarrow A^t + e_i^t$ **end if****end for**Observe $\{\mathbf{w}_t(e) : e \in A^t\}$, where $\mathbf{w}_t \sim P$

// Update statistics

 $T_e(t) \leftarrow T_e(t-1) \quad \forall e \in E$ $T_e(t) \leftarrow T_e(t) + 1 \quad \forall e \in A^t$ $\hat{w}_{e,T_e(t)} \leftarrow \frac{T_e(t-1)\hat{w}_{e,T_e(t-1)} + \mathbf{w}_t(e)}{T_e(t)} \quad \forall e \in A^t$ **end for**

The above optimization problem is equivalent to the problem in Equation 3. Therefore, it can be solved greedily by Algorithm 1 when the expected weights $\bar{\mathbf{w}}$ are known.

Our learning problem is *episodic*. In episode t , we choose a basis A^t and gain $f(A^t, \mathbf{w}_t)$, where \mathbf{w}_t is the realization of the stochastic weights in episode t . Our goal is to learn a policy, a sequence of bases, that minimizes the *expected cumulative regret* in n episodes:

$$R(n) = \mathbb{E}_{\mathbf{w}_1, \dots, \mathbf{w}_n} \left[\sum_{t=1}^n R_t(\mathbf{w}_t) \right], \quad (5)$$

where $R_t(\mathbf{w}_t) = f(A^*, \mathbf{w}_t) - f(A^t, \mathbf{w}_t)$ is the regret in episode t .

3.2 Algorithm

Our solution is designed based on the *optimism in the face of uncertainty* principle [17]. In particular, it is a variant of the greedy method for finding a maximum-weight basis of a matroid where the expected weight $\bar{\mathbf{w}}(e)$ of each item e is substituted with its optimistic estimate $U_t(e)$. Therefore, we refer to our approach as *Optimistic Matroid Maximization* (OMM).

The pseudocode of our algorithm is given in Algorithm 2. The algorithm can be summarized as follows. First, at the beginning of each episode t , we compute the *upper confidence bound (UCB)* on the weight of each item e :

$$U_t(e) = \hat{w}_{e,T_e(t-1)} + c_{t-1,T_e(t-1)}, \quad (6)$$

where $\hat{w}_{e,T_e(t-1)}$ is our estimate of $\bar{\mathbf{w}}(e)$ at the beginning of episode t , $c_{t-1,T_e(t-1)}$ represents the radius of the confidence interval around this estimate, and $T_e(t-1)$ is the number of times that OMM chooses item e before episode t . Second, we order all items e by their UCBs (Equation 6), from the highest to the lowest, and then add them greedily to A^t in this order. The item is added to the set A^t only if it does not make the set dependent. Finally, we choose the basis A^t , observe the weights of all items in the basis, and update our model \hat{w} of the world.

The radius:

$$c_{t,s} = \sqrt{2 \log(t)/s} \quad (7)$$

is defined such that each upper confidence bound $U_t(e)$ is with high probability an upper bound on the weight $\bar{\mathbf{w}}(e)$. The role of the UCBs is to encourage exploration of items that are not chosen very often. As the number of episodes increases, the estimates of the weights $\bar{\mathbf{w}}$ improve and OMM starts exploiting best items. The $\log(t)$ term increases with time t and enforces exploration, to avoid linear regret.

OMM is a greedy algorithm and therefore is extremely computationally efficient. In particular, let the time complexity of checking for independence, $e_i^t \in E(A^t)$, be $O(g(|A^t|))$. Then the time complexity of OMM is $O(L(\log L + g(K)))$ per episode, comparable to that of sorting L numbers. The design of our algorithm is not surprising and is motivated by prior work [12]. The main challenge is to derive a tight upper bound on the regret of OMM, which would reflect the structure of our problem.

4 Analysis

In this section, we analyze the regret of OMM. Our analysis is organized as follows. First, we introduce basic concepts and notation. Second, we show how to decompose the regret of OMM in a single episode. In particular, we partition the regret of a suboptimal basis into the sum of the regrets of individual items. This part of the analysis relies heavily on the structure of a matroid and is the most novel. Third, we derive two upper bounds, gap-dependent and gap-free, on the regret of OMM. Fourth, we prove a lower bound that matches the gap-dependent upper bound. Finally, we summarize the results of our analysis.

4.1 Notation

Before we present our results, we introduce notation used in our analysis. The *optimal basis* is $A^* = \{a_1^*, \dots, a_K^*\}$.

We assume that the items in A^* are ordered such that a_k^* is the k -th item with the highest expected weight. In episode t , OMM chooses a basis $A^t = \{a_1^t, \dots, a_K^t\}$, where a_k^t is the k -th item chosen by OMM. We say that item e is *suboptimal* if it belongs to $\bar{A}^* = E - A^*$, the *set of suboptimal items*. For any pair of suboptimal and optimal items, $e \in \bar{A}^*$ and a_k^* , we define a *gap*:

$$\Delta_{e,k} = \bar{\mathbf{w}}(a_k^*) - \bar{\mathbf{w}}(e) \quad (8)$$

and use it as a measure of how difficult it is to discriminate the items. For every item $e \in \bar{A}^*$, we define a set:

$$\mathcal{O}_e = \{k : \Delta_{e,k} > 0\}, \quad (9)$$

the indices of items in A^* whose expected weight is higher than that of item e . The cardinality of \mathcal{O}_e is $K_e = |\mathcal{O}_e|$.

4.2 Regret Decomposition

Our decomposition is motivated by the observation that all bases of a matroid are of the same cardinality. As a result, the difference in the expected values of any two bases can be always written as the sum of differences in the weights of their items. In particular:

$$\mathbb{E}_{\mathbf{w}}[f(A^*, \mathbf{w}) - f(A^t, \mathbf{w})] = \sum_{k=1}^K \Delta_{a_k^t, \pi(k)}, \quad (10)$$

where $\pi : \{1, \dots, K\} \rightarrow \{1, \dots, K\}$ is an arbitrary bijection from A^t to A^* such that $\pi(k)$ is the index of the item in A^* that is paired with the k -th item in A^t . In this work, we focus on one particular bijection.

Lemma 1. *For any two matroid bases A^* and A^t , there exists a bijection $\pi : \{1, \dots, K\} \rightarrow \{1, \dots, K\}$ such that:*

$$\{a_1^t, \dots, a_{k-1}^t, a_{\pi(k)}^*\} \in \mathcal{I} \quad \forall k = 1, \dots, K.$$

In addition, $\pi(k) = i$ when $a_k^t = a_i^*$ for some i .

Proof. The lemma is proved in Appendix. ■

The bijection π in Lemma 1 has two important properties. First, $\{a_1^t, \dots, a_{k-1}^t, a_{\pi(k)}^*\} \in \mathcal{I}$ for all k . In other words, OMM can choose item $a_{\pi(k)}^*$ at step k . However, OMM selects item a_k^t . By the design of OMM, this can happen only when the UCB of item a_k^t is larger or equal to that of item $a_{\pi(k)}^*$. As a result, we know that $U_t(a_k^t) \geq U_t(a_{\pi(k)}^*)$ in all steps k . Second, Lemma 1 guarantees that every optimal item in A^t is paired with the same item in A^* .

In the rest of the paper, we represent the bijection π using an indicator function. The indicator function:

$$\mathbb{1}_{e,k}(t) = \mathbb{1}\{\exists i : a_i^t = e, \pi(i) = k\} \quad (11)$$

indicates the event that item e is chosen instead of item a_k^* in episode t . Based on our new representation, we rewrite Equation 10 as:

$$\begin{aligned} \sum_{k=1}^K \Delta_{a_k^t, \pi(k)} &= \sum_{e \in \bar{A}^*} \sum_{k=1}^K \Delta_{e,k} \mathbb{1}_{e,k}(t) \\ &\leq \sum_{e \in \bar{A}^*} \sum_{k=1}^{K_e} \Delta_{e,k} \mathbb{1}_{e,k}(t) \end{aligned} \quad (12)$$

and then bound it from above. The last inequality is due to neglecting the negative gaps.

The above analysis applies to any basis A^t in any episode t . The results of our analysis are summarized below.

Theorem 1. *The expected regret of choosing any basis A^t in episode t is bounded as:*

$$\mathbb{E}_{\mathbf{w}}[f(A^*, \mathbf{w}) - f(A^t, \mathbf{w})] \leq \sum_{e \in \bar{A}^*} \sum_{k=1}^{K_e} \Delta_{e,k} \mathbb{1}_{e,k}(t).$$

The indicator function $\mathbb{1}_{e,k}(t)$ indicates the event that item e is chosen instead of item a_k^* in episode t . When the event $\mathbb{1}_{e,k}(t)$ happens, $U_t(e) \geq U_t(a_k^*)$. Moreover:

$$\begin{aligned} \sum_{e \in \bar{A}^*} \sum_{k=1}^{K_e} \mathbb{1}_{e,k}(t) &\leq K \quad \forall t \\ \sum_{k=1}^{K_e} \mathbb{1}_{e,k}(t) &\leq 1 \quad \forall t, e \in \bar{A}^*. \end{aligned}$$

The last two inequalities follow from the fact that $\mathbb{1}_{e,k}(t)$ is a bijection from A^t to A^* , every item in the suboptimal basis A^t is matched with one unique item in A^* .

One remarkable aspect of our regret decomposition is that the exact form of the bijection is not required in the rest of our analysis. We only rely on the properties of $\mathbb{1}_{e,k}(t)$ that are stated in Theorem 1.

4.3 Upper Bounds

Our first result is a gap-dependent bound.

Theorem 2 (gap-dependent bound). *The expected cumulative regret of OMM is bounded as:*

$$R(n) \leq \sum_{e \in \bar{A}^*} \frac{16}{\Delta_{e,K_e}} \log n + \sum_{e \in \bar{A}^*} \sum_{k=1}^{K_e} \Delta_{e,k} \frac{4}{3} \pi^2.$$

Proof. First, we bound the expected regret in episode t us-

ing Theorem 1:

$$\begin{aligned}
R(n) &= \sum_{t=1}^n \mathbb{E}_{\mathbf{w}_1, \dots, \mathbf{w}_{t-1}} [\mathbb{E}_{\mathbf{w}_t} [R_t(\mathbf{w}_t)]] \\
&\leq \sum_{t=1}^n \mathbb{E}_{\mathbf{w}_1, \dots, \mathbf{w}_{t-1}} \left[\sum_{e \in \bar{A}^*} \sum_{k=1}^{K_e} \Delta_{e,k} \mathbb{1}_{e,k}(t) \right] \\
&= \sum_{e \in \bar{A}^*} \sum_{k=1}^{K_e} \Delta_{e,k} \mathbb{E}_{\mathbf{w}_1, \dots, \mathbf{w}_n} \left[\sum_{t=1}^n \mathbb{1}_{e,k}(t) \right]. \quad (13)
\end{aligned}$$

Second, we bound the expected cumulative regret associated with each item $e \in \bar{A}^*$. The key idea of this step is to decompose the indicator $\mathbb{1}_{e,k}(t)$ as:

$$\begin{aligned}
\mathbb{1}_{e,k}(t) &= \mathbb{1}_{e,k}(t) \mathbb{1}\{T_e(t-1) \leq \ell_{e,k}\} + \\
&\quad \mathbb{1}_{e,k}(t) \mathbb{1}\{T_e(t-1) > \ell_{e,k}\} \quad (14)
\end{aligned}$$

and choose $\ell_{e,k}$ appropriately. By Lemma 2, the regret associated with $T_e(t-1) > \ell_{e,k}$ is bounded as:

$$\begin{aligned}
&\sum_{k=1}^{K_e} \Delta_{e,k} \mathbb{E}_{\mathbf{w}_1, \dots, \mathbf{w}_n} \left[\sum_{t=1}^n \mathbb{1}_{e,k}(t) \mathbb{1}\{T_e(t-1) > \ell_{e,k}\} \right] \\
&\leq \sum_{k=1}^{K_e} \Delta_{e,k} \frac{4}{3} \pi^2 \quad (15)
\end{aligned}$$

when $\ell_{e,k} = \left\lfloor \frac{8}{\Delta_{e,k}^2} \log n \right\rfloor$. For the same value of $\ell_{e,k}$, the regret associated with $T_e(t-1) \leq \ell_{e,k}$ is bounded as:

$$\begin{aligned}
&\sum_{k=1}^{K_e} \Delta_{e,k} \mathbb{E}_{\mathbf{w}_1, \dots, \mathbf{w}_n} \left[\sum_{t=1}^n \mathbb{1}_{e,k}(t) \mathbb{1}\{T_e(t-1) \leq \ell_{e,k}\} \right] \\
&\leq \max_{\mathbf{w}_1, \dots, \mathbf{w}_n} \left[\sum_{t=1}^n \sum_{k=1}^{K_e} \Delta_{e,k} \mathbb{1}_{e,k}(t) \times \right. \\
&\quad \left. \mathbb{1}\left\{ T_e(t-1) \leq \frac{8}{\Delta_{e,k}^2} \log n \right\} \right]. \quad (16)
\end{aligned}$$

The next step of our proof is based on three observations. First, the gaps are ordered such that $\Delta_{e,1} \geq \dots \geq \Delta_{e,K_e}$. Second, by the design of OMM, the counter $T_e(t)$ increases when the event $\mathbb{1}_{e,k}(t)$ happens, for any k . Finally, by Theorem 1, $\sum_{k=1}^{K_e} \mathbb{1}_{e,k}(t) \leq 1$ for any given e and t . Based on these facts, we bound Equation 16 from above by:

$$\left[\Delta_{e,1} \frac{1}{\Delta_{e,1}^2} + \sum_{k=2}^{K_e} \Delta_{e,k} \left(\frac{1}{\Delta_{e,k}^2} - \frac{1}{\Delta_{e,k-1}^2} \right) \right] 8 \log n. \quad (17)$$

By Lemma 3, the above term is bounded by $\frac{16}{\Delta_{e,K_e}} \log n$.

Finally, we combine all of the above inequalities and get:

$$\begin{aligned}
&\sum_{k=1}^{K_e} \Delta_{e,k} \mathbb{E}_{\mathbf{w}_1, \dots, \mathbf{w}_n} \left[\sum_{t=1}^n \mathbb{1}_{e,k}(t) \right] \\
&\leq \frac{16}{\Delta_{e,K_e}} \log n + \sum_{k=1}^{K_e} \Delta_{e,k} \frac{4}{3} \pi^2. \quad (18)
\end{aligned}$$

Our main claim is obtained by summing over all suboptimal items $e \in \bar{A}^*$. ■

We also prove a gap-free bound.

Theorem 3 (gap-free bound). *The expected cumulative regret of OMM is bounded as:*

$$R(n) \leq 8\sqrt{KLn \log n} + \frac{4}{3}\pi^2 KL.$$

Proof. The key idea is to decompose the expected cumulative regret of OMM into two parts, where the gaps are larger than ε and at most ε . We analyze each part separately and then set ε to get the desired result.

Let $K_{e,\varepsilon}$ be the number of optimal items whose expected weight is higher than that of item e by more than ε and:

$$Z_{e,k}(n) = \mathbb{E}_{\mathbf{w}_1, \dots, \mathbf{w}_n} \left[\sum_{t=1}^n \mathbb{1}_{e,k}(t) \right]. \quad (19)$$

Then, based on Equation 13, the regret of OMM is bounded for any ε as:

$$\begin{aligned}
R(n) &\leq \sum_{e \in \bar{A}^*} \sum_{k=1}^{K_{e,\varepsilon}} \Delta_{e,k} Z_{e,k}(n) + \\
&\quad \sum_{e \in \bar{A}^*} \sum_{k=K_{e,\varepsilon}+1}^{K_e} \Delta_{e,k} Z_{e,k}(n). \quad (20)
\end{aligned}$$

The first term can be bounded similarly to Equation 18:

$$\begin{aligned}
&\sum_{e \in \bar{A}^*} \sum_{k=1}^{K_{e,\varepsilon}} \Delta_{e,k} Z_{e,k}(n) \\
&\leq \sum_{e \in \bar{A}^*} \frac{16}{\Delta_{e,K_{e,\varepsilon}}} \log n + \sum_{e \in \bar{A}^*} \sum_{k=1}^{K_{e,\varepsilon}} \Delta_{e,k} \frac{4}{3} \pi^2 \\
&\leq \frac{16}{\varepsilon} L \log n + \frac{4}{3} \pi^2 KL. \quad (21)
\end{aligned}$$

The second term is bounded trivially as:

$$\sum_{e \in \bar{A}^*} \sum_{k=K_{e,\varepsilon}+1}^{K_e} \Delta_{e,k} Z_{e,k}(n) \leq \varepsilon Kn \quad (22)$$

because all gaps $\Delta_{e,k}$ are bounded by ε and the maximum number of suboptimally chosen items in n episodes is Kn (Theorem 1). Based on our upper bounds, we get:

$$R(n) \leq \frac{16}{\varepsilon} L \log n + \varepsilon Kn + \frac{4}{3} \pi^2 KL \quad (23)$$

and then set $\varepsilon = 4\sqrt{\frac{L \log n}{Kn}}$. This concludes our proof. ■

4.4 Lower Bounds

We derive an asymptotic lower bound on the expected cumulative regret $R(n)$ that has the same dependence on the gap and n as the upper bound in Theorem 2. This bound is proved on a class of matroid bandits that are equivalent to K Bernoulli bandits.

Specifically, we prove the lower bound on a *partition matroid bandit*, which is defined as follows. Let E be a set of L items and B_1, \dots, B_K be a partition of this set. Let the family of independent sets be defined as:

$$\mathcal{I} = \{I \subseteq E : (\forall k : |I \cap B_k| \leq 1)\}. \quad (24)$$

Then $M = (E, \mathcal{I})$ is a *partition matroid* of rank K . Let P be a probability distribution over the weights of the items, where the weight of each item is distributed independently of the other items. Let the weight of item e be drawn i.i.d. from a Bernoulli distribution with mean:

$$\bar{\mathbf{w}}(e) = \begin{cases} 0.5 & e = \min_{i \in B_k} i \\ 0.5 - \Delta & \text{otherwise,} \end{cases} \quad (25)$$

where $\Delta > 0$. Then $\tilde{B} = (M, P)$ is our partition matroid bandit. The key property of \tilde{B} is that it is equivalent to K independent Bernoulli bandits, one for each partition. The optimal item in each partition is the item with the smallest index, $\min_{i \in B_k} i$. All gaps are Δ .

To formalize our result, we need to introduce the notion of *consistent algorithms*. We say that the algorithm is consistent if for any matroid bandit, any suboptimal $e \in \bar{A}^*$, and any $\alpha > 0$, $\mathbb{E}[T_e(n)] = o(n^\alpha)$, where $T_e(n)$ is the number of times that item e is chosen in n episodes. In the rest of our analysis, we focus only on consistent algorithms. This is without loss of generality. In particular, by definition, an inconsistent algorithm performs poorly on some problems, and therefore extremely well on others. Because of this, it is difficult to prove good problem-dependent lower bounds for inconsistent algorithms. Our main claim is below.

Theorem 4. *For any partition matroid bandit \tilde{B} that is defined in Equations 24 and 25, and parameterized by L, K , and $0 < \Delta < 0.5$; the regret of any consistent algorithm is bounded from below as:*

$$\liminf_{n \rightarrow \infty} \frac{R(n)}{\log n} \geq \frac{L - K}{4\Delta}.$$

Proof. The theorem is proved as follows:

$$\begin{aligned} \liminf_{n \rightarrow \infty} \frac{R(n)}{\log n} &\geq \sum_{k=1}^K \sum_{e \in B_k - A^*} \frac{\Delta}{\text{kl}(0.5 - \Delta, 0.5)} \\ &= \frac{(L - K)\Delta}{\text{kl}(0.5 - \Delta, 0.5)} \\ &\geq \frac{L - K}{4\Delta}, \end{aligned} \quad (26)$$

where $\text{kl}(0.5 - \Delta, 0.5)$ is the KL divergence between two Bernoulli variables with means $0.5 - \Delta$ and 0.5 . The first inequality is due to Theorem 2.2 [4], which is applied separately to each partition B_k . The second inequality is due to $\text{kl}(p, q) \leq \frac{(p-q)^2}{q(1-q)}$, where $p = 0.5 - \Delta$ and $q = 0.5$. ■

4.5 Summary of Theoretical Results

We prove two upper bounds on the regret of OMM, one gap-dependent and one gap-free. These bounds can be summarized as:

$$\begin{aligned} \text{Theorem 2} & \quad O(L(1/\Delta) \log n) \\ \text{Theorem 3} & \quad O(\sqrt{KLn \log n}), \end{aligned} \quad (27)$$

where $\Delta = \min_e \min_{k \in \mathcal{O}_e} \Delta_{e,k}$. Both bounds are sublinear in the number of episodes n , and at most linear in the rank K of the matroid and the number of items L . In other words, they scale favorably with all quantities of interest and as a result we expect them to be practical.

Our upper bounds are reasonably tight. More specifically, the gap-dependent upper bound in Theorem 2 matches the lower bound in Theorem 4, which is proved on a partition matroid bandit. Furthermore, the gap-free upper bound in Theorem 3 matches the lower bound of Audibert *et al.* [2] in adversarial combinatorial semi-bandits, up to a factor of $\sqrt{\log n}$.

Our gap-dependent upper bound has the same form as the bound of Auer *et al.* [3] for multi-armed bandits. This observation suggests that the sample complexity of learning a maximum-weight basis of a matroid is comparable to that of the multi-armed bandit. The only major difference is in the definitions of the gaps. We conclude that learning with matroids is extremely sample efficient.

5 Experiments

Our algorithm is evaluated on three matroid bandit problems: graphic (Section 5.1), transversal (Section 5.2), and linear (Section 5.3).

All experiments are episodic. In each episode, OMM selects a basis A^t , observes the weights of the individual items in that basis, and then updates its model of the environment. The performance of OMM is measured by the *expected per-step return* in n episodes:

$$\frac{1}{n} \mathbb{E}_{\mathbf{w}_1, \dots, \mathbf{w}_n} \left[\sum_{t=1}^n f(A^t, \mathbf{w}_t) \right], \quad (28)$$

the expected cumulative return in n episodes divided by n . OMM is compared to two baselines. The first baseline is the maximum-weight basis A^* in expectation. The basis A^* is computed as in Equation 4 and is our notion of optimality.

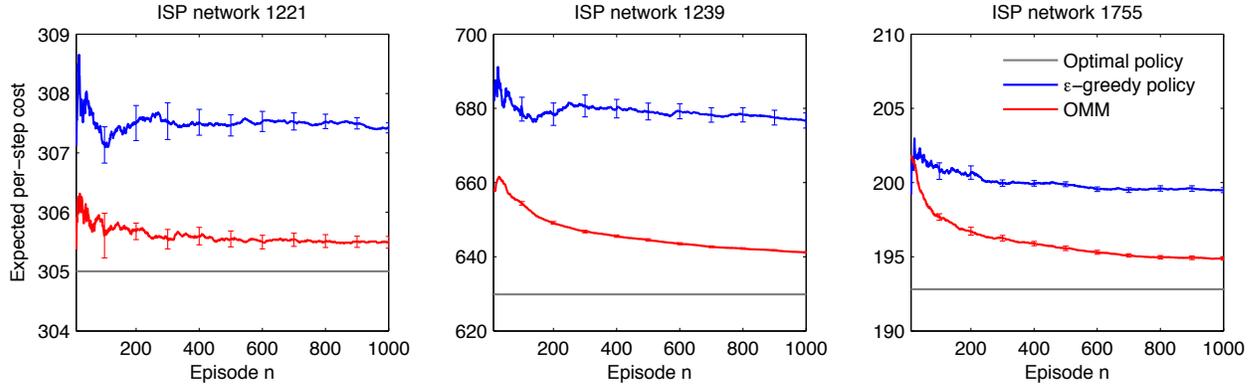

Figure 1: The expected per-step cost of building three minimum spanning trees in up to 10^3 episodes.

ISP network	Number of nodes	Number of edges	Minimum latency	Maximum latency	Average latency	Optimal policy	ϵ -greedy policy	OMM
1221	108	153	1	17	2.78	305.00	307.42 ± 0.08	305.49 ± 0.10
1239	315	972	1	64	3.20	629.88	676.74 ± 2.03	641.17 ± 0.18
1755	87	161	1	31	2.91	192.81	199.49 ± 0.16	194.88 ± 0.11
3257	161	328	1	47	4.30	550.85	570.35 ± 0.63	559.80 ± 0.10
3967	79	147	1	44	5.19	306.80	320.30 ± 0.52	308.54 ± 0.08
6461	141	374	1	45	6.32	376.27	424.78 ± 1.54	381.48 ± 0.07

Table 1: The description of six ISP networks from our experiments and the expected per-step cost of building minimum spanning trees on these networks in 10^3 episodes. All latencies and costs are in milliseconds.

The second baseline is an ϵ -greedy policy, where $\epsilon = 0.1$. This setting of ϵ is common in practice and corresponds to 10% exploration.

5.1 Graphic Matroid

In the first experiment, we evaluate OMM on the problem of learning a routing network for an Internet service provider (ISP). We make the assumption that the routing network is a spanning tree. Our objective is to learn a tree that has the lowest expected latency on its edges.

Our problem can be formulated as a *graphic matroid bandit*. The ground set E are the edges of a graph, which represents the topology of a network. We experiment with six networks from the *RocketFuel* dataset [23], which contain up to 300 nodes and 10^3 edges (Table 1). A set of edges is considered *independent* if it does not contain a cycle. The latency of edge e is $w(e) = \bar{w}(e) - 1 + \epsilon$, where $\bar{w}(e)$ is the expected latency, which is recorded in our dataset; and $\epsilon \sim \text{Exp}(1)$ is exponential noise. The latency $\bar{w}(e)$ ranges from one to 64 milliseconds. Our noise model is motivated by the following observation. The latency in ISP networks can be mostly explained by geographical distances [7], the expected latency $\bar{w}(e)$. The noise tends to be small, on the order of a few hundred microseconds, and it is unlikely to cause high latency.

In Figure 1, we report our results from three ISP networks.

We observe the same trends on all networks. First, the expected cost of OMM approaches that of the optimal solution A^* as the number of episodes increases. Second, OMM outperforms the ϵ -greedy policy in less than 10 episodes. The expected costs of all policies on all networks are reported in Table 1. We observe again that OMM consistently outperforms the ϵ -greedy policy, often by a large margin.

OMM learns quickly because all of our networks are sparse. In particular, the number of edges in each network is never more than four times larger than the number of edges in its spanning tree. Therefore, at least in theory, each edge can be observed at least once in four episodes and our method can learn quickly the mean latency of each edge.

5.2 Transversal Matroid

In the second experiment, we study the assignment of lending institutions (known as *partners*) to *lenders* in a micro-finance setting, such as Kiva [1]. This problem can be formulated under a family of matroids, called *transversal matroids* [9]. The ground set E of a transversal matroid is the set of left vertices of the corresponding bipartite graph, and the independence set \mathcal{I} consists of the sets of left vertices that belong to all possible matchings in the graph such that no two edges in a matching share an endpoint. The weight $\bar{w}(e)$ is the weight associated with the left vertices of the bipartite graph. The goal is to learn a transversal of the bipartite graph that maximizes the overall weight of selected

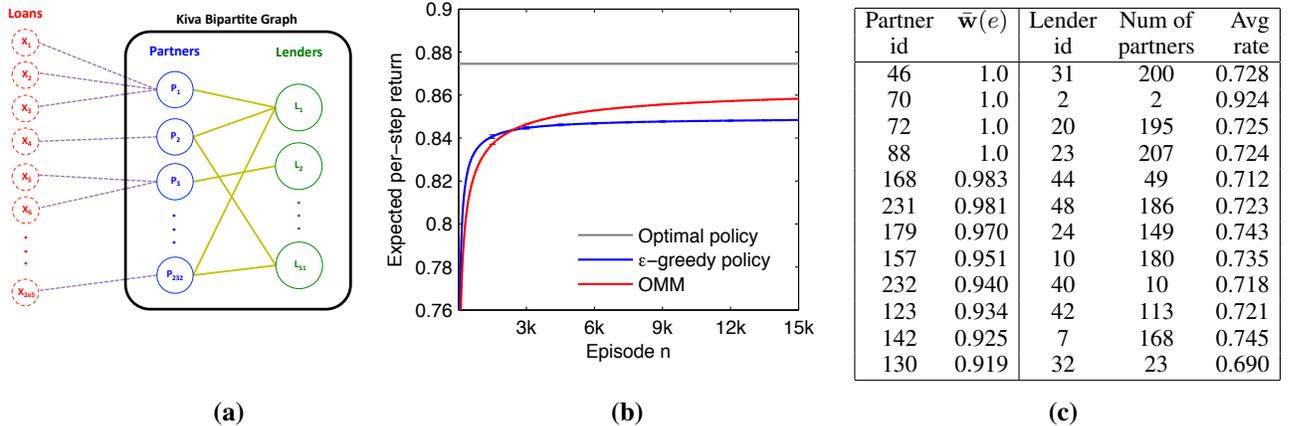

Figure 2: **(a)** The Kiva dataset can be modeled as a bipartite graph connecting lenders to field partners, which, in turn, fund several loans in the region. **(b)** The expected per-step return of finding maximum weight transversal in up to 15k episodes. **(c)** Top 12 selected partners assigned based on their mean success rate in the optimal solution A^* . The optimal solution involves 46 partner/lender assignments.

left vertices.

We used a sample of 194, 876 loans from the Kiva microfinance dataset [1], and created a bipartite graph. Every loan is handled by a partner (Figure 2-a). There are a total of 232 partners in the dataset that represent the left vertices of the bipartite graph and therefore the ground set E of the matroid. There are 286, 874 lenders in the dataset. We grouped these lenders into 51 clusters according to their location: 50 representing each individual state in United States, and 1 representing all foreign lenders. These 51 lender clusters constitute the right vertices of the bipartite graph. There is an edge between a partner and a lender if the lender is among the top 50% supporters of the partner, resulting in approximately 5k edges in the bipartite graph. The weight $\bar{w}(e)$ is the probability that a loan handled by partner e will be paid back. We estimate it from the dataset as $\bar{w}(e) = \frac{1}{n_l} \sum_{i=1}^{n_l} w_i(e)$, where n_l is the number of loans handled by this partner. We assume $w_i(e)$ is 0.7 if the loan i is in repayment, 1 if it is paid, and 0 otherwise. At the beginning of each episode, we choose the loan i at random.

The optimal solution A^* is a transversal in the graph that maximizes the overall success rate of the selected partners. Top twelve partners selected based on their mean success rate in the optimal solution are shown in Figure 2-c. For each partner, the id of the lender to which this partner was assigned along with the number of eligible partners of the lender and their average success rate are listed in the Table. The objective of OMM and ϵ -greedy policies is similar to the optimal policy with the difference that success rates (i.e. $w(e)$) are not known beforehand, and they must be learned by interacting repeatedly with the environment. Comparison results of the three policies are reported in Figure 2-b. Similar to the previous experiment, we observe the following trends. First, the expected return of OMM approaches

that of the optimal solution A^* as the number of episodes increases. Second, OMM outperforms the ϵ -greedy policy.

5.3 Linear Matroid

In the last experiment, we evaluate OMM on the problem of learning a set of diverse and popular movies. This kind of movies is typically recommended by existing content recommender systems. The movies are popular, and therefore the user is likely to choose them. The movies are diverse, and therefore cover many potential interests of the user.

Our problem can be formulated as a *linear matroid bandit*. The ground set E are movies from the *MovieLens* dataset [16], a dataset of 6 thousand people who rated one million movies. We restrict our attention to 25 most rated movies and 75 movies that are not well known. So the cardinality of E is 100. For each movie e , we define a feature vector $\mathbf{u}_e \in \{0, 1\}^{18}$, where $\mathbf{u}_e(j)$ indicates that movie e belongs to genre j . A set of movies X is considered *independent* if for any movie $e \in X$, the vector \mathbf{u}_e cannot be written as a linear combination of the feature vectors of the remaining movies in X . This is our notion of diversity. The expected weight $\bar{w}(e)$ is the probability that movie e is chosen. We estimate it as $\bar{w}(e) = \frac{1}{n_p} \sum_{i=1}^{n_p} w_i(e)$, where $w_i(e)$ is the indicator that person i rated movie e and n_p is the number of people in our dataset. At the beginning of each episode, we choose the person i at random.

Twelve most popular movies from the optimal solution A^* are listed in Figure 3. These movies cover a wide range of movie genres and appear to be diverse. This validates our assumption that linear independence is suitable for modeling diversity. The expected return of OMM is reported in the same figure. We observe the same trends as in the previous experiments. More specifically, the expected return of OMM

Movie title	$\bar{w}(e)$	Movie genres
American Beauty	0.568	Comedy Drama
Jurassic Park	0.442	Action Adventure Sci-Fi
Saving Private Ryan	0.439	Action Drama War
Matrix	0.429	Action Sci-Fi Thriller
Back to the Future	0.428	Comedy Sci-Fi
Silence of the Lambs	0.427	Drama Thriller
Men in Black	0.420	Action Adventure Comedy Sci-Fi
Fargo	0.416	Crime Drama Thriller
Shakespeare in Love	0.392	Comedy Romance
L.A. Confidential	0.379	Crime Film-Noir Mystery Thriller
E.T. the Extra-Terrestrial	0.376	Children's Drama Fantasy Sci-Fi
Ghostbusters	0.361	Comedy Horror

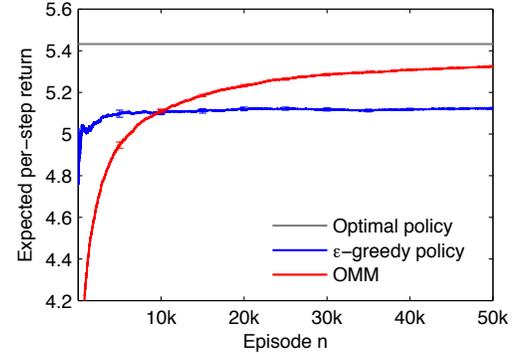

Figure 3: **Left.** Twelve most popular movies in the optimal solution A^* . The optimal solution involves 17 movies. **Right.** The expected per-step return of three movie recommendation policies in up to 50k episodes.

approaches that of A^* as the number of episodes increases and OMM outperforms the ε -greedy policy in 10k episodes.

6 Related Work

Our problem can be viewed as a stochastic combinatorial semi-bandit [12], where all feasible solutions are the independent sets of a matroid. Stochastic combinatorial semi-bandits were pioneered by Gai *et al.* [12], who proposed a UCB algorithm for solving these problems. Chen *et al.* [6] proved that the expected cumulative regret of this method is $O(K^2 L(1/\Delta) \log n)$. Our gap-dependent regret bound is $O(L(1/\Delta) \log n)$, a factor of K^2 tighter than the bound of Chen *et al.* [6]. Our analysis relies heavily on the properties of our problem and therefore we can derive a much tighter bound.

COMBAND [5], OSMD [2], and FPL [19] are algorithms for adversarial combinatorial semi-bandits. The main limitation of COMBAND and OSMD is that they are not guaranteed to be computationally efficient. More specifically, COMBAND needs to sample from a distribution over exponentially many solutions and OSMD needs to project to the convex hull of these solutions. FPL is computationally efficient but not very practical because its time complexity increases with time. On the other hand, OMM is guaranteed to be computationally efficient but can only solve a special class of combinatorial bandits, matroid bandits.

Matroids are a broad and important class of combinatorial optimization problems [21], which has been an active area of research for the past 80 years. This is the first paper that studies a well-known matroid problem in the bandit setting and proposes a learning algorithm for solving it.

Our work is also related to submodularity [18]. In particular, let:

$$g(X) = \max_{Y: Y \subseteq X, Y \in \mathcal{I}} f(Y, \bar{w}) \quad (29)$$

be the maximum weight of an independent set in X . Then

it is easy to show that $g(X)$ is submodular and monotonic in X , and that the maximum-weight basis of a matroid is a solution to $A^* = \arg \max_{A: |A|=K} g(A)$. Many algorithms for learning how to maximize a submodular function have been proposed recently [13, 26, 10, 24, 11]. None of these algorithms are suitable for solving our problem. There are two reasons. First, each algorithm is designed to maximize a specific submodular function and our function g may not be of that type. Second, the algorithms are only near optimal, learn a set A such that $g(A) \geq (1 - 1/e)g(A^*)$. Note that our method is guaranteed to be optimal and learn A^* .

7 Conclusions

This is the first work that studies the problem of learning a maximum-weight basis of a matroid, where the weights of the items are initially unknown, and have to be learned by interacting repeatedly with the environment. We propose a practical algorithm for solving this problem and bound its regret. The regret is sublinear in time and at most linear in all other quantities of interest. We evaluate our method on three real-world problems and show that it is practical.

Our regret bounds are $\Omega(\sqrt{L})$. Therefore, OMM is not practical when the number of items L is large. We believe that these kinds of problems can be solved efficiently by introducing additional structure, such as *linear generalization*. In this case, the weight of each item would be modeled as a linear function of its features and the goal is to learn the parameters of this function.

Many combinatorial optimization problems can be viewed as optimization on a matroid or its generalizations, such as *maximum-weight matching* on a bipartite graph and *minimum cost flows*. In a sense, these are the hardest problems in combinatorial optimization that can be solved optimally in polynomial time [22]. In this work, we show that one of these problems is efficiently learnable. We believe that the key ideas in our work are quite general and can be applied to other problems that involve matroids.

Abstract

In this paper, we present a novel probabilistic label enhancement model to tackle multi-label image classification problem. Recognizing multiple objects in images is a challenging problem due to label sparsity, appearance variations of the objects and occlusions. We propose to tackle these difficulties from a novel perspective by constructing auxiliary labels in the output space. Our idea is to exploit label combinations to enrich the label space and improve the label identification capacity in the original label space. In particular, we identify a set of informative label combination pairs by constructing a tree-structured graph in the label space using the maximum spanning tree algorithm, which naturally forms a conditional random field. We then use the produced label pairs as auxiliary new labels to augment the original labels and perform piecewise training under the framework of conditional random fields. In the test phase, max-product message passing is used to perform efficient inference on the tree graph, which integrates the augmented label pair classifiers and the standard individual binary classifiers for multi-label prediction. We evaluate the proposed approach on several image classification datasets. The experimental results demonstrate the superiority of our label enhancement model in terms of both prediction performance and running time comparing to the state-of-the-art multi-label learning methods.

1 INTRODUCTION

With the development of internet and digital devices, the availability of visual data has been dramatically increasing in recent decades, which provides billions of images and videos. An important task for information retrieval and processing over such image and video data is object-

based image annotation, which requires identifying a set of objects presented in each image from a given set of desired object concepts. The image annotation problem for object recognition is an inherent multi-label classification problem, since each image usually contains more than one object of interest. Multi-label classification generalizes the standard multi-class classification by allowing each instance to be simultaneously assigned into multiple label categories. A key challenge for multi-label classification is label sparsity. That is, the multiple labels are supported by the training data at different levels and many rare labels may lack sufficient training supports to be reliably recognized individually. Hence instead of learning binary classifiers independently for each label, many multi-label learning methods have proposed to exploit label correlations or label dependence to improve multi-label classification performance, including second-order strategy methods [7, 11, 15], which model pairwise label correlations, and high-order strategy methods [16, 19, 36], which consider the interactions among subsets of labels.

Moreover, on image classification, multi-label learning also faces the general intra-class variation challenge of standard multi-class classification which is caused by viewpoint and context variations and occlusions, as shown in Figure 1. From the figures, we can see that the appearance of the object *people* can be profoundly different across different images, by co-occurring with different objects and having different occlusion patterns. In such cases, an individual binary classifier may not be reliable for recognizing a target object. But other co-occurred objects can likely provide some useful information. For example, in the image “*people riding a bike*”, many parts of the *bike* are invisible, but the *people* is easy to recognize and can provide information about the *bike*; in the image “*people sitting in the car*”, each *people* is severely occluded but the *car* can be detected easily and help the recognition of the *people* if they often co-occur; in the image “*people riding a horse*”, the objects *people* and *horse* can be helpful to each other as well. Moreover, the recognition of such composite co-occurrence patterns can also help the correct recognition of individual objects, especially for the ones that are occluded

Figure 1: Examples of image occlusion and object co-occurrence patterns in object recognition tasks.

or difficult to be recognized individually.

Motivated by these observations, in this paper, we propose a novel probabilistic label enhancement model that utilizes the label combination patterns to improve multi-label image classification performance. Our assumption is that visual composites can be helpful when single classifier fails. For example, assume the composite “*people riding horses*” often stays in similar poses. A classifier for this visual composite can then capture the co-appearance of the two objects even though both *people* and *horse* classifiers fail to reliably recognize them separately. We propose to construct label combinations, in particular label pairs, as auxiliary new labels to augment the original labels and improve label identification capacity in the original label space. In particular, we identify a set of informative label combination pairs by constructing a tree-structured graph in the label space using the maximum spanning tree algorithm, according to the label co-occurrence information in the training data. This naturally forms a conditional random field framework, under which we perform piecewise training. The label pairs identified by the edges of the tree are used as auxiliary new labels, and a binary classifier is trained for each label in the augmented label space. To integrate the augmented multiple binary classifiers for multi-label prediction in the original label space, we perform exact inference on the tree-structured conditional random field using max-product message passing. We evaluate the proposed approach on a number of multi-label image classification datasets. The experimental results show that the proposed label enhancement model effectively outperforms the related state-of-the-art methods in terms of both prediction performance and running time.

The rest of the paper is organized as follows. In Section 2, we present a brief review over the related work. The proposed approach is presented in Section 3. We report the experimental results in Section 4 and finally conclude the paper in Section 5.

2 RELATED WORK

A considerable amount of research has been devoted to addressing image annotation and multi-label classification

problems in the literature. In this section, we will provide a brief review over the most related work to the proposed approach from the perspectives of image annotation, object interaction and multi-label classification.

Image Annotation There are three major groups of image annotation techniques [13]: (i) Generative models. Some methods in this group use generative topic models such as latent Dirichlet allocation [1], probabilistic latent semantic analysis [24], and hierarchical Dirichlet processes [33]. They model annotated images as samples from a mixture of topics, where each topic is a distribution over image features. Some other methods use mixture models to define a joint distribution over image features and annotation tags [4, 9, 22]. However, generative models perform training by maximizing generative data likelihoods, which are not necessarily optimal for the target prediction performance. (ii) Discriminative models. The methods in this group address image annotation as a classification problem. For example, simple methods in [23, 12] treat labels independently and learn a classifier for each label, while more advanced methods in [30, 3] improve the classification performance by considering the co-occurrences of different labels. (iii) Nearest neighbor based models. For example, the label propagation method in [13] constructs a similarity graph for all images, and propagates the label information via the graph; and the search based method in [10] exploits a regression based kernel metric.

Object Interaction There are a number of works on object interaction that share the same intuition as our proposed work, that is, visual composites can be helpful while single components fail. The work in [18] learns object interactions by modeling the prepositions and adjectives that relate nouns. The work in [34] models the co-occurrence of objects and human poses in human-object interaction activities. In [8], the interactions between objects are modeled implicitly in the context of predicting sentences for images. [28] introduces a complex visual composite concept called visual phrase for object detection, which treats each phrase as a new label. Though this work shares similarity with our proposed work in exploiting visual composites, there are significant differences between it and our work. First, its visual phrases are not automatically discovered but predefined. By contrast, the label combinations in our work are

constructed automatically. Second, it addresses very different problems from ours. It tackles object detection tasks while we address multi-label image annotation problems; its goal is to find a bounding box where the visual composite occurs, while our goal is to predict the category labels of an image.

Multi-label Classification The most straightforward multi-label classification method is binary relevance [2], which trains a binary classifier for each label. The obvious flaw of such method is the complete ignorance of label correlations. Hence, numerous methods that encode label correlations have been proposed. One group is the ranking based methods [7, 11, 32], which rank the relevant labels higher than irrelevant ones and capture label correlations implicitly in the loss function. This technique however relies on a good distance metric and a fine-tuned threshold in determining the number of relevant labels. The method in [15] hence further eliminates this drawback by developing a novel calibrated separation ranking loss function. Another group is the graph-based methods, which implicitly incorporate label correlations into label propagation algorithms as either part of the graph weights [20, 5] or additional constraints [30, 35]. There are also a set of probabilistic graph-based methods [6, 14, 17, 27]. The method in [14] uses directed graphs over the label variables to capture label dependence under a probabilistic conditional dependency network model. [17] further improves this model by learning sparse conditional dependency graphs. [6, 27] integrate multiple classifiers in a chain graph to capture label correlations. These methods share similarity with our proposed approach in capturing label correlations by integrating probabilistic classifiers on graphs over labels. However, [6, 27] are limited to chain graphs and they apply greedy heuristics to search for the best label vector on each test instance; [14, 17] use cyclic directed graphs and their test phases involve approximate inference. By contrast, our method can exploit any automatically generated acyclic tree graphs, not necessarily chains, while using a max-product message passing algorithm to perform efficient exact inference.

3 PROPOSED MODEL

3.1 Preliminaries

Multi-label Classification systems can be described as below. Given the input feature space $\mathcal{X} \in \mathbb{R}^d$ and the output label space $\mathcal{Y} = \{0, 1\}^L$, a mapping function $\mathbf{h}: \mathcal{X} \rightarrow \mathcal{Y}$ can be used to predict the corresponding label vector $\mathbf{y} \in \mathcal{Y}$ for each input data instance $\mathbf{x} \in \mathcal{X}$. Multi-label learning focuses on identifying a good mapping function \mathbf{h} from the training data. The most straightforward method to learn such a mapping function is the binary relevance method, which assumes labels are independently generated and learns one binary classifier h_i for each label. The out-

put of \mathbf{h} is a L -length binary vector

$$\mathbf{h}(\mathbf{x}) = [h_1(\mathbf{x}), h_2(\mathbf{x}), \dots, h_L(\mathbf{x})].$$

The binary classifier h_i can be trained by minimizing different loss functions, such as log-loss and hinge loss.

Conditional Random Fields (CRFs) are undirected graphical models that model the conditional distribution of the output labels given an input vector based on undirected graphs. An undirected graph $G = (V, E)$ in the label space is formed by a set of vertices V , each of which represents a label variable, and a set of undirected edges E , where each edge consists of a pair of vertices $(s, t) \in E$ and represents the dependence relationship between the label variables. The joint probability of a configuration of the label variables in a CRF can be given by

$$P(\mathbf{y}_1, \mathbf{y}_2, \dots, \mathbf{y}_L | \mathbf{x}) = \frac{1}{Z(\mathbf{x})} \prod_{c \in \mathcal{C}} \psi_c(\mathbf{y}_c, \mathbf{x})$$

where $Z(\mathbf{x})$ is a partition function that ensures a valid conditional distribution given the input data instance \mathbf{x} , \mathcal{C} is the set of cliques of the graph, and ψ_c is the potential function for clique c , which maps the clique label configuration \mathbf{y}_c and the input data instance \mathbf{x} into a positive scalar value. The standard training procedure of conditional random fields typically involves first-order gradient descent or second-order Newton methods, which require performing inference over each training instance in each iterative parameter update step. For general graphs, performing exact inference in CRFs is intractable, and approximate inference algorithms are usually used instead. Moreover, performing inference in each parameter update step can make the training process computationally expensive, especially for large and densely connected graphs and large training sets.

3.2 Probabilistic Label Enhancement Model

The straightforward method for multi-label image classification casts the problem as a set of independent binary classification problems, one for each object label, and trains one binary classifier for each label using the one-vs-all scheme. Training binary classifiers is computationally efficient and the one-vs-all training scheme can scale linearly with the increasing of the label set. However, as we discussed before, such binary classifiers can fail to accurately recognize the individual objects in an image, due to label sparsity, intra-class variations, and occlusions. In this work, we propose to enhance these standard binary classifiers by exploiting the label combination patterns which typically present as co-occurred object composites in images of the training data, as shown in Figure 1. We first identify the informative label combination pairs by learning a tree-structured undirected graph in the label space, which forms the structure of a conditional random field.

Then we use the label combination pairs as augmenting new labels and formulate the learning process as a piecewise training procedure under the framework of conditional random fields. Finally we apply the trained probabilistic model to predict labels for test images using a max-product exact inference algorithm.

3.2.1 Learning Tree-Structured Graph

Given the labeled training images $D = \{(\mathbf{x}^{(i)}, \mathbf{y}^{(i)})\}_{i=1}^n$, where each label vector $\mathbf{y}^{(i)}$ contains $\{0,1\}$ values with length L , corresponding to the L label classes, we aim to identify the useful object composites by finding the informative label co-occurrence patterns. Though in principle we can consider any label combination patterns, for computational simplicity we focus on second-order patterns, i.e., label pairs. We take all possible label pairs as candidates by constructing a fully connected graph over the L label variables. Then we measure the combination strength of each label pair as the weight of the corresponding edge using an appropriate criterion. One standard criterion is the empirical *mutual information* measure, which is popularly used to measure the dependence strength of two variables and can be computed from the training data. For example, the empirical mutual information between label variables Y_i and Y_j can be computed as

$$MI(Y_i; Y_j) = \sum_{y_i, y_j \in \{0,1\}} \hat{P}(y_i, y_j) \log \left(\frac{\hat{P}(y_i, y_j)}{\hat{P}(y_i)\hat{P}(y_j)} \right)$$

with the empirical probabilities computed from the training data. However, this measure treats the co-presence of the two labels and the co-missing of them equivalently, while we want to find the label composites that have significant co-presence patterns. Hence we propose a simple new measure, *normalized co-occurrence*, to use. For two label variables Y_i and Y_j , the normalized co-occurrence measure is defined as

$$NC(Y_i; Y_j) = \frac{\text{count}(Y_i, Y_j)}{\min(\text{count}(Y_i), \text{count}(Y_j))}$$

where $\text{count}(Y_i, Y_j)$ is the number of co-occurrence of the two labels in the training data, such that

$$\text{count}(Y_i, Y_j) = \sum_{\ell=1}^n I[\mathbf{y}_i^{(\ell)} = 1, \mathbf{y}_j^{(\ell)} = 1] \quad (1)$$

and $I[\cdot]$ denotes an indicator function. Similarly, $\text{count}(Y_i)$ and $\text{count}(Y_j)$ are the numbers of occurrences of single labels in the training data. By normalizing the co-occurrence counts of the two labels with the minimum of their individual occurrence counts, the measure emphasizes the relative relatedness of the two objects and favors the less frequently appeared objects. For example, assume there are 15 images containing *people* and *dogs*, and 10 images containing *people* and *cars*, while there are totally 100 people images, 80

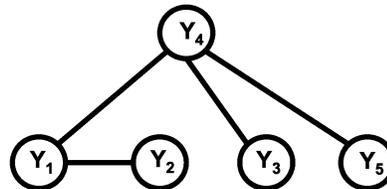

Figure 2: An example of the constructed tree-structured graph over labels.

dog images and 20 car images. The composite of *people* and *cars* can be more important to capture than the composite of *people* and *dogs*, towards the goal of assisting the objects with sparse supports in the training data. Our proposed measure encodes this principle.

Given the proposed normalized co-occurrence criterion, we can compute the weights for all edges between the label variables. Then we use a maximum spanning tree algorithm to select $(L - 1)$ edges according to the computed weights to form a tree-structured graph. In our implementation, we used Prim’s algorithm [26] to produce the maximum spanning tree. Figure 2 demonstrates an example of the constructed tree graph over the label variables. The label pair connected by each edge on the constructed tree graph will be used as a constructed new label to augment the original labels. For example, for the tree graph in Figure 2, since there is an edge between the node Y_1 and the node Y_2 , we will consider a constructed new label $Y_{1\sim 2}$, which has binary values $\{0, 1\}$. The label value for $Y_{1\sim 2}$ in each instance can be produced based on that $Y_{1\sim 2} = 1$ is equivalent to $Y_1 = 1 \wedge Y_2 = 1$. Then for each instance $\mathbf{x}^{(i)}$, we set $\mathbf{y}_{1\sim 2}^{(i)} = 1$ if and only if the instance has been assigned both label Y_1 and label Y_2 such that $\mathbf{y}_1^{(i)} = 1$ and $\mathbf{y}_2^{(i)} = 1$. Otherwise, we have $\mathbf{y}_{1\sim 2}^{(i)} = 0$. Thus each constructed new label can be treated as a new prediction class from the prediction perspective. The reason that we produce tree graphs instead of densely connected cyclic graphs is that tree graphs have acyclic structures and permit efficient exact inference in the test phase to integrate the augmented label classifiers with the binary classifiers in the original label space.

3.2.2 Piecewise Training of CRFs

The tree-structured graph constructed in the label space actually forms a standard CRF model that permits label vector prediction from the input data, where we treat each node and each edge as separate cliques. Based on our motivation of capturing object composite concept to help the multi-label prediction in the original label space, we propose to perform piecewise training for the tree-structured CRF by learning the potential functions for each node clique and each edge clique separately. That is, we train a set of L binary classifiers independently from the data, one for each

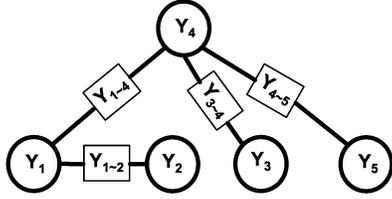

Figure 3: The factor graph constructed from the tree graph in Figure 2. The circle nodes are variable nodes and the rectangle nodes are factor nodes.

label in the original label space, as the potential functions for the node cliques, and train a set of $(L - 1)$ binary classifiers independently from the data for the constructed new labels as the potential functions for the corresponding edge cliques. Piecewise training can effectively avoid the repeated inference required for each step of parameter updates in the standard CRF training procedure and make the learning process efficient and scalable. It has been shown in [29] that piecewise training of a CRF can be justified as minimizing a family of upper bounds on the log partition function of the data log-likelihood.

To have the outputs of potential functions compatible to each other, we propose to use binary probabilistic classifiers, in particular binary logistic regression classifiers, for training. Each binary logistic regression classifier can be trained efficiently by using second-order Newton methods to minimize the regularized log-likelihood. For the k -th classifier, this is to minimize

$$\min_{\mathbf{w}} \sum_{i=1}^n \log \left(1 + e^{-\hat{\mathbf{y}}_k^{(i)} \mathbf{w}^\top \mathbf{x}^{(i)}} \right) + \frac{\beta}{2} \mathbf{w}^\top \mathbf{w} \quad (2)$$

where β is a trade-off parameter, and $\hat{\mathbf{y}}_k^{(i)}$ is simply the translation of $\mathbf{y}_k^{(i)}$ from values $\{1, 0\}$ to $\{1, -1\}$.

3.2.3 Inference with Max-product Algorithm

Given the trained tree-structured CRF model, the multi-label prediction on a test instance can be performed using the max-product inference algorithm [21]. The max-product algorithm conducts label decoding through message passing which operates in factor graphs. Given the trained pairwise CRF model, we then first transfer it into a factor graph by simply keeping all variable nodes and adding a factor node for each edge clique. For example, the factor graph constructed for the tree-structured CRF in Figure 2 is given in Figure 3, where each variable node is represented as a circle and each factor node is represented as a rectangle. For a given test instance \mathbf{x} , the potentials of the two types of nodes in the factor graph can be computed using the probabilistic binary classifiers produced in the training phase, such as $\psi(\mathbf{y}_i) = P(\mathbf{y}_i|\mathbf{x})$ and $\psi(\mathbf{y}_i, \mathbf{y}_j) = \psi(\mathbf{y}_{i \sim j}) = P(\mathbf{y}_{i \sim j}|\mathbf{x})$.

The decoding process on the test instance \mathbf{x} aims to find the maximum a posteriori (MAP) label assignment by solving

$$\mathbf{y}^* = \arg \max_{\mathbf{y}} P(\mathbf{y}|\mathbf{x}) \quad (3)$$

The max-product algorithm performs this decoding on the factor graph using the following message passing. First, we randomly select a variable node r as the root of the tree, and pass messages from leaves until they reach the root. There are two types of messages: node-to-factor messages and factor-to-node messages. The message from the node i to the factor a (e.g., $a = i \sim j$) can be computed as

$$\mu_{i \rightarrow a}(\mathbf{y}_i) = \psi(\mathbf{y}_i) \prod_{c \in N(i) \setminus a} \mu_{c \rightarrow i}(\mathbf{y}_i) \quad (4)$$

where $N(i) \setminus a$ represents all the neighboring factor nodes of node i excluding factor node a . The message from the factor $a = i \sim j$ to the node j can be computed as

$$\mu_{a \rightarrow j}(\mathbf{y}_j) = \max_{\mathbf{y}_i} \left(\psi_a(\mathbf{y}_i, \mathbf{y}_j) \mu_{i \rightarrow a}(\mathbf{y}_i) \right) \quad (5)$$

Back pointers are kept for each value that achieves the maximum at a max operation. At the root, we multiply all incoming messages to obtain the maximum probability and the MAP configuration of the root node \mathbf{y}_r^*

$$P^* = \max_{\mathbf{y}_r} \left(\psi(\mathbf{y}_r) \prod_{a \in N(r)} \mu_{a \rightarrow r}(\mathbf{y}_r) \right) \quad (6)$$

$$\mathbf{y}_r^* = \arg \max_{\mathbf{y}_r} \left(\psi(\mathbf{y}_r) \prod_{a \in N(r)} \mu_{a \rightarrow r}(\mathbf{y}_r) \right) \quad (7)$$

We then back trace the pointers and find the complete values \mathbf{y}^* that lead to P^* . For tree graphs, this max-product algorithm provides an exact inference solution. But for an arbitrary graph with loops, it can only provide an approximate solution.

4 EXPERIMENTS

To evaluate the proposed approach, we conducted experiments on several standard multi-label image classification datasets, comparing to a few state-of-the-art multi-label learning methods and baselines. We report our empirical results in this section.

4.1 Datasets

We used the following three image datasets in our experiments: *Pascal VOC 2007 (Pascal07)*, *Corel5K*, and *SUN 2012*. *Pascal07* is one of the most famous image datasets for classification and detection and it contains 20 different object classes. *Corel5K* is a standard image set for multi-label classification with 5,000 instances and 260 classes. To have a fair comparison with a few comparison methods,

some of which are too slow to deal with many classes, we selected two subsets with 50 most frequent labels and 100 most frequent labels respectively to use. *SUN 2012* [31] is a recently released large-scale image set for object detection. Similarly, we used two subsets with 50 labels and 100 labels respectively. The properties of the datasets used in our experiment are briefly summarized in Table 1, where cardinality denotes the average number of labels assigned to one image. In these datasets, each image is represented as a 512-dimension *GIST* [25] feature vector.

Table 1: Summary information of the datasets.

Dataset	#images	#labels	cardinality
Pascal07	4168	20	2.26
Corel5K(s50)	4999	50	2.32
Corel5K(s100)	4999	100	2.89
SUN12(s50)	5000	50	8.98
SUN12(s100)	5000	100	11.18

4.2 Experimental Results

On each of five datasets, we compared the proposed approach to the following state-of-the-art multi-label classification methods and baseline method:

- *Ensembled Probabilistic Classifier Chain (EPCC)*. This probabilistic multi-label learning method is developed in [6] and it integrates base classifiers in a chain structure in the label space.
- *Maximum Margin Output Coding (MMOC)*. This is a multi-label learning method developed in [36], which performs classification on a simultaneously learned lower-dimensional label space within a maximum margin framework.
- *Logistic Regression (LR)*. This is a baseline method that trains a set of independent binary logistic regression classifiers, one for each label, to perform multi-label classification.

For our proposed approach, there is one regularization trade-off parameter β to set for the logistic regression classifiers. We found that logistic regression classifiers are not very sensitive to this parameter. In our experiments, we set β as a very small value around 0.0002. For the comparison methods *EPCC* and *MMOC*, we used the code packages released on the internet¹. These packages contain parameter selection procedures and settings.

On each dataset, we performed a 5-fold cross validation to compare all the methods. To evaluate the multi-label classification results from different perspective, we used five

standard criteria: macro-F1, micro-F1, hamming loss, precision and recall. The average results and standard deviations in terms of the five criteria for all the four methods are reported in Table 2. We can see that our proposed method outperforms all the other comparison methods across all five datasets and in terms of all the four measure criteria: macro-F1, micro-F1, Precision and Recall. In terms of hamming loss, the proposed approach produced the best results on four out of the five datasets. Moreover, the proposed approach significantly outperforms the baseline *LR* method across all different settings. This clearly shows that the augmenting new labels in our model are very effective in assisting identifying the individual labels, and it is very beneficial to exploit the label co-occurrence patterns. By comparing the results on the *Corel5k(s50)* dataset and the *Corel5k(s100)* dataset, we can see that with the increasing of the label set size, the performance of all methods in terms of the four measures, macro-F1, micro-F1, precision and recall, has the general trend of decreasing. In terms of the hamming loss, however, the results of all approaches are even better on *Corel5k(s100)* than on *Corel5k(s50)*. This seems very strange. But if we check the two datasets, we can see that though *Corel5k(s100)* contains 50 more labels than *Corel5k(s50)*, the difference between their label cardinality values is very small. This indicates that the labels are even more sparse in *Corel5k(s100)* than in *Corel5k(s50)*. By producing similar number of positive labels, the performance of each approach will automatically get better in terms of hamming loss, with the increasing of the label set size. This result suggests that hamming loss is not an appropriate criterion for multi-label classification when the label cardinality is small while the number of label classes is large. Similar results are observed across *SUN12(s50)* and *SUN12(s100)* as well. Another observation over the table is that *EPCC* produced the second best results in most cases. The *EPCC* method greatly outperforms the baseline *LR* almost on all the datasets and in terms of all criteria, except that on *SUN12(s100)* in terms of macro-F1 and on *SUN12(s50)* in terms of precision, where it produces similar results with *LR*. The *MMOC* method is much more time-consuming than other methods. On the two datasets with 100 labels, it fails to yield any result within reasonable period of running time. It has inferior performance comparing to the proposed approach and *EPCC* in most cases.

Running time To compare the empirical efficiency of the approaches, we have also recorded the training time and testing time of each approach on a 64-bit machine with 16GB memory and quad core intel i7 processors. The results of average running time are reported in Figure 4. We can see the baseline *LR* is the most efficient method in terms of both training and testing time, since it only needs to train a set of binary classifiers and perform classification independently for each label. Among the remaining three methods, our proposed approach is significantly more ef-

ficient than the other two methods in terms of the testing time. For training time, the proposed approach is similar to *EPCC* on the dataset *Pascal07* which has small label set, and is more efficient than *EPCC* on the other larger scale datasets. *MMOC* is the most inefficient one among all the four methods. It even fails to produce any results on the two datasets with 100 labels.

Illustration of the Results To have an illustrative understanding about the image annotation problem and the prediction results, in Table 3 we presented the predicted labels on four testing images from the *SUN12(s50)* dataset by the four methods. The true positive labels are shown in bold font. We can see that our proposed approach is in general more accurate than the other methods, though *EPCC* has

Table 3: The predicted labels on four test images of SUN12(s50) by the comparison methods. The true positive labels are shown in bold font.

good precision result on the first image as well.

All these results suggest that by capturing the object combination patterns in newly created labels, the proposed probabilistic label enhancement model provides an effective and efficient framework for multi-label image classification.

4.3 Experiments with Dense Graphs

Our proposed approach constructs a tree-graph to identify the informative label combination patterns. In order to produce the tree structure, the maximum spanning tree algorithm needs to ignore the edges with larger (normalized co-occurrence) weights to avoid cycles. To investigate whether this is problematic, we tried an alternative version of the proposed approach by constructing a densely connected graph for label combinations, instead of restricting to singly connected trees. Specifically, we produce the dense graph by simply keeping a proportion of the existing edges (there is no edge between label pairs that never co-occur) with largest weights. In the experiments, we kept the top 30% of the edges.

We compared the two variants of the proposed model across the five datasets. In particular, Figure 5 shows the examples of the dense graph and the tree graph constructed on the Pascal07 dataset. The tree graph only has 19 edges, while the dense graph has 37 edges. We can see that the two graphs have many common edges but also capture some very different label combination patterns. There are

some interesting pairs missing in the tree graph. For example, *sofa* and *tv monitor* can be observed in most sitting rooms, but their combination pair is not kept in the tree graph. On the other hand, the tree graph captured many important co-occurrence patterns with *much less* number of edges. For example, the tree graph captures the frequent co-occurrences between *person* and many other objects. By looking at the images in Pascal07, we can find many images containing *person* in different classes, which explains why the tree graph is *person*-centric. Moreover, even with much more edges, there are two isolated nodes in the dense graph, while none of nodes can be isolated in the tree graph.

The classification results of these two variants are reported in Table 4, in terms of macro-F1, micro-F1 and hamming loss. We can see that though the tree graph sacrificed edges with larger weights to maintain a singly connected tree structure, its performance is similar or even slightly better than the performance of the dense graph in most cases. In terms of the three measures, the dense graph only outperforms the tree graph on *Corel5k(s50)* and *SUN12(s50)* in terms of macro-F1, and on *Pascal07* in terms of hamming loss. With cyclic dense graphs, the max-product algorithm in the test phase can only produce approximate inference results. This can contribute to the inferior performance of the dense graph in many cases. Moreover, with more edges kept in the graph, there will be more auxiliary classifiers to train in the training phase, this makes the dense graph variant to have larger training time. All these information suggests that the tree graph is a desirable structure.

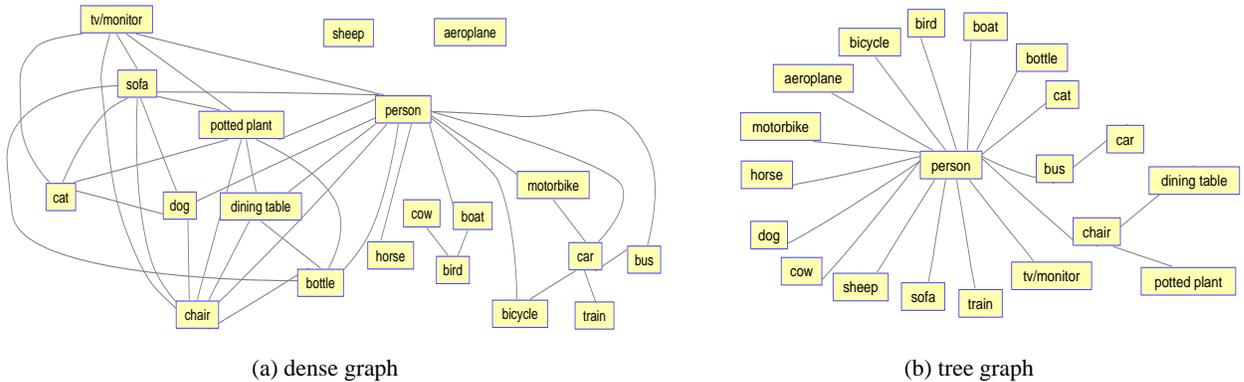

Figure 5: The densely connected graph and tree graph constructed on Pascal07.

Table 4: The average comparison results between the proposed approach (with tree graph) and its alternative version with a dense graph.

5 CONCLUSION

In this paper, we presented a novel probabilistic label enhancement model for multi-label image classification. The idea is to use informative label combination pairs (i.e., the object composite concepts in images) to augment the original labels which can be difficult to predict individually due to label sparsity, intra-class variations and occlusions, aiming to enhance the overall multi-label prediction performance. We formulated our model under the conditional random field framework by first constructing a tree graph in the label space based on the label co-occurrence patterns in the training data, and then performing efficient piecewise training. The learning process of the proposed model only requires training a set of independent binary classifiers, while its tree structure permits efficient and exact max-product inference in the test phase. Our experiments on several image classification datasets showed the proposed approach has superior performance in terms of both prediction quality and empirical computational complexity, comparing to the state-of-the-art comparison methods.

Abstract

One of the most tedious tasks in the application of machine learning is model selection, i.e. hyperparameter selection. Fortunately, recent progress has been made in the automation of this process, through the use of sequential model-based optimization (SMBO) methods. This can be used to optimize a cross-validation performance of a learning algorithm over the value of its hyperparameters. However, it is well known that ensembles of learned models almost consistently outperform a single model, even if properly selected. In this paper, we thus propose an extension of SMBO methods that automatically constructs such ensembles. This method builds on a recently proposed ensemble construction paradigm known as Agnostic Bayesian learning. In experiments on 22 regression and 39 classification data sets, we confirm the success of this proposed approach, which is able to outperform model selection with SMBO.

1 INTRODUCTION

The automation of hyperparameter selection is an important step towards making the practice of machine learning more approachable to the non-expert and increases its impact on data reliant sciences. Significant progress has been made recently, with many methods reporting success in tuning a large variety of algorithms Bergstra et al. [2011], Hutter et al. [2011], Snoek et al. [2012], Thornton et al. [2013]. One successful general paradigm is known as Sequential Model-Based Optimization (SMBO). It is based on a process that alternates between the proposal of a new hyperparameter configuration to test and the update of an adaptive model of the relationship between hyperparameter configurations and their holdout set performances. Thus, as the model learns about this relationship, it increases its ability to suggest improved hyperparameter configurations

and gradually converges to the best solution.

While finding the single best model configuration is useful, better performance is often obtained by, instead, combining several (good) models into an ensemble. This was best illustrated by the winning entry of the Netflix competition, which combined a variety of models [Bell et al., 2007]. Even if one concentrates on a single learning algorithm, combining models produced by using different hyperparameters is also helpful. Intuitively, models with comparable performances are still likely to generalize differently across the input space and produce different patterns of errors. By averaging their predictions, we can hope that the majority of models actually perform well on any given input and will move the ensemble towards better predictions globally, by dominating the average. In other words, the averaging of several comparable models reduces the variance of our predictor compared to each individual in the ensemble, while not sacrificing too much in terms of bias.

However, constructing such ensembles is just as tedious as performing model selection and at least as important in the successful deployment of machine-learning-based systems. Moreover, unlike the model selection case for which SMBO can be used, no comparable automatic ensemble construction methods have been developed thus far. The current methods of choice remain trial and error or exhaustive grid search for exploring the space of models to combine, followed by a selection or weighting strategy which is often an heuristic. One exception is the work of Thornton et al. [2013], which can support the construction of ensembles, but only of up to 5 models.

In this paper, we propose a method for leveraging the recent research on SMBO in order to generate an ensemble of models, as opposed to the single best model. The proposed approach builds on the Agnostic Bayes framework [Lacoste et al., 2014], which provides a successful strategy for weighting a predetermined and finite set of models (already trained) into an ensemble. Using a successful SMBO method, we show how we can effectively generalize this framework to the case of an infinite space of models (indexed by its hyperparameter space). The result-

ing method is simple and highly efficient. Our experiments on 22 regression and 39 classification data sets confirm that it outperforms the regular SMBO model selection method.

The paper develops as follows. First, we describe SMBO and its use for hyperparameter selection (Section 2). We follow with a description of the Agnostic Bayes framework and present a bootstrap-based implementation of it (Section 3). Then, we describe the proposed algorithm for automatically constructing an ensemble using SMBO (Section 4). Finally, related work is discussed (Section 5) and the experimental comparisons are presented (Section 6).

2 HYPERPARAMETER SELECTION WITH SMBO

Let us first lay down the notation we will be using to describe the task of model selection for a machine learning algorithm. In this setup, a task D corresponds to a probability distribution over the input-output space $\mathcal{X} \times \mathcal{Y}$. Given a set of examples $S \sim D^m$ (which will be our holdout validation set), the objective is to find, among a set \mathcal{H} , the *best* function $h^* : \mathcal{X} \rightarrow \mathcal{Y}$. In general, \mathcal{H} can be any set and we refer to a member as a predictor. In the context of hyperparameter selection, \mathcal{H} corresponds to the set of models trained on a training set $T \sim D^n$ (disjoint from S), for different configurations of the learning algorithm’s hyperparameters γ . Namely, let \mathcal{A}_γ be the learning algorithm with a hyperparameter configuration $\gamma \in \Gamma$, we will note $h_\gamma = \mathcal{A}_\gamma(T)$ the predictor obtained after training on T . The set \mathcal{H} contains all predictors obtained from each $\gamma \in \Gamma$ when \mathcal{A}_γ is trained on T , i.e. $\mathcal{H} \stackrel{\text{def}}{=} \{h_\gamma | \gamma \in \Gamma\}$.

To assess the quality of a predictor, we use a loss function

$$\mathcal{L} : \mathcal{Y} \times \mathcal{Y} \rightarrow \mathbb{R},$$

that quantifies the penalty incurred when h_γ predicts $h_\gamma(x)$ while the true target is y . Then, we can define the risk $R_D(h_\gamma)$ as being the expected loss of h_γ on task D , i.e. $R_D(h_\gamma) \stackrel{\text{def}}{=} \mathbf{E}_{x,y \sim D} [\mathcal{L}(h_\gamma(x), y)]$. Finally, the *best*¹ function is simply the one minimizing the risk, i.e.

$$h^* \stackrel{\text{def}}{=} \underset{h_\gamma \in \mathcal{H}}{\text{argmin}} R_D(h_\gamma).$$

Here, estimating h^* thus corresponds to hyperparameter selection.

For most of machine learning history, the state of the art in hyperparameter selection has been testing a list of predefined configurations and selecting the best according to the loss function \mathcal{L} on some holdout set of examples S . When a learning algorithm has more than one hyperparameter, a grid search is required, forcing $|\Gamma|$ to grow exponentially with the number of hyperparameters. In addition, the

¹The best solution may not be unique but any of them are equally good.

search may yield a suboptimal result when the minimum lies outside of the grid or when there is not enough computational power for an appropriate grid resolution. Recently, randomized search has been advocated as a better replacement to grid search [Bergstra and Bengio, 2012]. While it tends to be superior to grid search, it remains inefficient since its search is not informed by results of the sequence of hyperparameters that are tested.

To address these limitations, there has been an increasing amount of work on automatic hyperparameter optimization [Bergstra et al., 2011, Hutter et al., 2011, Snoek et al., 2012, Thornton et al., 2013]. Most rely on an approach called sequential model based optimization (SMBO). The idea consists in treating $R_S(h_\gamma) \stackrel{\text{def}}{=} f(\gamma)$ as a learnable function of γ , which we can learn from the observations $\{(\gamma_i, R_S(h_{\gamma_i}))\}$ collected during the hyperparameter selection process.

We must thus choose a model family for f . A common choice is a Gaussian process (GP) representation, which allows us to represent our uncertainty about f , i.e. our uncertainty about the value of $f(\gamma^*)$ at any unobserved hyperparameter configuration γ^* . This uncertainty can then be leveraged to determine an *acquisition function* that suggests the most promising hyperparameter configuration to test next.

Namely, let functions $\mu : \Gamma \rightarrow \mathbb{R}$ and $K : \Gamma \times \Gamma \rightarrow \mathbb{R}$ be the mean and covariance kernel functions of our GP over f . Let us also denote the set of the M previous evaluations as

$$\mathcal{R} \stackrel{\text{def}}{=} \{(\gamma_i, R_S(h_{\gamma_i}))\}_{i=1}^M \quad (1)$$

where $R_S(h_{\gamma_i})$ is the empirical risk of h_{γ_i} on set S , i.e. the holdout set error for hyperparameter γ .

The GP assumption on f implies that the conditional distribution $p(f(\gamma^*) | \mathcal{R})$ is Gaussian, that is

$$\begin{aligned} p(f(\gamma^*) | \mathcal{R}) &= \mathcal{N}(f(\gamma^*); \mu(\gamma^*; \mathcal{R}), \sigma^2(\gamma^*; \mathcal{R})), \\ \mu(\gamma^*; \mathcal{R}) &\stackrel{\text{def}}{=} \mu(\gamma^*) + \mathbf{k}^\top \mathbf{K}^{-1}(\mathbf{r} - \boldsymbol{\mu}), \\ \sigma^2(\gamma^*; \mathcal{R}) &\stackrel{\text{def}}{=} K(\gamma^*, \gamma^*) - \mathbf{k}^\top \mathbf{K}^{-1} \mathbf{k} \end{aligned}$$

where $\mathcal{N}(f(\gamma^*); \mu(\gamma^*; \mathcal{R}), \sigma^2(\gamma^*; \mathcal{R}))$ is the Gaussian density function with mean $\mu(\gamma^*; \mathcal{R})$ and variance $\sigma^2(\gamma^*; \mathcal{R})$. We also have vectors

$$\begin{aligned} \boldsymbol{\mu} &\stackrel{\text{def}}{=} [\mu(\gamma_1), \dots, \mu(\gamma_M)]^\top, \\ \mathbf{k} &\stackrel{\text{def}}{=} [K(\gamma^*, \gamma_1), \dots, K(\gamma^*, \gamma_M)]^\top, \\ \mathbf{r} &\stackrel{\text{def}}{=} [R_S(h_{\gamma_1}), \dots, R_S(h_{\gamma_M})]^\top, \end{aligned}$$

and matrix \mathbf{K} is such that $\mathbf{K}_{ij} = K(\gamma_i, \gamma_j)$.

There are several choices for the acquisition function. One that has been used with success is the one maximizing the *expected improvement*:

$$\text{EI}(\gamma^*; \mathcal{R}) \stackrel{\text{def}}{=} \mathbf{E} [\max\{r_{\text{best}} - f(\gamma^*), 0\} | \mathcal{R}] \quad (2)$$

which can be shown to be equal to

$$\sigma^2(\gamma^*; \mathcal{R}) (d(\gamma^*; \mathcal{R})\Phi(d(\gamma^*; \mathcal{R})) + \mathcal{N}(d(\gamma^*; \mathcal{R}), 0, 1)) \quad (3)$$

where Φ is the cumulative distribution function of the standard normal and

$$r_{\text{best}} \stackrel{\text{def}}{=} \min_i R_S(h_{\gamma_i}),$$

$$d(\gamma^*; \mathcal{R}) \stackrel{\text{def}}{=} \frac{r_{\text{best}} - \mu(\gamma^*; \mathcal{R})}{\sigma(\gamma^*; \mathcal{R})}.$$

The acquisition function thus maximizes Equation 3 and returns its solution. This optimization can be performed by gradient ascent initialized at points distributed across the hyperparameter space according to a Sobol sequence, in order to maximize the chance of finding a global optima. One advantage of expected improvement is that it directly offers a solution to the exploration-exploitation trade-off that hyperparameter selection faces.

An iteration of SMBO requires fitting the GP to the current set of tested hyperparameters \mathcal{R} (initially empty), invoking the acquisition function, running the learning algorithm with the suggested hyperparameters and adding the result to \mathcal{R} . This procedure is expressed in Algorithm 1. Fitting the GP corresponds to learning the mean and covariance functions hyperparameters to the collected data. This can be performed either by maximizing the data’s marginal likelihood or defining priors over the hyperparameters and sampling from the posterior using sampling (see Snoek et al. [2012] for more details).

Algorithm 1 SMBO Hyperparameter Optimization with GPs

```

 $\mathcal{R} \leftarrow \{\}$ 
for  $k \in \{1, 2, \dots, M\}$  do
   $\gamma \leftarrow \text{SMBO}(\mathcal{R})$  {Fit GP and maximize EI}
   $h_\gamma \leftarrow \mathcal{A}_\gamma(T)$  {Train with suggested  $\gamma$ }
   $\mathcal{R} \leftarrow \mathcal{R} \cup \{(\gamma, R_S(h_\gamma))\}$  {Add to collected data}
end for
 $\gamma^* \leftarrow \underset{(\gamma, R_S(h_\gamma)) \in \mathcal{R}}{\text{argmin}} R_S(h_\gamma)$ 
return  $h_{\gamma^*}$ 

```

While SMBO hyperparameter optimization can produce very good predictors, it can also suffer from overfitting on the validation set, especially for high-dimensional hyperparameter spaces. This is in part why an ensemble of predictors are often preferable in practice. Properly extending SMBO to the construction of ensembles is, however, not obvious. Here, we propose one such successful extension, building on the framework of Agnostic Bayes learning, described in the next section.

3 AGNOSTIC BAYES

In this section, we offer a brief overview of the Agnostic Bayes learning paradigm presented in Lacoste et al. [2014] and serving as a basis for the algorithm we present in this paper. Agnostic Bayes learning was used in Lacoste et al. [2014] as a framework for successfully constructing ensembles when the number of predictors in \mathcal{H} (i.e. the potential hyperparameter configurations Γ) was constrained to be finite (e.g. by restricting the space to a grid). In our context, we can thus enumerate the possible hyperparameter configurations from γ_1 to $\gamma_{|\Gamma|}$. This paper will generalize this approach to the infinite case later.

Agnostic Bayes learning attempts to directly address the problem of inferring what is the *best* function h^* in \mathcal{H} , according to the loss function \mathcal{L} . It infers a posterior $p_{h^*}(h_\gamma|S)$, i.e. a distribution over how likely each member of \mathcal{H} is the best predictor. This is in contrast with standard Bayesian learning, which implicitly assumes that \mathcal{H} contains the true data-generating model and infers a distribution for how likely each member of \mathcal{H} has generated the data (irrespective of what the loss \mathcal{L} is). From $p_{h^*}(h_\gamma|S)$, by marginalizing h^* , we obtain a probabilistic estimate for the best prediction $y^* \stackrel{\text{def}}{=} h^*(x)$

$$p_{y^*}(y|x, S) = \sum_{\gamma \in \Gamma} p_{h^*}(h_\gamma|S) I[h_\gamma(x) = y].$$

Finally, to commit to a final prediction, for a given x , we use the most probable answer². This yields the following ensemble decision rule

$$E^*(x) \stackrel{\text{def}}{=} \underset{y \in \mathcal{Y}}{\text{argmax}} p_{y^*}(y|x, S). \quad (4)$$

To estimate $p_{h^*}(h_\gamma|S)$, Agnostic Bayes learning uses the set of losses $l_{\gamma,i} \stackrel{\text{def}}{=} \mathcal{L}(h_\gamma(x_i), y_i)$ of each example $(x_i, y_i) \in S$ as evidence for inference. In Lacoste et al. [2014], a few different approaches are proposed and analyzed. A general strategy is to assume a joint prior $p(\mathbf{r})$ over the risks $r_\gamma \stackrel{\text{def}}{=} R_D(h_\gamma)$ of all possible hyperparameter configurations and choose a joint observation $p(l_{\gamma,i} \forall \gamma \in \Gamma | \mathbf{r})$ for the losses. From Bayes rule, we obtain the posterior $p(\mathbf{r}|S)$ from which we can compute

$$p_{h^*}(h_\gamma|S) = \mathbb{E}_{\mathbf{r}} [I[r_\gamma < r_{\gamma'}, \forall \gamma' \neq \gamma] | S] \quad (5)$$

with a Monte Carlo estimate. This would result in repeatedly sampling from $p(\mathbf{r}|S)$ and counting the number of times each γ has the smallest sampled risk r_γ to estimate $p_{h^*}(h_\gamma|S)$. Similarly, samples from $p_{h^*}(h_\gamma|S)$ could be obtained by sampling a risk vector \mathbf{r} from $p(\mathbf{r}|S)$ and returning the predictor h_γ with the lowest sampled risk. The

²As noted in Lacoste et al. [2014], $p_{y^*}(y|x, S)$ does not correspond to the probability of observing y given x and cannot be used with the optimal Bayes theory, thus justifying the usage of the most probable answer

ensemble decision rule of Equation 4 could then be implemented by repeatedly sampling from $p_{h^*}(h_\gamma|S)$ to construct the ensemble of predictors and using their average as the ensemble’s prediction.

Among the methods explored in Lacoste et al. [2014] to obtain samples from $p(\mathbf{r}|S)$, the bootstrap approach stands out for its efficiency and simplicity. Namely, to obtain a sample from $p(\mathbf{r}|S)$, we sample with replacement from S to obtain S' and return the vector of empirical risks $[R_{S'}(h_{\gamma_1}), \dots, R_{S'}(h_{\gamma_{|\Gamma|}})]^\top$ as a sample. While bootstrap only serves as a “poor man’s” posterior, it can be shown to be statistically related to a proper model with Dirichlet priors and its empirical performance was shown to be equivalent [Lacoste et al., 2014].

When the bootstrap method is used to obtain samples from $p_{h^*}(h_\gamma|S)$, the complete procedure for generating each ensemble member can be summarized by

$$\widetilde{h^*} = \operatorname{argmin}_{\gamma \in \Gamma} R_{S'}(h_\gamma), \quad (6)$$

where $\widetilde{h^*}$ corresponds to a sample from $p_{h^*}(h_\gamma|S)$. In this work, we use SMBO to address the optimization part. Thus, we can now extend to an uncountable set Γ .

This method can be seen as applying bagging on the validation set instead of the training set. However, we stand by the Agnostic Bayes theory since it offers a strong theoretical backbone to bagging as well as few refinements. Most importantly, the normal assumption of Section 3.3 in Lacoste et al. [2014] suggests that methods based on the covariance of the predictions such as ensemble pruning [Zhang et al., 2006] and MinCq [Roy et al., 2011] are simply different approximations of this idea. This connection allows us to be confident that the fast and simple algorithm we propose in this paper is at least equivalent in generalization performance to other state of the art ensemble methods. Finally, this claim is supported by the strong experimental section of Lacoste et al. [2014].

4 AGNOSTIC BAYES ENSEMBLE WITH SMBO

We now present our proposed method for automatically constructing an ensemble, without having to restrict Γ (or, equivalently \mathcal{H}) to a finite subset of hyperparameters.

As described in Section 3, to sample a predictor from the Agnostic Bayes bootstrap method, it suffices to obtain a bootstrap S' from S and solve the optimization problem of Equation 6. In our context where \mathcal{H} is possibly an infinite set of models trained on the training set T for any hyperparameter configuration γ , Equation 6 corresponds in fact to hyperparameter optimization where the holdout set is S' instead of S .

This suggests a simple procedure for building an ensemble of N predictors according to Agnostic Bayes i.e., that reflects our uncertainty about the true best model h^* . We could repeat the full SMBO hyperparameter optimization process N times, with different bootstrap S'_j , for $j \in \{1, 2, \dots, N\}$. However, for large ensembles, performing N runs of SMBO can be computationally expensive, since each run would need to train its own sequence of models.

We can notice however that predictors are always trained on the same training set T , no matter in which run of SMBO they were trained on. We propose a handy trick that exploits this observation to greatly accelerate the construction of the ensemble by almost a factor of N . Specifically, we propose to simultaneously optimize all N problems in a round-robin fashion. Thus, we maintain N different histories of evaluation \mathcal{R}_j , for $j \in \{1, 2, \dots, N\}$ and when a new predictor $h_\gamma = \mathcal{A}_\gamma(T)$ is obtained, we update all \mathcal{R}_j with $(\gamma, R_{S'_j}(h_\gamma))$. Notice that the different histories \mathcal{R}_j contain the empirical risks on different bootstrap holdout sets, but they are all updated at the cost of training only a single predictor. Also, to avoid recalculating multiple times $\mathcal{L}(h_\gamma(x_i), y_i)$, these values can be cached and shared in the computation of each \mathcal{R}_j . This leaves the task of updating all \mathcal{R}_j insignificant compared to the computational time usually required for training a predictor. This procedure is detailed in Algorithm 2.

Algorithm 2 Agnostic Bayes Ensemble with SMBO

```

for  $j \in \{1, 2, \dots, N\}$  do
   $\mathcal{R}_j \leftarrow \{\}$ 
   $S'_j \leftarrow \text{bootstrap}(S)$ 
end for

 $\mathcal{E} \leftarrow \{\}$  {Will contain all trained predictors}
for  $k \in \{1, 2, \dots, M\}$  do
   $v \leftarrow (k - 1) \text{ modulo } N + 1$ 
   $\gamma \leftarrow \text{SMBO}(\mathcal{R}_v)$ 
   $h_\gamma \leftarrow \mathcal{A}_\gamma(T)$ 
   $\mathcal{E} \leftarrow \mathcal{E} \cup \{h_\gamma\}$ 
  for  $j \in \{1, 2, \dots, N\}$  do
     $\mathcal{R}_j \leftarrow \mathcal{R}_j \cup \left\{ \left( \gamma, R_{S'_j}(h_\gamma) \right) \right\}$ 
  end for
end for

 $\mathcal{H}' \leftarrow \{\}$  {Will contain  $N$  selected predictors}
for  $j \in \{1, 2, \dots, N\}$  do
   $h_j \leftarrow \operatorname{argmin}_{h_\gamma \in \mathcal{E}} R_{S'_j}(h_\gamma)$ 
   $\mathcal{H}' \leftarrow \mathcal{H}' \cup \{h_j\}$ 
end for

 $p_{h^*}(h_\gamma|S) = \text{Uniform}(\mathcal{H}')$ 
return  $p_{h^*}(h_\gamma|S)$ 

```

By updating all \mathcal{R}_j at the same time, we *trick* each SMBO run by updating its history with points it did not suggest. This implies that the GP model behind each SMBO run will be able to condition on more observations than it would if the runs had been performed in isolation. This can only benefit the GPs and improve the quality of their suggestions.

While Algorithm 2 is sequential, it can be easily adapted to the parallelized version of SMBO presented in Snoek et al. [2012]. Also, it can be extended to use cross validation, based on the method developed in [Lacoste et al., 2014].

In our experiments, we fix $N = \lfloor \frac{M}{2} \rfloor$. This maximizes the number of samples used to estimate $p_{y^*}(y|x, S)$ while ensuring at least one SMBO step with a reasonably large history for each bootstrap. When the prediction time on the test set is a concern, we suggest to choose $N \approx 10$. We observed that it was usually enough to obtain most of the generalization gain.

Finally, since $p_{y^*}(y|x, S)$ is only estimated, finding the maximum, as requested in Equation 4, requires some form of density estimation. In the case of classification, we simply use the most probable class. However, in the regression case, we fit a normal distribution³. Thus, the maximum coincide with the average prediction. For a more complex \mathcal{Y} , such as in structured output tasks, we recommend to use an appropriate density estimation and increase the number of samples N .

5 RELATED WORK

In the Bayesian learning literature, a common way of dealing with hyperparameters in probabilistic predictors is to define hyperpriors and perform posterior inference to integrate them out. This process often results in also constructing an ensemble of predictors with different hyperparameters, sampled from the posterior. Powerful MCMC methods have been developed in order to accommodate for different types of hyperparameter spaces, including infinite spaces.

However, this approach requires that the family of predictors in question be probabilistic in order to apply Bayes rule. Moreover, even if the predictor family is probabilistic, the construction of the ensemble will entirely ignore the nature of the loss function that determines the measure of performance. The comparative advantage of the proposed Agnostic Bayes SMBO approach is thus that it can be used for any predictor family (probabilistic or not) and is loss-sensitive.

On the other hand, traditional ensemble methods such as Laviolette et al. [2011], Kim and Ghahramani [2012], and

³It is also possible to use a more elaborated method, such as kernel density estimation.

Zhang et al. [2006] require a predefined set of models and are not straightforward to adapt to an infinite set of models.

6 EXPERIMENTS

We now compare the SMBO ensemble approach (ESMBO) to three alternative methods for building a predictor from a machine learning algorithm with hyperparameters:

- A single model, whose hyperparameters were selected by hyperparameter optimization with SMBO (SMBO).
- A single model, whose hyperparameters were selected by a randomized search (RS), which in practice is often superior to grid search [Bergstra and Bengio, 2012].
- An Agnostic Bayes ensemble constructed from a randomly selected set of hyperparameters (ERS).

Both ESMBO and SMBO used GP models of the hold-out risk, with hyperparameters trained to maximize the marginal likelihood. A constant was used for the mean function, while the Matérn 5/2 kernel was used for the covariance function, with length scale parameters. The GP’s parameters were obtained by maximizing the marginal likelihood and a different length scale was used for each dimension⁴.

Each method is allowed to evaluate 150 hyperparameter configurations. To compare their performances, we perform statistical tests on several different hyperparameter spaces over two different collections of data sets.

6.1 HYPERPARAMETER SPACES

Here, we describe the hyperparameter spaces of all learning algorithms we employ in our experiments. Except for a custom implementation of the multilayer perceptron, we used scikit-learn⁵ for the implementation of all other learning algorithms.

Support Vector Machine We explore the soft margin parameter C for values ranging from 10^{-2} to 10^3 on a logarithmic scale. We use the RBF kernel $K(x, x') = e^{\gamma \|x - x'\|_2^2}$ and explore values of γ ranging from 10^{-5} to 10^3 on a logarithmic scale.

Support Vector Regressor We also use the RBF kernel and we explore the same values as for the Support Vector Machine. In addition, we explore the ϵ -tube parameter [Drucker et al., 1997] for values ranging between 10^{-2} and 1 on a logarithmic scale.

⁴We used the implementation provided by spearmin: <https://github.com/JasperSnoek/spearmin>

⁵<http://scikit-learn.org/>

Random Forest We fix the number of trees to 100 and we explore two different ways of producing them: either the original Breiman [2001] method or the extremely randomized trees method of Geurts et al. [2006]. We also explore the choice of bootstrapping or not the training set before generating a tree. Finally, the ratio of randomly considered features at each split for the construction of the trees is varied between 10^{-4} and 1 on a linear scale.

Gradient Boosted Classifier This is a tree-based algorithm using boosting [Friedman, 2001]. We fix the set of weak learners to 100 trees and take the maximum depth of each tree to be in $\{1, 2, \dots, 15\}$. The learning rate ranges between 10^{-2} and 1 on a logarithmic scale. Finally, the ratio of randomly considered features at each split for the construction of the trees varies between 10^{-3} and 1 on a linear scale.

Gradient Boosted Regressor We use the same parameters as for Gradient Boosted Classifier except that we explore a convex combination of the least square loss function and the least absolute deviation loss function. We also fix the ratio of considered features at each split to 1.

Multilayer Perceptron We use a 2 hidden layers perceptron with tanh activation function and a softmax function on the last layer. We minimize the negative log likelihood using the L-BFGS algorithm. Thus there is no learning rate parameter. However, we used a different L2 regularization weight for each of the 3 layers with values ranging from 10^{-5} to 100 on a logarithmic scale. Also, the number of neurons on each layer can take values in $\{1, 2, \dots, 100\}$. In total, this yields a 5 dimensional hyperparameter space.

6.2 COMPARING METHODS ON MULTIPLE DATA SETS

To assess the generalization performances, we use a separate test set S^{test} , which is obtained by randomly partitioning the original data set. More precisely, we use the ratios 0.4, 0.3, and 0.3 for T , S and S^{test} respectively⁶. However, testing on a single data set is insufficient to testify the quality of a method that is meant to work across different tasks. Hence, we evaluate our methods on several data sets using metrics that do not assume commensurability across tasks [Demšar, 2006]. The metrics of choice are thus the expected rank and the pairwise winning frequency. Let $\mathcal{A}_i(T_j, S_j)$ be either one of our $K = 4$ model selection/ensemble construction algorithms run on the j^{th} data set, with training set T_j and validation set S_j . When comparing K algorithms, the rank of (best or ensemble)

⁶Is is also possible to perform cross-validation as mentioned in Lacoste et al. [2014].

predictor $h_i = \mathcal{A}_i(T_j, S_j)$ on test set S_j^{test} is defined as

$$\text{Rank}_{h_i, S^{\text{test}}} \stackrel{\text{def}}{=} \sum_{l=1}^K I \left[R_{S_j^{\text{test}}}(h_l) \leq R_{S_j^{\text{test}}}(h_i) \right].$$

Then, the expected rank of the i^{th} method is obtained from the empirical average over the L data sets i.e., $\mathbf{E}[R]_i \stackrel{\text{def}}{=} \frac{1}{L} \sum_{j=1}^L \text{Rank}_{h_i, S_j^{\text{test}}}$. When comparing algorithm \mathcal{A}_i against algorithm \mathcal{A}_l , the winning frequency⁷ of \mathcal{A}_i is

$$\rho_{i,l} \stackrel{\text{def}}{=} \frac{1}{L} \sum_{i=1}^L I[R_{S_j^{\text{test}}}(h_i) < R_{S_j^{\text{test}}}(h_l)]$$

In the case of the expected rank, lower is better and for the winning frequency, it is the converse. Also, when $K = 2$, $\mathbf{E}[R]_i = 1 + (1 - \rho_{i,l})$.

When the winning frequency $\rho_{i,l} > 0.5$, we say that method \mathcal{A}_i is better than method \mathcal{A}_l . However, to make sure that this is not the outcome of chance, we use statistical tests such as the sign test and the Poisson Binomial test (PB test) [Lacoste et al., 2012]. The PB test derives a posterior distribution over $\rho_{i,l}$ and integrates the probability mass above 0.5, denoted as $\Pr(A \succ B)$. When $\Pr(A \succ B) > 0.9$, we say that it is significant. Similarly for the sign test, when the p -value is lower than 0.05, it corresponds to a significant result. To report more information, we also use other thresholds for lightly significant and highly significant as described in Table 1.

To build a substantial collection of data sets, we used the AYSU collection [Ulař et al., 2009] coming from the UCI and the Delve repositories and we added the MNIST data set. We also converted the multiclass data sets to binary classification by either merging classes or selecting pairs of classes. The resulting benchmark contains 39 data sets. We have also collected 22 regression data sets from the Louis Torgo collection⁸.

6.3 TABLE NOTATION

The result tables present the winning frequency for each pair of methods, where grayed out values represent redundant information. As a complement, we also add the expected rank of each method in the rightmost column and sort the table according to this metric. To report the conclusion of the sign test and the PB test, we use different symbols to reflect different level of significance. The exact notation is presented in Table 1. The first symbol reports the result of the PB test and the second one, the sign test. For more stable results, we average the values obtained during the last 15 iterations.

⁷We deal with ties by attributing 0.5 to each method except for the sign test where the sample is simply discarded.

⁸These data sets were obtained from the following source : <http://www.dcc.fc.up.pt/~ltorgo/Regression/DataSets.html>

Table 1: Significance Notation Used in Result Tables.

Meaning	Symbol	$\Pr(A \succ B)$	p-value

RS	0.09 [◦]	0.00 [◦]	0.34 [◦]	0.50 [◦]	3.57

6.4 ANALYSIS

Looking at the overall results over 7 different hyperparameter spaces in Table 2 and Table 3, we observe that ESMBO is never significantly outperformed by any other method and often outperforms the others. More precisely, it is either ranked first or tightly following ERS. Looking more closely, we see that the cases where ESMBO does not significantly outperform ERS concerns hyperparameter spaces of low complexity. For example, most hyperparameter configurations of Random Forest yield good generalization performances. Thus, these cases do not require an elaborate hyperparameter search method. On the other hand, when looking at more challenging hyperparameter spaces such as Support Vector Regression and Multilayer Perceptrons, we clearly see the benefits of combining SMBO with Agnostic Bayes.

As described in Section 4, ESMBO is alternating between N different SMBO optimizations and deviates from the natural sequence of SMBO. To see if this aspect of ESMBO can influence its convergence rate, we present a temporal analysis of the methods in Figure 1 and Figure 2. The left columns depict $\Pr(A \succ B)$ for selected pairs of methods and the right columns present the expected rank of each method over time.

Table 3: Pairwise Win Frequency for the 4 Different Classification Hyperparameter Spaces (Refer to Section 6.3 for the notation).

Support Vector Machine					E[rank]
	ESMBO	RS	SMBO	ERS	
ESMBO	0.50	0.54	0.55	0.56	2.35
RS	0.46 [◦]	0.50	0.51	0.51	2.52
SMBO	0.45 [◦]	0.49 [◦]	0.50	0.53	2.54
ERS	0.44 [◦]	0.49 [◦]	0.47 [◦]	0.50	2.59

Gradient Boosting Classifier					E[rank]
	ESMBO	ERS	RS	SMBO	
ESMBO	0.50	0.51	0.59	0.65 ^{◦•}	2.25
ERS	0.49 [◦]	0.50	0.59	0.64 ^{◦◦}	2.28
RS	0.41 [◦]	0.41 [◦]	0.50	0.55	2.64
SMBO	0.35 [◦]	0.36 [◦]	0.45 [◦]	0.50 [◦]	2.83

Random Forest					E[rank]
	ERS	ESMBO	RS	SMBO	
ERS	0.50	0.52	0.60 [◦]	0.64 ^{◦•}	2.24
ESMBO	0.48 [◦]	0.50	0.60	0.67 ^{◦•}	2.25
RS	0.40 [◦]	0.40 [◦]	0.50	0.57	2.63
SMBO	0.36 [◦]	0.33 [◦]	0.43 [◦]	0.50 [◦]	2.89

Multilayer Perceptron					E[rank]
	ESMBO	SMBO	ERS	RS	
ESMBO	0.50	0.57 [◦]	0.76 ^{••}	0.75 ^{••}	1.92
SMBO	0.43 [◦]	0.50	0.68 ^{◦•}	0.68 ^{◦•}	2.21
ERS	0.24 [◦]	0.32 [◦]	0.50	0.54	2.91
RS	0.25 [◦]	0.32 [◦]	0.46 [◦]	0.50 [◦]	2.96

A general analysis clearly shows that there is no significant degradation in terms of convergence speed. In fact, we generally observe the opposite. More precisely, looking at $\Pr(\text{ESMBO} \succ \text{SMBO})$, the green curve of the left columns, it usually reaches a significantly better state right at the beginning or within the first few iterations. A notable exception to that trend occurs with the Multilayer Perceptrons, where SMBO is significantly better than ESMBO for a few iterations at the beginning. Then, it gets quickly outperformed by ESMBO.

7 CONCLUSION

We described a successful method for automatically constructing ensembles without requiring hand-selection of models or a grid search. The method can adapt the SMBO hyperparameter optimization algorithm so that it can produce an ensemble instead of a single model. Theoretically, the method is motivated by an Agnostic Bayesian paradigm which attempts to construct ensembles that reflect the uncertainty over which a model actually has the smallest true risk. The resulting method is easy to implement and comes with no extra computational cost at learning time. Its generalization performance and convergence speed are also dominant according to experiments on 22 regression and 39 classification data sets.

Abstract

ListMLE is a state-of-the-art listwise learning-to-rank algorithm, which has been shown to work very well in application. It defines the probability distribution based on Plackett-Luce Model in a top-down style to take into account the position information. However, both empirical contradiction and theoretical results indicate that ListMLE cannot well capture the position importance, which is a key factor in ranking. To amend the problem, this paper proposes a new listwise ranking method, called position-aware ListMLE (p-ListMLE for short). It views the ranking problem as a sequential learning process, with each step learning a subset of parameters which maximize the corresponding stepwise probability distribution. To solve this *sequential multi-objective optimization* problem, we propose to use *linear scalarization* strategy to transform it into a single-objective optimization problem, which is efficient for computation. Our theoretical study shows that p-ListMLE is better than ListMLE in statistical consistency with respect to typical ranking evaluation measure NDCG. Furthermore, our experiments on benchmark datasets demonstrate that the proposed method can significantly improve the performance of ListMLE and outperform state-of-the-art listwise learning-to-rank algorithms as well.

1 INTRODUCTION

Ranking is an important problem in various applications, such as information retrieval, meta search and collaborative filtering. In recent years, machine learning technologies have been widely applied for ranking, and a new research branch named learning to rank has emerged. A learning-to-rank process can be described as follows. In training,

a number of sets (queries) of objects (documents) are given and within each set the objects are labeled by assessors, mainly based on multi-level ratings. The target of learning is to create a model that provides a ranking over the objects that best respects the observed labels. In testing, given a new set of objects, the trained model is applied to generate a ranking list of the objects. To evaluate the performance of a ranking system, many position-aware evaluation measures such as NDCG [9], MAP [2], ERR [5] are used to reflect users' bias on different positions. That is, users often care more about the results on top positions in a ranking [3, 16, 21].

In literature, pointwise algorithms such as McRank [14] were first proposed to solve the ranking problem, which transformed ranking into (ordinal) regression or classification on individual documents. The idea is natural but it is comprehensively criticized for using different objectives from ranking. Therefore, pairwise algorithms such as RankSVM [10], RankBoost [7] and RankNet [1] were then proposed to view a pair of items as the object, and transform ranking into the pairwise classification problem. However, the pairwise approach highly ignores the position information over different pairs, which is quite important for ranking as mentioned above. To overcome the weakness of pairwise ranking algorithms, listwise ranking algorithms such as ListMLE [21], ListNet [4], RankCosine [17] and AdaRank [22] were proposed, which view the whole ranking list as the object. For example, ListMLE utilized the likelihood loss of the probability distribution based on Plackett-Luce model for optimization. According to previous studies [4, 15, 17, 21], the listwise approach can outperform the other two approaches on benchmark datasets.

Seemingly listwise approaches can well solve the ranking problem by directly modeling the ranking lists and thus taking into account the position information. However, both empirical contradiction and theoretical results indicate that listwise approaches cannot well capture the position importance, which is a key factor in ranking [13, 6]. In this paper, we take the typical listwise method ListMLE as an example to illustrate this problem. Empirically, given two

ranking functions f_1 and f_2 , the error of f_1 occurs in the top positions and that of f_2 occurs in the bottom positions. We find that ListMLE will prefer f_1 to f_2 , leading to lower performance under the IR evaluation measure such as NDCG. Theoretically, it has been proven in [21] that ListMLE is consistent¹ with permutation level 0-1 loss, a loss without considering the importance of different positions.

We analyze the underlying reason behind these above results. We find that the probability in ListMLE is defined in a top-down style which seems to reflect the position importance in ranking. However, due to the chain rule of probability, the decomposition of probability in ListMLE is not unique, indicating that different positions are actually equally important in such definition. To amend this problem, we propose a new listwise ranking approach, namely position-aware ListMLE (p-ListMLE for short), which views ranking as a sequential learning process. Specifically, at step 1, it aims to maximize the top 1 probability distribution of Plackett-Luce model. At step i , it aims to maximize the i -th conditional probability distribution of Plackett-Luce model given the top $i-1$ items. To solve the sequential learning problem, we propose to transform it into a single-objective optimization problem, which is equivalent to minimizing a new surrogate loss.

Theoretically, we study the statistical consistency issue of p-ListMLE. Following the technique used in [11], we can prove that with RDPS as the assumption, p-ListMLE will be consistent with Weighted Pairwise Disagreement Loss (WPD L for short), which is equivalent to a certain NDCG. Further considering the previous result that ListMLE is consistent with permutation level 0-1 loss, we can see that p-ListMLE is better than ListMLE theoretically. We further conduct extensive experiments on benchmark datasets LETOR4.0, and the empirical results demonstrate that the proposed p-ListMLE can significantly outperform the original ListMLE as well as other state-of-the-art listwise learning-to-rank algorithms.

The contribution of this paper lies in the following aspects:

- (1) We provide a novel view of ranking as a sequential learning process, with each step to learn a subset of parameters which maximize the corresponding stepwise probability distribution;
- (2) We propose a new ranking algorithm to incorporate positions into the learning process;
- (3) We provide theoretical analysis on the consistency of the proposed ranking algorithm.

The remainder of the paper are organized as follows. In section 2, we provide some backgrounds on ListMLE, in-

¹Please note that Xia et al. [19] prove that a modification to ListMLE is consistent with top-k 0-1 loss, however, top-k 0-1 loss take the top k positions as equal, therefore cannot well capture the position importance.

cluding the framework of listwise learning to rank, the algorithm of ListMLE, and the theoretical results on ListMLE. Section 3 describes the motivation of this paper and section 4 presents our main results, including the novel sequential view of ranking and the loss function of the new algorithm. Section 5 and 6 presents our theoretical and experimental results, respectively. Section 7 concludes the paper.

2 BACKGROUNDS

In this section, we give some backgrounds on ListMLE, which is a famous listwise ranking algorithm. Listwise learning to rank addresses the ranking problem in the following way. In learning, it takes ranking lists of objects as instances and trains a ranking function through the minimization of a listwise loss function defined on predicted list and the ground-truth list. Following [21], we give the mathematical description of listwise learning-to-rank framework as follows.

2.1 Listwise Learning to Rank

Let $\mathbf{x} = \{x_1, \dots, x_n\} \in X$ be a set of objects to be ranked, and $\mathbf{y} = \{y_1, \dots, y_n\} \in Y$ be the ground-truth permutation of these objects, where y_i stands for the position of x_i and $\mathbf{y}^{-1}(i)$ stands for the index of items in the i -th position of \mathbf{y} . We assume that (\mathbf{x}, \mathbf{y}) are sampled according to a fixed but unknown joint probability distribution P_{XY} . Let $f : X \rightarrow \mathbb{R}^n$ be a ranking function, where \mathbb{R}^n denotes a n -dimensional real-valued vector space. The task of listwise learning to rank is to learn a ranking function that can minimize the *expected risk* $R_0(h)$, defined as:

$$R_0(h) = \int_{X \times Y} L_0(f; \mathbf{x}, \mathbf{y}) dP_{XY}(\mathbf{x}, \mathbf{y}),$$

where L_0 is a true loss of listwise learning to rank. For example, Xia et al. [21] utilized permutation level 0-1 loss as the true loss, which takes the following form.

$$L_{0-1}(f; \mathbf{x}, \mathbf{y}) = I_{\{\pi_f(\mathbf{x}) \neq \mathbf{y}\}}, \quad (1)$$

where $I_{\{A\}}$ is an indicator function, with $I_A = 1$, if A is true, and $I_A = 0$, otherwise. π_f stands for the output permutation induced by sorting the objects in descending order of scores produced by f , that is,

$$\pi_f(\mathbf{x}) = \text{sort}(f(x_1), \dots, f(x_n)).$$

Since P_{XY} is unknown, the optimal ranking function which minimizes the expected loss cannot be easily obtained. In practice, we are usually given independently and identically distributed samples $S = \{\mathbf{x}_i, \mathbf{y}_i\}_{i=1}^N \sim P_{XY}$, where $\mathbf{x}_i = (x_1^{(i)}, \dots, x_{n_i}^{(i)})$ and $\mathbf{y}_i = (y_1^{(i)}, \dots, y_{n_i}^{(i)})$.

Therefore, we instead try to obtain a ranking function that minimize the *empirical risk*.

$$\hat{R}(h) = \frac{1}{N} \sum_{i=1}^N L_0(h; \mathbf{x}_i, \mathbf{y}_i).$$

However, the true loss is usually nonconvex, which poses a challenge to the optimization of the empirical risk. As is done in the literature of machine learning, people usually use surrogate losses as an approximation of the true loss, and turn to minimize the corresponding *surrogate empirical risk* instead.

$$R_\phi(f, \mathbf{x}, \mathbf{y}) = \frac{1}{N} \sum_{i=1}^N L_\phi(f; \mathbf{x}_i, \mathbf{y}_i).$$

2.2 ListMLE

ListMLE is such a listwise ranking algorithms which utilize a likelihood loss as the surrogate loss, defined as follows.

$$L(f; \mathbf{x}, \mathbf{y}) = -\log P(\mathbf{y}|\mathbf{x}; f), \quad (2)$$

where,

$$P(\mathbf{y}|\mathbf{x}; f) = \prod_{i=1}^n \frac{\exp(f(x_{\mathbf{y}^{-1}(i)}))}{\sum_{k=i}^n \exp(f(x_{\mathbf{y}^{-1}(k)}))}. \quad (3)$$

The above probability is defined according to Plackett-Luce model. That is to say, the probability of a permutation is first decomposed to the product of a stepwise conditional probability, with the i -th conditional probability standing for the probability that the document is ranked at the i -th position given the top $i - 1$ objects are ranked correctly. The precise form are given in the following equations.

$$\begin{aligned} & P(\mathbf{y}|\mathbf{x}; f) \quad (4) \\ &= P(\mathbf{y}^{-1}(1), \mathbf{y}^{-1}(2), \dots, \mathbf{y}^{-1}(n)|\mathbf{x}; f) \\ &= P(\mathbf{y}^{-1}(1)|\mathbf{x}; f) \prod_{i=2}^n P(\mathbf{y}^{-1}(i)|\mathbf{x}, \mathbf{y}^{-1}(1), \dots, \mathbf{y}^{-1}(i-1); f) \end{aligned}$$

where,

$$P(\mathbf{y}^{-1}(1)|\mathbf{x}; f) = \frac{\exp(f(x_{\mathbf{y}^{-1}(1)}))}{\sum_{k=1}^n \exp(f(x_{\mathbf{y}^{-1}(k)}))}, \quad (5)$$

$$\begin{aligned} & P(\mathbf{y}^{-1}(i)|\mathbf{x}, \mathbf{y}^{-1}(1), \mathbf{y}^{-1}(2), \dots, \mathbf{y}^{-1}(i-1); f) \\ &= \frac{\exp(f(x_{\mathbf{y}^{-1}(i)}))}{\sum_{k=j}^n \exp(f(x_{\mathbf{y}^{-1}(k)}))}, \forall i = 2, \dots, n \quad (6) \end{aligned}$$

2.3 Consistency

Previous theoretical analyses on ListMLE were mainly focused on generalization and consistency. For generalization analysis, Lan et al. [12] has derived the generalization bounds of listwise ranking methods, including ListMLE [21], ListNet [4] and RankCosine [17]. As to the statistical consistency analysis, the loss function in ListMLE has been proven to be consistent with permutation level 0-1 loss [20], where consistency is defined as follows.

Definition 1. We say a surrogate loss L_ϕ is statistically consistent with respect to the true loss L_0 , if $\forall \epsilon_1 > 0, \exists \epsilon_2 > 0$, such that for any ranking function $f \in \mathcal{F}$, $R_\phi(f) \leq \inf_{h \in \mathcal{F}} R_\phi(h) + \epsilon_2$ implies $R_0(f) \leq \inf_{h \in \mathcal{F}} R_0(h) + \epsilon_1$.

Statistical consistency is a desired property for a good surrogate loss, which measures whether the expected true risk of the ranking function obtained by minimizing a surrogate loss converges to the expected true risk of the optimal ranking in the large sample limit. Therefore, the consistency of ListMLE with respect to permutation level 0-1 loss means that the the surrogate loss of ListMLE is a good surrogate of permutation level 0-1 loss theoretically. However, 0-1 loss is not a ‘good’ loss for the ranking problem, since it largely ignores the impact of positions, which is crucial in ranking. Therefore, in this paper, we propose to study how to improve ListMLE to make it consistent with a better loss for ranking.

3 MOTIVATIONS

The motivation of this work comes from both empirical contradiction and theoretical results in ListMLE, indicating that position importance, which is a key factor in ranking, is actually ignored in this listwise approach.

3.1 Empirical Contradiction

Firstly, we take a case study on some toy data to show that position importance is actually not considered in ListMLE.

We are given a set of documents $\mathbf{x} = \{x_1, \dots, x_5\}$ and their ground-truth labels $\mathbf{z} = (z_1, \dots, z_5)$ in terms of 5-level ratings, where $z_i = i$. That is to say, the best ranking list is $\mathbf{y} = (1, 2, 3, 4, 5)$. Suppose we are given two ranking functions f_1 and f_2 with corresponding scores $\mathbf{y}_1 = (\ln 4, \ln 5, \ln 3, \ln 2, \ln 1)$ and $\mathbf{y}_2 = (\ln 5, \ln 4, \ln 1, \ln 2, \ln 3)$, where $\mathbf{y}_i(j) = f_i(x_j)$. As we can see, the first two documents are mistakenly ranked by f_1 , while the last three documents are mistakenly ranked by f_2 . The corresponding likelihood losses of these two rank-

ing functions in ListMLE are listed as follows.

$$\begin{aligned}
& L(f_1, \mathbf{x}, \mathbf{y}) \\
&= -\log\left(\frac{4}{4+5+3+2+1} \cdot \frac{5}{5+3+2+1} \cdot \frac{3}{3+2+1} \cdot \frac{2}{2+1} \cdot \frac{1}{1}\right), \\
& L(f_2, \mathbf{x}, \mathbf{y}) \\
&= -\log\left(\frac{5}{5+4+3+2+1} \cdot \frac{4}{4+3+2+1} \cdot \frac{1}{1+2+3} \cdot \frac{2}{2+3} \cdot \frac{3}{3}\right).
\end{aligned}$$

Through comparison, we can see that f_1 is better than f_2 in terms of likelihood loss of ListMLE, as indicated by the fact that $L(f_1, \mathbf{x}, \mathbf{y}) < L(f_2, \mathbf{x}, \mathbf{y})$.

However, from the view of IR evaluation measure NDCG, we can see that $NDCG(f_1, \mathbf{x}, \mathbf{y}) < NDCG(f_2, \mathbf{x}, \mathbf{y})$, showing that f_2 should be preferred to f_1 .

$$\begin{aligned}
& NDCG@5(f_1, \mathbf{x}, \mathbf{y}) \\
&= \frac{1}{N_5} \left((2^5 - 1) \log \frac{1}{3} + (2^4 - 1) \log \frac{1}{2} + (2^3 - 1) \log \frac{1}{4} \right) \\
&\quad + \frac{1}{N_5} \left((2^2 - 1) \log \frac{1}{5} + (2^1 - 1) \log \frac{1}{6} \right), \\
& NDCG@5(f_2, \mathbf{x}, \mathbf{y}) \\
&= \frac{1}{N_5} \left((2^5 - 1) \log \frac{1}{2} + (2^4 - 1) \log \frac{1}{3} + (2^3 - 1) \log \frac{1}{6} \right) \\
&\quad + \frac{1}{N_5} \left((2^2 - 1) \log \frac{1}{5} + (2^1 - 1) \log \frac{1}{4} \right),
\end{aligned}$$

As we know, IR evaluation measures such as NDCG reflect the fact that users are more concerned on results in top positions in a ranking. Therefore, the mistakes in top positions will be more severe than that in low positions. The empirical contradiction between ListMLE and IR evaluation measures thus indicates that the loss of ListMLE cannot well capture the position importance.

3.2 Theoretical Result

In [21], it was proven that the loss functions of ListMLE [21] are consistent with permutation level 0-1 loss. However, permutation level 0-1 loss actually does not take position importance into account. Therefore, theoretical consistency between ListMLE and permutation level 0-1 loss also demonstrates that the position importance cannot be well captured by the loss of ListMLE.

4 POSITION-AWARE LISTMLE

The above results indicates that ListMLE ignores the position importance, which is a key factor for ranking. However, the probability in ListMLE is defined in a top-down style

which seems to reflect the position importance in ranking. This contradiction makes us revisit the algorithm of ListMLE. As we can see, the probability on permutation in ListMLE can be decomposed as follows.

$$\begin{aligned}
& P(\mathbf{y}|\mathbf{x}; f) \\
&= P(\mathbf{y}^{-1}(1), \mathbf{y}^{-1}(2), \dots, \mathbf{y}^{-1}(n)|\mathbf{x}; f) \\
&= P(\mathbf{y}^{-1}(1)|\mathbf{x}; f) \prod_{i=2}^n P(\mathbf{y}^{-1}(i)|\mathbf{x}, \mathbf{y}^{-1}(1), \dots, \mathbf{y}^{-1}(i-1); f)
\end{aligned} \tag{7}$$

However, the *chain rule of probability* described as follows tells us that this is not the unique decomposition.

$$\begin{aligned}
& P(A_1, \dots, A_n) \\
&= P(A_{i_1})P(A_{i_2}|A_{i_1}) \dots P(A_{i_n}|A_{i_1}, \dots, A_{i_{n-1}}),
\end{aligned}$$

where (i_1, \dots, i_n) is any permutation of $(1, \dots, n)$.

As a consequence, the probability is equal to any decomposition described as follows.

$$\begin{aligned}
& P(\mathbf{y}|\mathbf{x}; f) \\
&= P(\mathbf{y}^{-1}(1), \mathbf{y}^{-1}(2), \dots, \mathbf{y}^{-1}(n)|\mathbf{x}; f) \\
&= P(\mathbf{y}^{-1}(i_1)|\mathbf{x}; f) \prod_{j=2}^n P(\mathbf{y}^{-1}(i_j)|\mathbf{x}, \mathbf{y}^{-1}(i_1), \dots, \mathbf{y}^{-1}(i_{j-1}); f)
\end{aligned} \tag{8}$$

where (i_1, \dots, i_n) is any permutation of $(1, \dots, n)$. In this way, different positions are actually equally important under the probability definition of ListMLE. In other words, the loss of ListMLE cannot reflect the position importance in a top-down style. Therefore, we propose a new listwise ranking approach, namely p-ListMLE, to capture the position importance in a ‘true’ top-down style.

4.1 Ranking As a Sequential Process

To reflect the position importance in a top-down style, i.e. higher position is more important, we propose a new sequential learning process for ranking as follows.

Step 1: Maximizing the probability that the top 1 object is selected with mathematical description as follows.

$$\max_{f \in \mathcal{F}} P(\mathbf{y}^{-1}(1)|\mathbf{x}; f);$$

Step i: For $i = 2, \dots, n$, we denote the subset of ranking functions that reach the maximum in Step $i - 1$ as S_{i-1} . The task of step i is to maximize the probability that the object with position i in ground-truth permutation is selected given the top $i - 1$ objects ranked correctly. The mathematical formulation is described as follows.

$$\max_{f \in S_{i-1}} P(\mathbf{y}^{-1}(i)|\mathbf{x}, \mathbf{y}^{-1}(1), \dots, \mathbf{y}^{-1}(i-1); f);$$

Step n+1: The learning process ends, and the ranking function f is randomly selected from S_{n-1} as the output ranking function.

4.2 Loss Function

In order to solve the above *sequential multi-objective optimization* problem, we propose to use *linear scalarization* strategy [8] to transform it into a single-objective optimization problem, and emphasize the early steps to reflect the position importance.

$$\begin{aligned} & \min_{f \in \mathcal{F}} \Phi(f), \\ \Phi(f) = & - \sum_{i=2}^n \alpha(i) \log P(\mathbf{y}^{-1}(i) | \mathbf{x}, \mathbf{y}^{-1}(1), \dots, \mathbf{y}^{-1}(i-1); f) \\ & - \alpha(1) \log P(\mathbf{y}^{-1}(1) | \mathbf{x}; f), \end{aligned}$$

where $\alpha(\cdot)$ is a decreasing function, i.e. $\alpha(i) > \alpha(i+1)$.

Incorporating the probability based on Plackett-Luce model as described in Eq. (5) and Eq. (6) into the above optimization problem, we obtain a new algorithm which minimizes the following likelihood loss function for p-ListMLE.

$$\begin{aligned} & L_p(f; \mathbf{x}, \mathbf{y}) \\ = & \sum_{i=1}^n \alpha(i) (-f(x_{\mathbf{y}^{-1}(i)}) + \log(\sum_{j=i}^n \exp(f(x_{\mathbf{y}^{-1}(j)}))))). \end{aligned} \quad (9)$$

4.3 Case Revisit

Here, we revisit the case used in section 3.1 to show that after introducing position factor α into ListMLE, the empirical contradiction will disappear. We first compute the likelihood losses of p-ListMLE with respect to f_1 and f_2 , which are listed as follows.

$$\begin{aligned} & L_p(f_1, \mathbf{x}, \mathbf{y}) \\ = & -\alpha(1) \log\left(\frac{4}{4+5+3+2+1}\right) - \alpha(2) \log\left(\frac{5}{5+3+2+1}\right) \\ & - \alpha(3) \log\left(\frac{3}{3+2+1}\right) - \alpha(4) \log\left(\frac{2}{2+1}\right), \end{aligned}$$

$$\begin{aligned} & L_p(f_2, \mathbf{x}, \mathbf{y}) \\ = & -\alpha(1) \log\left(\frac{5}{5+4+3+2+1}\right) - \alpha(2) \log\left(\frac{4}{4+3+2+1}\right) \\ & - \alpha(3) \log\left(\frac{1}{1+2+3}\right) - \alpha(4) \log\left(\frac{2}{2+3}\right). \end{aligned}$$

In this way, the following equality holds:

$$\begin{aligned} & L_p(f_1, \mathbf{x}, \mathbf{y}) - L_p(f_2, \mathbf{x}, \mathbf{y}) \\ = & (\alpha(1) - \alpha(2) - \alpha(4)) \ln 5 - (\alpha(1) - \alpha(2)) \ln 4 \\ & - (\alpha(3) - \alpha(4)) \ln 3 + \alpha(2)(\ln 11 - \ln 10) \\ > & (\alpha(1) - \alpha(2) - \alpha(4)) \ln 5 - (\alpha(1) - \alpha(2)) \\ & + \alpha(3) - \alpha(4)) \ln 4, \end{aligned}$$

Therefore, as long as α satisfies the following condition in Eq. (10), we will have $L_p(f_1, \mathbf{x}, \mathbf{y}) > L_p(f_2, \mathbf{x}, \mathbf{y})$.

$$\frac{\alpha(1) - \alpha(2) - \alpha(4)}{\alpha(1) - \alpha(2) + \alpha(3) - \alpha(4)} > \frac{\ln 4}{\ln 5}. \quad (10)$$

That is, f_2 is preferred to f_1 in terms of p-ListMLE, which is consistent with *NDCG* as shown in Section 3.1. This condition is easy to be satisfied as long as $\alpha(1)$ is far larger than the other $\alpha(i)$, $i = 2, \dots, 5$.

5 STATISTICAL CONSISTENCY OF P-LISTMLE

In this section, we study the statistical consistency of p-ListMLE. In [21], it is proved that ListMLE is consistent with permutation level 0-1 loss. Since position factor $\alpha(\cdot)$ is introduced in p-ListMLE, we consider weighted pairwise loss (WPD) defined in [11] as the true loss.

$$L_{\text{WPD}}(f; \mathbf{x}, \mathbf{y}) = \sum_{i,j:r_i > r_j} D(r_i, r_j) I_{\{f(x_i) - f(x_j) \leq 0\}}, \quad (11)$$

where $r_i = n - y_i$, $D(r_i, r_j) = \alpha(r_j) - \alpha(r_i) > 0$.

Firstly, we introduce the definition of a rank-differentiable probability space (RDPS for short), with which we can prove that p-ListMLE is consistent with WPD. Hereafter, we will also refer to data from RDPS as having a rank-differentiable property.

5.1 A Rank-Differentiable Probability Space

Before introducing the definition of RDPS, we give two definitions, *an equivalence class of ratings* and *dual ratings*. Intuitively, we say two ratings are equivalent if they induce the same ranking or preference relationships. Meanwhile, we say two ratings are the dual ratings with respect to a pair of objects, if the two ratings only exchange the ratings of the two objects while keeping the ratings of other objects unchanged. The formal definitions are given as follows.

Definition 2. A ratings \mathbf{r} is called equivalent to $\tilde{\mathbf{r}}$, denoted as $\mathbf{r} \sim \tilde{\mathbf{r}}$, if $\mathcal{P}(\mathbf{r}) = \mathcal{P}(\tilde{\mathbf{r}})$. Where $\mathcal{P}(\mathbf{r}) = \{(i, j) : r_i > r_j\}$ and $\mathcal{P}(\tilde{\mathbf{r}}) = \{(i, j) : \tilde{r}_i > \tilde{r}_j\}$ stand for the preference relationships induced by \mathbf{r} and $\tilde{\mathbf{r}}$, respectively.

Therefore, an equivalence class of the ratings \mathbf{r} , denoted as $[\mathbf{r}]$, is defined as the set of ratings which are equivalent to \mathbf{r} . That is, $[\mathbf{r}] = \{\tilde{\mathbf{r}} \in \mathcal{R} : \tilde{\mathbf{r}} \sim \mathbf{r}\}$.

Definition 3. Let $R(i, j) = \{\mathbf{r} \in \mathcal{R} : r_i > r_j\}$, \mathbf{r}' is called the dual ratings of $\mathbf{r} \in R(i, j)$ with respect to (i, j) if $r'_j = r_i, r'_i = r_j, r'_k = r_k, \forall k \neq i, j$.

Now we give the definition of RDPS. An intuitive explanation on this definition is that there exists a unique equivalence class of ratings that for each induced pairwise preference relationship, the probability will be able to separate the two dual ratings with respect to that pair.

Definition 4. Let $R(i, j) = \{\mathbf{r} \in \mathcal{R} : r_i > r_j\}$, a probability space is called rank-differentiable with (i, j) , if for any $\mathbf{r} \in R(i, j)$, $P(\mathbf{r}|\mathbf{x}) \geq P(\mathbf{r}'|\mathbf{x})$, and there exists at least one ratings $\mathbf{r} \in R(i, j)$, s.t. $P(\mathbf{r}|\mathbf{x}) > P(\mathbf{r}'|\mathbf{x})$, where \mathbf{r}' is the dual ratings of \mathbf{r} .

Definition 5. A probability space is called rank-differentiable, if there exists an equivalence class $[\mathbf{r}^*]$, s.t. $\mathcal{P}(\mathbf{r}^*) = \{(i, j) : \text{the probability space is rank-differentiable with } (i, j)\}$, where $\mathcal{P}(\mathbf{r}^*) = \{(i, j) : r_i^* > r_j^*\}$. We will also call this probability space a RDPS or rank-differentiable with $[\mathbf{r}^*]$.

5.2 Consistency with WPD

Following the proof technique in [11], we prove that p-ListMLE is consistent with WPD, as shown in the following theorem.

Theorem 1. We assume that the probability space is rank-differentiable, then the surrogate loss function in p-ListMLE is consistent with WPD.

The proof of the theorem is similar to Theorem 5 in [11], and is based on the following theorem.

Theorem 2. We assume that the probability space is rank-differentiable with an equivalence class $[\mathbf{r}^*]$. let f be a function such that $R_p(f|\mathbf{x}) = \inf_{h \in \mathcal{F}} R_p(h|\mathbf{x})$, then for any object pair $(x_i, x_j), r_i^* > r_j^*$, we have $f(x_i) > f(x_j)$.

Proof. (1) We assume that $f(x_i) < f(x_j)$, and define f' as the function such that $f'(x_i) = f(x_j), f'(x_j) = f(x_i), f'(x_k) = f(x_k), \forall k \neq i, j$. We can then get the

following equation,

$$\begin{aligned} & R_p(f'|\mathbf{x}) - R_p(f|\mathbf{x}) \\ &= \sum_{\substack{\mathbf{r}, \mathbf{r}' \\ \mathbf{r} \in R(i, j)}} \sum_{k: r_j < r_k < r_i} \alpha(r_k) [P(\mathbf{r}|\mathbf{x}) - P(\mathbf{r}'|\mathbf{x})] \\ & \quad \times \log \left(\frac{\sum_{l=y_k, l \neq y_j}^n \exp(f(x_{\mathbf{y}^{-1}(l)})) + \exp(f(x_i))}{\sum_{l=y_k, l \neq y_j}^n \exp(f(x_{\mathbf{y}^{-1}(l)})) + \exp(f(x_j))} \right) \\ &+ \sum_{\substack{\mathbf{r}, \mathbf{r}' \\ \mathbf{r} \in R(i, j)}} [\alpha(r_i) - \alpha(r_j)] [\log(f(x_i)) - \log(f(x_j))] \\ & \quad \times [P(\mathbf{r}|\mathbf{x}) - P(\mathbf{r}'|\mathbf{x})] \\ &+ \sum_{\substack{\mathbf{r}, \mathbf{r}' \\ \mathbf{r} \in R(i, j)}} \alpha(r_j) [P(\mathbf{r}|\mathbf{x}) - P(\mathbf{r}'|\mathbf{x})] \\ & \quad \times \log \left(\frac{\sum_{l=y_j+1}^n \exp(f(x_{\mathbf{y}^{-1}(l)})) + \exp(f(x_i))}{\sum_{l=y_j+1}^n \exp(f(x_{\mathbf{y}^{-1}(l)})) + \exp(f(x_j))} \right), \end{aligned}$$

According to the conditions of RDPS and the requirements of $\alpha(\cdot)$, we can obtain

$$R_p(f'|\mathbf{x}) < R_p(f|\mathbf{x}).$$

This is a contradiction with $R_p(f|\mathbf{x}) = \inf_{h \in \mathcal{F}} R_p(h|\mathbf{x})$. Therefore, we have proven that $f(x_i) \leq f(x_j)$.

(2) Now we assume that $f(x_i) = f(x_j) = f_0$. From the assumption $R_p(f|\mathbf{x}) = \inf_{h \in \mathcal{F}} R_p(h|\mathbf{x})$, we can get

$$\left. \frac{\partial R_p(f|\mathbf{x})}{\partial f(x_i)} \right|_{f_0} = 0, \quad \left. \frac{\partial R_p(f|\mathbf{x})}{\partial f(x_j)} \right|_{f_0} = 0.$$

Accordingly, we can obtain two equations as follows:

$$\sum_{\substack{\mathbf{r}, \mathbf{r}' \\ \mathbf{r} \in R(i, j)}} A_1 P(\mathbf{r}|\mathbf{x}) + A_2 P(\mathbf{r}'|\mathbf{x}) = 0, \quad (12)$$

$$\sum_{\substack{\mathbf{r}, \mathbf{r}' \\ \mathbf{r} \in R(i, j)}} B_1 P(\mathbf{r}|\mathbf{x}) + B_2 P(\mathbf{r}'|\mathbf{x}) = 0, \quad (13)$$

where,

$$\begin{aligned} & A_1 = B_2 \\ &= \sum_{k: r_j < r_k < r_i} \alpha(r_k) \frac{\exp(f_0)}{\sum_{l=y_k}^n \exp(f(x_{\mathbf{y}^{-1}(k)}))} \\ & \quad + \alpha(r_i) \left(-1 + \frac{\exp(f_0)}{\sum_{l=y_i}^n \exp(f(x_{\mathbf{y}^{-1}(k)}))} \right), \end{aligned}$$

$$\begin{aligned}
& A_2 = B_1 \\
& = \sum_{k:r_j < r_i < r_k} \alpha(r_k) \frac{\exp(f_0)}{\sum_{l=y_k}^n \exp(f(x_{\mathbf{y}^{-1}(k)}))} \\
& \quad + \sum_{k:r_i < r_k < r_j} \alpha(r_k) \frac{\exp(f_0)}{\sum_{l=y_k}^n \exp(f(x_{\mathbf{y}^{-1}(k)}))} \\
& \quad + \alpha(r_i) \frac{\exp(f_0)}{\sum_{l=y_i}^n \exp(f(x_{\mathbf{y}^{-1}(l)}))} \\
& \quad + \alpha(r_j) \left(-1 + \frac{\exp(f_0)}{\sum_{l=y_j}^n \exp(f(x_{\mathbf{y}^{-1}(k)}))} \right)
\end{aligned}$$

Based on the requirements of RDPS and $\alpha(\cdot)$, we can obtain that,

$$\begin{aligned}
& \sum_{\substack{\mathbf{r}, \mathbf{r}' \\ \mathbf{r} \in R(i, j)}} (A_1 - B_1)P(\mathbf{r}|\mathbf{x}) + (A_2 - B_2)P(\mathbf{r}'|\mathbf{x}) \\
& = \sum_{\substack{\mathbf{r}, \mathbf{r}' \\ \mathbf{r} \in R(i, j)}} (A_1 - A_2)[P(\mathbf{r}|\mathbf{x}) - P(\mathbf{r}'|\mathbf{x})] \\
& \leq \sum_{\substack{\mathbf{r}, \mathbf{r}' \\ \mathbf{r} \in R(i, j)}} (\alpha(r_j) - \alpha(r_i))[P(\mathbf{r}|\mathbf{x}) - P(\mathbf{r}'|\mathbf{x})] < 0.
\end{aligned}$$

This is a contradiction with Eq. (12). Therefore, we actually have proven that $f(x_i) > f(x_j)$. \square

5.3 Discussion

In [21], ListMLE is proved to be consistent with permutation level 0-1 loss. However, consistency with permutation level 0-1 loss does not mean consistency with NDCG. For example, it has been proven in [18] that losses in RankCosine [17] and ListNet [4] are not consistent with NDCG. Since that we have proven that p-ListMLE is consistent with WPDL, it is natural to study the relationship between WPDL and NDCG. Here we show that WPDL with a certain weight, referred to as *difference-weight pairwise disagreement loss* (DWPDL for short), is equivalent to NDCG with a certain discount function, referred to as *sharp-NDCG*. In this way, p-ListMLE is better than ListMLE theoretically.

The formal definition of NDCG is as follows.

$$NDCG@n(f; \mathbf{x}, \mathbf{y}) = \frac{1}{N_n} \sum_{i=1}^n Gain(r(y_i)) Disc(\pi_f(i)),$$

where *Gain* is the gain function which gives larger scores to objects with larger labels and *Disc* is the discount function which gives larger scores to objects ranked higher in π_f . $r(y_i)$ is a function to mapping position y_i into relevance score. For consistency with above formulation, we use r_i to denote $r(y_i)$, and define $r_i = n - y_i$, $\pi_f(i)$ is the position of document x_i in permutation π_f and N_n is a normalization factor.

We define WPDPL, and sharp-NDCG as follows, respectively.

$$\begin{aligned}
& l_w(f; \mathbf{x}, \mathbf{y}) \\
& = \sum_{i, j, r_i > r_j} (Gain(r_i) - Gain(r_j)) \mathbf{1}_{\{f(x_i) \leq f(x_j)\}}, \\
& \text{sharp-NDCG}@n(f; \mathbf{x}, \mathbf{y}) = \frac{\sum_{i=1}^n (n - \pi(i)) Gain(r_i)}{N'_n},
\end{aligned}$$

where N'_n is a normalization factor.

The following theorem shows the relationship between D-WPDL and sharp-NDCG.

Theorem 3. We denote $\mathcal{F}_0 = \{f \in \mathcal{F} : \forall \mathbf{x}, f(x_i) \neq f(x_j), \forall i, j\}$, then $\forall (\mathbf{x}, \mathbf{y}), f, g \in \mathcal{F}_0$, we have

$$\begin{aligned}
& l_w(f; \mathbf{x}, \mathbf{y}) < l_w(g; \mathbf{x}, \mathbf{y}) \\
& \Leftrightarrow \text{sharp-NDCG}@n(\pi_f, \mathbf{x}, \mathbf{y}) > \text{sharp-NDCG}@n(\pi_g, \mathbf{x}, \mathbf{y}).
\end{aligned}$$

Proof. According to the definition of sharp-NDCG, it has the following form:

$$\text{sharp-NDCG}@n(\pi, \mathbf{y}) = \sum_{i=1}^n Gain(r_i)(n - \pi(i)).$$

Rewrite $n - \pi(i)$ and $n - \pi_y(j)$ as $\sum_{j=1}^m \mathbf{1}_{\{\pi(i) - \pi(j) < 0\}}$ and $\sum_{j=1}^m \mathbf{1}_{\{\pi_y(i) - \pi_y(j) < 0\}}$, respectively, then the following equation holds,

$$\begin{aligned}
& \sum_{i=1}^n (n - \pi_y) Gain(r_i) - \text{sharp-NDCG}@n(\pi; \mathbf{x}, \mathbf{y}) \\
& = \sum_{i=1}^n \sum_{j \neq i} Gain(r(y_i)) (\mathbf{1}_{\{\pi_y(i) - \pi_y(j) < 0\}} - \mathbf{1}_{\{\pi(i) - \pi(j) < 0\}}),
\end{aligned}$$

Thus, for each pair (i, j) , $r_i > r_j$, the term becomes:

$$\begin{aligned}
& Gain(r_i) \mathbf{1}_{\{\pi(i) - \pi(j) > 0\}} - Gain(r(y_j)) \mathbf{1}_{\{\pi(j) - \pi(i) < 0\}} \\
& = Gain(r_i) \mathbf{1}_{\{\pi(i) - \pi(j) > 0\}} - Gain(j) \mathbf{1}_{\{\pi(i) - \pi(j) > 0\}} \\
& = (Gain(r_i) - Gain(r(y_j))) \mathbf{1}_{\{\pi(i) - \pi(j) > 0\}},
\end{aligned}$$

Further considering the relationship between π and f , the following equation holds:

$$\begin{aligned}
& \sum_{i=1}^m (n - \pi_y) Gain(r_i) - \text{sharp-NDCG}@m(\pi; \mathbf{x}, \mathbf{y}) \\
& = l_w(f; \mathbf{x}, \mathbf{y}).
\end{aligned}$$

Since $\sum_{i=1}^m (n - \pi_y) Gain(r_i)$ is just dependent on \mathbf{y} , the result in the theorem has been proved. \square

Note that in applications such as information retrieval, people usually use the following specific discount and gain functions.

$$Gain(i) = 2^{r(y_i)} - 1, \quad Disc(\pi(i)) = \frac{1}{\log_2(1 + \pi(i))}.$$

According to the original paper of NDCG [9], however, this is not the only choice. Actually, the only difference between sharp-NDCG and the above NDCG is that the discount function in sharp-NDCG is sharper.

In summary, we have obtain that:

(1) p-ListMLE is statistically consistent with WPD, where $D(r_i, r_j) = \alpha(r_j) - \alpha(r_i)$;

(2) WPD with $D(r_i, r_j) = Gain(r_i) - Gain(r_j)$ is equivalent to sharp-NDCG;

(3) sharp-NDCG is intrinsic similar with NDCG.

Therefore, we can expect to obtain better performance w.r.t NDCG if we define $\alpha(r_i) = Gain(r_i) = 2^{n-y_i} - 1$.

6 EXPERIMENTS

In this section, we conduct experiments on benchmark data sets LETOR 4.0² to show that p-ListMLE can achieve better performances compared to ListMLE as well as other state-of-the-art listwise learning-to-rank algorithms.

As the setting in this paper is listwise ranking, we choose two datasets in LETOR, i.e. MQ2007-list and MQ2008-list, in which the ground-truth is a full order ranking list. In MQ2007-list, there are about 1700 queries and 700 documents per query on average. In MQ2008-list, there are about 800 queries and 1000 documents per query on average. Both query sets are from Million Query track of TREC 2007 and TREC 2008.

We implement both ListMLE and p-ListMLE by Stochastic Gradient Descent (SGD). In p-ListMLE, we set $\alpha(i)$ as $2^{n-i} - 1$, as guided in the above section. The stopping criteria is chosen from $\{0.1^i\}_{i=1}^5$ to control when to stop, and the learning rates are selected from $\{0.1^i\}_{i=1}^5$ with the maximal number of iterations 500. Evaluation measure NDCG is adopted to evaluate the test performances of both algorithms, where the multi-level ground-truth label is taken as $l(x_i) = n - y_i$, where y_i is the rank of item i in the listwise ground-truth. For empirical comparison, we also include two other state-of-the-art listwise learning-to-rank algorithms such as ListNet and RankCosine, and the implementation is conducted strictly under the standard setting as shown in [4] and [17]. The experimental results are shown in Figure 1.

From the results, we can see that p-ListMLE significantly outperform ListMLE with NDCG as evaluation measure on both datasets. Taking NDCG@10 as an example, the improvement of p-ListMLE over ListMLE is 0.95% and 0.54% on MQ2007-list and MQ2008-list, respectively.

²<http://research.microsoft.com/en-us/um/beijing/projects/letor/>.

Moreover, when comparing p-ListMLE with the other two baseline methods, we can see that it can also outperform traditional listwise ranking methods significantly. We also take NDCG@10 as an example, the improvement of p-ListMLE over ListNet is 0.85% and 0.22% on MQ2007-list and MQ2008-list, respectively. While, the improvement of p-ListMLE over RankCosine is 1.48% and 0.32% on MQ2007-list and MQ2008-list, respectively.

7 CONCLUSION

In this paper, we address the problem of ListMLE that the position importance is highly ignored, which is however very important for ranking. We propose a new listwise ranking algorithm, namely position-aware ListMLE (p-ListMLE) to amend the problem. In p-ListMLE, ranking is viewed as a sequential learning process, with each step learning a subset of parameters which minimize the corresponding stepwise probability distribution. We prove that p-ListMLE is consistent with WPD, which is equivalent to a certain form of NDCG. In addition, our experimental results on benchmark datasets show that p-ListMLE can significantly outperform ListMLE. Therefore, we have demonstrated both theoretically and empirically that p-ListMLE is better than ListMLE.

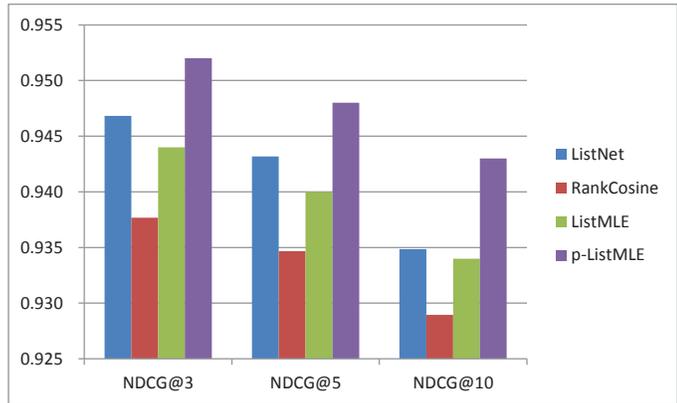

For the future work, we plan to further investigate the problem of how to set the position factor $\alpha(\cdot)$ in practice, or how to guide the settings from other theoretical aspects.

Abstract

This paper introduces an extension to undirected graphical models of the classical *continuous time* Markov chains. This model can be used to solve a transductive or unsupervised multi-class classification problem at each point of a network defined as a set of nodes connected by segments of different lengths. The classification is performed not only at the nodes, but at every point of the edge connecting two nodes. This is achieved by constructing a *Potts process* indexed by the continuum of points forming the edges of the graph.

We propose a homogeneous parameterization which satisfies Kolmogorov consistency, and show that classical inference and learning algorithms can be applied.

We then apply our model to a problem from geomatics, namely that of labelling city blocks automatically with a simple typology of classes (e.g. collective housing) from simple properties of the shape and sizes of buildings of the blocks. Our experiments shows that our model outperform standard MRFs and a discriminative model like logistic regression.

1 INTRODUCTION

Connections in networks typically have a length or weight that gives a measure of distance between the nodes connected, or the intensity of their interaction. This length information has been used to perform unsupervised or semi-supervised classification on graphs based among others on graph partitioning algorithms (see e.g. Zhu and Goldberg, 2009). When defining probabilistic graphical models on such networks, it is not clear how to take this distance into account naturally so that the interaction decreases with the distance. In this paper, we propose an unoriented counterpart of the continuous-time Markov process on a tree proposed by Holmes and Rubin (2002) which is naturally generalized to any unoriented graph.

In a continuous time Markov chain, a random state X_t is associated with every point $t \in \mathbb{R}_+$. The generalization to a continuous tree mode considered by Holmes and Rubin (2002) is most simply described through its application in phylogenetics. The phylogenetic tree of a family of species is assumed given as a directed tree with branches of different lengths. The length of the branches measure the genetic distance between extant or extinct species. Branching nodes are associated with speciation events. Each point of each branch of the tree corresponds to the form taken by a species as it existed at one time in the past and the variable modeled as a random process and defined at each such point is typically a discrete trait of that species such as the nucleic acid among $\{A, C, T, G\}$ at a certain position in the DNA. In the absence of speciation event, the state evolves like a continuous-time Markov chain, with time here being measure in terms of the genetic distance along an edge. When a branching occurs, the Markov chain is split into two identical states which continue to evolve independently. For that process, if the edges of the trees are identified with line segments, there is a random variable X_t associated with every point t of each of these segments. Since a tree is simply connected, removing point t will split the tree in at least two components, and with this model we have the fundamental Markov property that the subprocesses defined on each component are conditionally independent given X_t .

We aim to extend these models in two ways. First, these continuously indexed processes are fundamentally oriented. This stems for the fact that the continuous Markov chain in this model is *homogeneous*, which implies that the conditional distributions forward in time are constant, a property which, while true forward, is not in general true backwards in time. This implies in particular that all marginals of the process on any finite set of points including at least all nodes of degree different than two is naturally parameterized as a product of conditionals $p(x_s|x_t)$ whose value depends on the graph only through the distance between s and t . We aim to propose natural parameterization for *unoriented continuously indexed models* with the same Markov property as the oriented trees. Second,

the considered models are simply connected and we would like to propose an extension from weighted trees to general weighted graphs, where all edges are identified with a real segment of lengths equal to their weights, and which satisfy the Markov property in the sense that if a finite set of points A on these segments cuts the graph into several connected components, the processes on the two subgraphs are conditionally independent given $(X_a)_{a \in A}$. The obtained models will be Potts models that take into account in a natural way the length of the edges and such that the interaction between two nodes decreases with the distance separating them.

After a discussion of related work, we first consider the simplest case of an unoriented continuous chain for which we propose an exponential family parametrization. Next, we show how this parametrization is naturally extended to general unoriented continuous graphs. We derive the marginal log-likelihood of different subsets of nodes, as well as the form of its gradients, and show that inference and learning in these models can be obtained with classical algorithms. We then extend the model and algorithms to the hidden Markov random field case where a feature vector is attached to a certain number node. In terms of experiments, we consider first a transductive classification problem from geomatics, which consists in assigning city blocks to different classes from simple buildings characteristics, while taking into account the distances between the blocks. Then we illustrate the possibility of using the model for transfer learning in order to refine predictions for city blocks from a new entirely unlabelled city.

2 RELATED WORK

The model we consider in this work can be viewed as an extension to undirected graphs of the continuous time Markov chain (CTMC). The continuous-time Markov chain (Norris, 1997) is a fundamental model in probability and statistics for random variables that take values in a set of discrete states and that can transition at any point in continuous time from one state to another. Beyond its theoretical value, it has been applied directly in queuing theory, for the statistical modeling of chemical reactions and in genetics.

In genetics, CTMC models have been notably used to propose models of the evolution of DNA at the nucleotide level (Nielsen, 2005; Durrett, 2008), with among several others, the celebrated Jukes-Cantor model. In this context, these models have been extended to directed trees, where the tree corresponds to a phylogeny of species or of proteins, and which has been used to estimate rate matrices or for genetic sequence alignment (Von Bing and Speed, 2004). Like for CTMCs, the fact that these models are continuous arise from temporality, and the models derived are thus intrinsically oriented. For these CTMC on trees, Holmes and Rubin (2002) proposed an exponential family parametrization of the likelihood and showed that it was possible to

design an EM algorithm to learn the rate matrices modeling the substitution of DNA bases over time, in a way that generalizes the classical EM algorithm on trees.

As is the case for the CTMC, continuously indexed processes arise typically as the limit of discretely indexed processes. Along these lines, Yaple and Abrams (2013) consider a continuum limit of the Ising model on a regular grid where the lengths of the edges are infinitesimal and use it to characterize the patterns of magnetic polarity in ferromagnetic materials through the resolution of integro-differential equations.

A different but also recent line of research combining ideas from the graphical models literature with stochastic processes is known under the name of *continuous time Bayesian networks* (CTBNs, Nodelman et al., 2002). These are models of structured multivariate stochastic processes in time in which the interaction between the different components of the process can be modeled by a graphical model. These models are quite different than the continuous time tree models or the models we will propose in this paper in that, for CTBNs, the graphical model structure is somehow orthogonal to the direction of time which is the unique global oriented continuous variable for the process.

Last but not least, a common family of approaches which take into account the length of edges in a graph in the context of unsupervised or semi-supervised classification are the graph partitioning and related spectral clustering techniques (see e.g. Zhu and Goldberg, 2009, chap. 5). A review of these techniques is beyond the scope of this paper. We however discuss how these methods differ and are not directly comparable to ours in section 7.

3 NOTATIONS

All multinomial variables considered in the paper take values in $\mathcal{K} = \{1, \dots, K\}$ and are represented by the indicator vector $x \in \{0, 1\}^K$ whose sole non zero entry is x_k when the multinomial is the k th state. We thus define $\mathcal{X} = \{x \in \{0, 1\}^K \mid \sum_{k \in \mathcal{K}} x_k = 1\}$. Given a vector $x \in \mathbb{R}^K$, $\text{Diag}(x)$ is the diagonal matrix whose elements are the entries in x .

We use \odot (resp. \oslash) to denote the Hadamard product (resp. division), that is the entrywise multiplication (resp. division) of matrices.

We will denote nodes of graphical model with the sans-serif font a, b , and set of nodes with upper capitals of the same font: A, B .

4 CONTINUOUS GRAPH POTTS MODELS

4.1 An unoriented continuous chain model

To derive a parameterization of the model, we start with the case of an unoriented chain that we identify with the $[0, l]$

segment, where without loss of generality l is an integer. We will denote by X_a a multinomial random variable associated with the point $a \in [0, l]$. Before defining the process at any point of the segment, we model the joint distribution of the random variables X_k for k an integer in $\{0, \dots, l\}$. Denoting by $x_k \in \{0, 1\}^K$ an instance of X_k , and assuming that both unary and binary potentials are constant, the joint distribution of $(X_k)_{k \in \{0, 1, \dots, l\}}$ can be written in multiplicative form as

$$p(x_0, x_1, \dots, x_l; U, h) \propto \prod_{k=0}^l h^\top x_k \prod_{k=0}^{l-1} x_k^\top U x_{k+1},$$

with $h \in \mathbb{R}_{+*}^K$ the vector of unary potential values and $U \in \mathbb{R}_{+*}^{K \times K}$ the matrix of binary potential values. For reasons of symmetry and invariance along the chain, we assume that those parameters do not depend on the position k and that $U = U^\top$. Note that, while similar in spirit, the assumption that these parameters are constant is different from assuming that the Markov chain is homogeneous; we discuss this point in section 7. To get concise forms for the distributions induced on subsets of the X_k s by marginalization, we introduce further $H = \text{Diag}(h)$ and $W = H^{\frac{1}{2}} U H^{\frac{1}{2}}$. If in particular we marginalize all variables except for the extreme points of the segment we then have

$$\begin{aligned} p(x_0, x_l; W, h) &\propto \sum_{x_1 \dots x_{l-1}} \prod_{i=0}^{l-1} x_i^\top U x_{i+1} \prod_{i=0}^l h^\top x_i \\ &\propto h^\top x_0 \left(x_0^\top H^{-\frac{1}{2}} W^l H^{-\frac{1}{2}} x_l \right) h^\top x_l, \end{aligned}$$

(See appendix for details).

Similar calculations show that, for any sequence $\mathbf{a}_0 = 0 < \mathbf{a}_1 < \dots < \mathbf{a}_m = l$ with $\mathbf{a}_k \in \{0, \dots, l\}$, denoting $d_j = d(\mathbf{a}_j, \mathbf{a}_{j-1}) = \mathbf{a}_j - \mathbf{a}_{j-1}$ the distances between consecutive nodes and $\mathbf{A} = \{\mathbf{a}_0, \dots, \mathbf{a}_m\}$, we have:

$$p(x_{\mathbf{A}}; W, h) \propto \prod_{j=0}^m h^\top x_{\mathbf{a}_j} \prod_{j=1}^m x_{\mathbf{a}_{j-1}}^\top H^{-\frac{1}{2}} W^{d_j} H^{-\frac{1}{2}} x_{\mathbf{a}_j}.$$

By simply taking the logarithm of this expression we obtain a curved exponential family of distributions with log-likelihood

$$\ell(x_{\mathbf{A}}; \theta) = \sum_{j=0}^m \eta^\top x_{\mathbf{a}_j} + \sum_{j=0}^{m-1} x_{\mathbf{a}_j}^\top \Lambda(\theta, d_j) x_{\mathbf{a}_{j+1}} - A(\theta), \quad (4.1)$$

with $\forall k \in \mathcal{K}$, $\eta_k = \log(h_k)$, $\theta = (W, \eta)$, A the log-partition function and where $\Lambda(\theta, d)$ is defined entrywise by $[\Lambda(\theta, d)]_{kk'} = \log([H^{-\frac{1}{2}} W^d H^{-\frac{1}{2}}]_{kk'})$.

It is now very natural to try and use this formula to extend the definition of the process to any sequence of points $\mathbf{a}_0 = 0 < \mathbf{a}_1 < \dots < \mathbf{a}_m = l$ that are no longer restricted to take integer values. This requires however that for all

for all $s \geq 0$, W^s should be a well defined real valued matrix with non-negative (or for learning purposes positive) entries. The fact that W is real symmetric and that all its powers should be real implies that it should have non-negative eigenvalues. Since we can approximate a low rank matrix with a full rank matrix, we assume for convenience that all its eigenvalues are positive (any low rank matrix can be approximated by a full rank one). W is then a matrix exponential $W = \exp(\Pi)$. The fact that all its powers should have non-negative entries implies in particular that for any s , W^s is *completely positive*¹. We therefore need to characterize which conditions on Π are needed to obtain a valid W . Note that Π can be viewed as the counterpart of the rate matrix for CTMCs.

4.2 Infinitesimal generator Π

To easily compute the matrix exponential we use the eigen-decomposition of Π :

$$\Pi = P^\top \Sigma P, \quad \Sigma = \text{Diag}(\sigma), \quad P^\top P = P P^\top = I_K \quad (4.2)$$

and exponentiate its eigenspectrum².

In the context of learning, it is natural to assume that the entries of W^s are actually strictly positive so that the log-likelihood is always finite. The following lemma provides sufficient and necessary conditions on Π for the entries of $\exp(l\Pi)$ to be either non negative or positive.

Lemma 1. *For Π a square matrix, $[\exp(l\Pi)]_{i,j} \geq 0 \forall l \in \mathbb{R}_+$ and $\forall i, j$ if and only if $\Pi_{i,j} \geq 0$ for all $i \neq j$. Similarly, $[\exp(l\Pi)]_{i,j} > 0$ for all i, j and $\forall l \in \mathbb{R}_+^*$, if and only if the sequences $(u_{i,j}^{(k)})_{k \in \mathcal{N}}$ with $u_{i,j}^{(k)} = [\Pi^k]_{i,j}$ is such that its first non-zero value exists and is strictly positive, for all $i \neq j$.*

This lemma is proved in the appendix.

It is easy to see from the proof of the lemma that $\Pi_{i,j} > 0$ for $i \neq j$ is a sufficient condition for $[\exp(l\Pi)]_{i,j}$ to be positive for all i, j and for all $l \in \mathbb{R}_+^*$.

Note that the likelihood obtained in (4.1) is invariant by a multiplication of H or U and thus of W by a positive scalar, because of normalization. As a result it is also invariant by addition of a constant multiple of the identity matrix to Π or equivalently to σ .

This means that the likelihood is invariant by addition of an arbitrary identical constant to all the eigenvalues $(\sigma_i)_{i \in \mathcal{K}}$. In particular, it is possible to choose this constant sufficient large to guarantee that the diagonal of Π is positive. This implies that it will be conveniently possible to parameterize the model by the entrywise logarithm of Π .

¹ $A \in \mathbb{R}^{K \times K}$ is *completely positive* iff there exists $B \in \mathbb{R}_+^{K \times m}$ with $A = B B^\top$ (see e.g. Seber (2008) p. 223).

²One caveat of this parametrization is that if W is close to low rank, the corresponding eigenvalues in σ have to take large negative values. This could be addressed by working with $(\sigma_k^{-1})_{k \in \mathcal{K}}$.

4.3 Existence of the process on the chain

Proposition 2. *There exists a stochastic process $(X_a)_{a \in [0, l]}$ defined at all points of the segment $[0, l]$ whose finite marginal on any finite set of points containing a_0 and a_l is given by (4.1).*

Proof. Let $A = \{a_0, \dots, a_m\}$ and $B = \{b_0, \dots, b_n\}$ two such sets with $a_0 = b_0 = 0$ and $a_m = b_n = l$. It is clear that using (4.1) to define a joint probability distribution on $(X_a)_{a \in A \cup B}$, the distribution obtained by marginalization of elements of $A \setminus B$ using the same type of derivation used in (4.1) is still of the form of (4.1). Since the same holds for $B \setminus A$, we just showed that the collection of proposed marginals are consistent and by Kolmogorov's extension theorem (Chung and Speyer, 1998, chap. 6). This proves the existence of the process. \square

4.4 Extending the model to graphs

4.4.1 Real graphs

To extend the model we proposed on a segment to undirected trees and more generally to undirected graphs, we first define what we will call *continuous graphs* or *real graphs*³. Given a weighted graph $G = (V, E)$ with the weight d_{ab} associated with the edge $(a, b) \in E$, we define the associated *real graph* \mathcal{G} as the space constructed as the union of line segments of lengths d_{ab} associated with the edges $(a, b) \in E$ and whose extreme points are respectively identified with the nodes a and b through an equivalence relation. Put informally, a real graph is the set of line segments that we usually draw to represent an abstract graph. For any pair of points a', b' on the same segment $[a, b]$, we will denote by $d_{a'b'}$ the length of that subsegment.

It should be noted that, in a real graph, the segments connecting a node of degree two are essentially merged into a single segment by concatenation. We will call all nodes of degree different than two *junction nodes*. Conversely, identifying nodes and points in the real graph, any point that is not a junction node can actually be viewed as a degree two node.

Definition 3. *Let S be the set of junction nodes. Given A a set of points on the real graph, we will call the induced discrete graph on $A \cup S$, denoted by G_A the graph with vertices $A \cup S$ and whose edges E_A link the nodes that can be joined on the real graph by segments not containing elements of $A \cup S$: $E_A = \{(a, b) \mid [a, b] \cap (A \cup S) = \emptyset\}$. To distinguish them from $S \setminus A$, we will call the set of nodes in A observed nodes.*

³Real graphs extend the notion of real trees which have been introduced previously in the literature (Chiswell, 2001) and are of interest notably in mathematical cladistics and to construct Brownian trees.

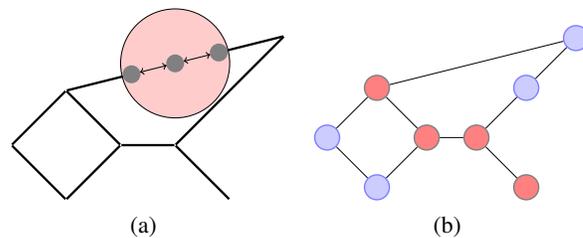

Figure 4.1: (a) Representation of a real graph with a zoom that shows that edges are actually a continuum of nodes linked by infinitesimal unoriented edges. (b) The induced discrete graph associated with the junction nodes in red and the observed nodes in blue.

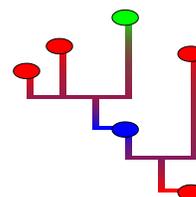

Figure 4.2: (left) Toy example illustrating that the process is defined at all points of the continuous graph. For a model on three classes (red, green blue) each point of each edge is colored with the mixture of these three colors corresponding to the probability of observing each of the classes, given that all the circle nodes are observed with the given colors.

The concepts of real graph, junction node, observed node and induced graph are illustrated on Figure 4.1.

4.4.2 Towards a Potts model on real graphs

To extend the stochastic process previously defined to real graphs, we first define its marginals. In particular, given a set of points $A = \{a_0, \dots, a_m\}$, the marginal on $A \cup S$ is naturally defined as follows: let $G_A = (A \cup S, E_A)$ be the induced discrete graph on $A \cup S$, we propose to define the log-marginal distribution on $(X_a)_{a \in A \cup S}$ as

$$\ell(x_{A \cup S}; \theta) = \sum_{a \in A \cup S} \eta^T x_a + \sum_{(a, b) \in E_A} x_a^T \Lambda(\theta, d_{ab}) x_b - A(\theta), \quad (4.3)$$

with $\theta = (\eta, W)$ which we reparametrize from now on with $\theta = (\eta, \Pi)$. If A does not contain S , then $p(x_A)$ is obtained by marginalizing $x_{S \setminus A}$ out in $p(x_{A \cup S})$.

4.4.3 Existence of the process on a real graph

The existence of the process on a real graph is again proven using Kolmogorov's theorem:

Proposition 4. *There exists a stochastic process $(X_a)_{a \in \mathcal{G}}$ defined at all points of the real graph \mathcal{G} with log-marginals on any set of nodes A containing the junction nodes given by Eq. (4.3).*

Proof. Let A and B be two subsets of nodes on the real graph \mathcal{G} , for which the distributions x_A and x_B are obtained

by marginalizing S out of $x_{A \cup S}$ and $x_{B \cup S}$ in Eq. (4.3). We note that a node on an edge is conditionally independent of any node on a different edge given x_S . Proposition 2 tells us that the marginals are consistent on each edge with fixed endpoints, from which we can deduce that the definition of the process on $A \cup S$ and $B \cup S$ provided in Eq. (4.3) is consistent since it is obtained by marginalization of the joint distribution at the nodes $A \cup B \cup S$. The process being consistent on A and $A \cup S$ by definition of $p(x_A)$, and similarly on B and $B \cup S$, we have proved Kolmogorov consistency between A and B which in turn proves the existence of the process on the real graph. \square

We will refer to the obtained process, illustrated on Figure 4.2, as a continuous graph Potts model or continuous graph Markov random field (CGMRF).

5 INFERENCE

Probabilistic inference is an operation which is key to learning and making predictions in graphical models. In the case of our continuous graph \mathcal{G} , if we consider any segment $[a, b]$ with $a, b \in S$ and any $a', b' \in [a, b]$, it should be noted that $p(x_{\{a, a', b', b\}}) = p(x_{\{a', b'\}} | x_{\{a, b\}}) p(x_{\{a, b\}})$ where $p(x_{\{a, b\}})$ is computed as a clique marginal of $p(x_S)$, and $p(x_{\{a', b'\}} | x_{\{a, b\}})$ has a simple analytical expression given that reduces to the model on the segment. This implies that marginal distributions on any finite collection of nodes on the same edge can be computed efficiently provided the edge marginals of the induced model on S can be computed efficiently. In spite of the fact that the graph has uncountably many nodes, inference can thus be performed by any classical inference algorithm, i.e. the sum-product algorithm if the graph is a tree and typically approximate inference techniques otherwise, such as loopy belief propagation.

6 LEARNING

In this section, we focus on learning the model from data. Since the process values are only observed at a finite number of points, we are somehow always in the situation where some nodes are unobserved. However, when all junction nodes are observed the joint likelihood of a given set of nodes has the closed form expression of Eq. (4.3). Since this a curved exponential family, the log-likelihood is in general not a concave function of the parameters⁴.

To avoid having to cope with positivity constraints, and given the rapid divergence of the likelihood on the boundary of the domain we parameterize the likelihood by η and the entrywise logarithm of Π , since given the remark following lemma 1, it possible to take Π positive entrywise.

⁴It is however clearly concave when all edges are of the same length, because the constraint of equality of the parameters for all potentials is a convex constraint.

For the CTMC directed tree, Holmes and Rubin (2002) consider the likelihood of the entire process, show that it has a canonical exponential family form with a small number of sufficient statistics and derive an EM algorithm based on this representation to learn the parameters. A similar exponential family form can be obtained for our process, with also a small number of sufficient statistics and in theory it is possible to construct a similar EM algorithm. Unfortunately, in our case the M-step of the algorithm would still require solving a convex optimization problem whose solution is not closed form. We therefore do not pursue further this approach or detail the corresponding canonical exponential family form of the process. We propose instead to optimize the likelihood using a gradient based method. We show that the gradient can be computed from the moments obtained by performing the probabilistic inference on the model in different settings. In the next sections (sections 6.1 - 6.4), we derive the form of the gradient of the likelihood, first when all junction nodes are observed, then, when any set of nodes is observed, and finally, when some nodes are observed and another (typically larger) set of nodes emits observed vectors of features that are each conditionally independent given the state of associated node, as in a hidden Markov random field setting. Since computing the inference is typically intractable in graphs, we introduce a variational approximation in 6.5 that allows for faster (linear) computation. The proofs of lemmas and propositions presented can be found in the appendix.

6.1 Gradient of the likelihood on a segment

Given that the model is parameterized by exponentials of Π , the gradients involve the differential of the matrix exponential. We will therefore repeatedly use the function $\psi_{l, \Pi}$ with $\psi_{l, \Pi}(X) = P^\top ((PXP^\top) \odot \Gamma_{l, \Pi}) P$, where $\Pi = P \text{Diag}(\sigma) P^\top$ is the eigenvalue decomposition of Π and

$$[\Gamma_{l, \Pi}]_{i, j} = \begin{cases} \frac{\exp(l\sigma_i) - \exp(l\sigma_j)}{\sigma_i - \sigma_j} & \text{if } \sigma_i \neq \sigma_j \\ l \exp(l\sigma_j) & \text{if } \sigma_i = \sigma_j. \end{cases}$$

The function ψ is such that the gradient of $x^\top \exp(l\Pi) y$ is $\psi_{l, \Pi}(xy^\top)$. It is essentially switching to the spectral space of Π , where the gradient has a simple multiplicative form given by Γ and then maps the result back to the original space. With this function, we thus have

Lemma 5. *The gradient with respect to variable Π of the log-likelihood ℓ of x_a and x_b on a segment of length l whose end points are a and b can be written as*

$$\nabla_{\Pi} \ell(x_a, x_b; \theta) = \psi_{l, \Pi}((x_a x_b^\top - \mathbb{E}[X_a X_b^\top]) \odot W^l).$$

6.2 Gradient of the likelihood in a real graph

We now compute the gradient of the log-likelihood for the joint distribution of the nodes $(x_a)_{a \in A}$, with the subset A

containing the junction nodes S . We still denote $G_A = (A, E_A)$ the *induced discrete graph* of A on \mathcal{G} . And since Π is identical for every edge, a direct application of the chain rule implies that:

Proposition 6. *The gradient of the likelihoods are computed⁵ as*

$$\begin{aligned}\nabla_{\Pi} \ell(x_A; \theta) &= \sum_{(a,b) \in E_A} \psi_{d_{ab}, \Pi}((x_a x_b^T - \mu_{ab}) \circledast W^{d_{ab}}) \\ \nabla_{\eta} \ell(x_A; \theta) &= \sum_{a \in A} (x_a - \mu_a) - \frac{1}{2} \sum_{(a,b) \in E_A} (x_a - \mu_a + x_b - \mu_b).\end{aligned}$$

with $\mu_a = \mathbb{E}[X_a]$ and $\mu_{ab} = \mathbb{E}[X_a X_b^T]$.

6.3 Partially observed junction nodes

To learn from partially labelled data it is necessary to consider the likelihood of X_B for B a set of nodes that does not necessarily contain S . Let B be a set of observed nodes, i.e. for which we know the states x_B , and A a set of unobserved nodes containing $S \setminus B$. We have the following distributions

$$\begin{aligned}\ell(x_{A \cup B}; \theta) &= \sum_{a \in A \cup B} \eta^T x_a + \sum_{(a,b) \in E_{A \cup B}} x_a^T \Lambda(\theta, d_{ab}) x_b - A_{A \cup B}(\theta) \\ \ell(x_A | x_B; \theta) &= \sum_{a \in A \cup B} \eta^T x_a + \sum_{(a,b) \in E_{A \cup B}} x_a^T \Lambda(\theta, d_{ab}) x_b - A_{A|B}(\theta, x_B)\end{aligned}$$

We can rewrite the log-likelihood as follows (Wainwright and Jordan, 2008) :

$$\ell(x_B; \theta) = A_{A|B}(\Pi, h, x_B) - A_{A \cup B}(\Pi, h),$$

and its gradient are therefore computed as

Proposition 7.

$$\begin{aligned}\nabla_{\Pi} \ell(x_B; \theta) &= \sum_{(a,b) \in E_{A \cup B}} \psi_{d_{ab}, \Pi}((\mu_{ab|B} - \mu_{ab}) \circledast W^{d_{ab}}) \\ \nabla_{\eta} \ell(x_B; \theta) &= \sum_{a \in A \cup B} \mu_{a|B} - \mu_a \\ &\quad - \frac{1}{2} \sum_{(a,b) \in E_{A \cup B}} (\mu_{a|B} - \mu_a + \mu_{b|B} - \mu_b).\end{aligned}$$

with $\mu_{ab|B} = \mathbb{E}[X_a X_b^T | X_B = x_B]$, $\mu_{a|B} = \mathbb{E}[X_a | X_B = x_B]$.

6.4 Hidden Markov model

We consider a hidden Markov random field variant of our model in which some nodes have, in addition to the state variable, a feature vector with a state specific distribution. More precisely, we envision to learn from data on a graph in which the states of a set of nodes B are observed and in

⁵Note that a single spectral decomposition of Π allows to compute $W^{d_{ab}}$ efficiently for all pairs (a, b) .

which each node in a set A (with $A \cap B \neq \emptyset$) provides an observed feature vectors y_a which is conditionally independent of the rest of the graph given the corresponding node state x_a . For simplicity, we assume that $S \subset A \cup B$.

The joint and conditional distribution of observed and unobserved variables are very similar as above

$$\begin{aligned}\ell(x_{A \cup B}, y_A; \theta, \kappa) &= \sum_{a \in A \cup B} \eta^T x_a + \sum_{a \in A} \log(p(y_a | x_a; \kappa)) \\ &\quad + \sum_{(a,b) \in E_{A \cup B}} x_a^T \Lambda(\theta, d_{ab}) x_b - A_{A \cup B}(\theta, \kappa) \\ \ell(x_A | y_A, x_B; \theta, \kappa) &= \sum_{a \in A \cup B} \eta^T x_a + \sum_{a \in A} \log(p(y_a | x_a; \kappa)) \\ &\quad + \sum_{(a,b) \in E_{A \cup B}} x_a^T \Lambda(\theta, d_{ab}) x_b - A_{A|B}(\theta, \kappa, x_B, y_A),\end{aligned}$$

which allows us to rewrite the likelihood of observations as $\ell(x_B, y_A) = A_{A|B}(\theta, \kappa, y_A, x_B) - A_{A \cup B}(\theta, \kappa)$.

Given that the model for $p(y_a | x_a)$ is Gaussian or at least an exponential family, when envisioning an EM algorithm to learn κ and θ , it is easy to see that the update for κ is closed form while that of θ is not. This motivates a variant of the EM algorithm which does not attempt to maximize with respect to both κ and θ simultaneously but which either maximizes the expected likelihood with respect to κ or maximizes it with respect to θ . The algorithm can then be summarized as an E-M1-E-M2 algorithm, where the E-step is the usual computation of expected sufficient statistics given current parameters, M1 solves for κ in closed form and M2 maximizes with respect to θ using gradient ascent⁶.

6.5 Variational approximation

For graphs with cycles, since inference is intractable, we replace the likelihood by a pseudo-likelihood obtained using a variational approximation of the log-partition. Our variational approximation is the one associated with the entropy of Bethe (see, e.g. section 4.1 in Wainwright and Jordan, 2008), but other choices would be possible. The main motivation behind this approximation is that the exact gradient of this pseudo-likelihood is directly obtained from the pseudo-moments given by loopy BP. In practice, damping needs to be used (see Wainwright and Jordan, 2008, chap. 7).

In term of complexity, the parametrization of CGMRF could suggest that inference is slower than in the discrete setting since the computation of the SVD of Π is required. However, since the number of states is typically much smaller than the number of nodes in the graph, the computational cost of the SVD is negligible compared to

⁶Note that gradient ascent itself requires to perform some inference to recompute the log-partition function

the overall cost of the algorithm. Hence, inference in the CGMRF is just as hard as for any discrete MRF.

The log-likelihood is a curved exponential family and is in particular not a convex function of the parameters, while it is convex for a standard MRF. As a consequence the pseudo log-likelihood based on the variational approximation is also non-convex. We use gradient descent with a line-search based on the Wolfe conditions to find a local minimum (see Nocedal and Wright, 1999, chap. 3). Empirically the algorithm is not trapped in bad local minima but takes more iterations to converge than the MRF counterpart. Experiments showed that the training for CGMRFs was only two times longer than for regular MRFs.

7 DISCUSSION

In this section, we discuss more precisely features of CGMRFs that are unique or common with other models and approaches existing in the literature.

First, we note that for a tree, our model is not equivalent to that of Holmes and Rubin (2002). Their model uses a constant rate matrix (i.e. the Markov process is homogeneous) while we use constant infinitesimal potentials, which do not lead to a constant rate matrix on any orientation of the tree. If the tree is just the segment $[0, L]$, for s and t with $0 < s < t < L$ a CTMC is such that $p(x_t|x_s)$ only depends on $t - s$ and not on L . By contrast for our model $\log p(x_t|x_s)$ depends also on $L - t$ and $L - s$ since $\log p(x_t|x_s) = x_s^T \Lambda (t-s) x_t + x_t^T \eta + x_t^T \Lambda (L-t) \mathbf{1} - x_s^T \Lambda (L-s) \mathbf{1}$, where for simplicity we omitted the dependance in θ , and $\mathbf{1}$ is the constant vector equal to 1. See the appendix for an illustration and further discussion of the differences between the models.

Our model has in common with graph partitioning techniques and spectral clustering (SC) that the distance between nodes are taken into account. But there are several important differences: first, in SC, there is no model learning in the sense that no parameters are learned to optimize the model (Bach and Jordan (2006) who learn the metric for SC, are an exception). Second, our model captures that there could be different transition probabilities between different classes along the graph which is not possible in SC. Then, the main assumption in SC is that classes are separated by edges of smaller weights so that each class is as disconnected as possible. By contrast, our model authorizes (to some extent) transitions between classes on short edges and moreover permits that each class corresponds to several connected components. Our models extends naturally to a hidden Markov model that makes it possible to include feature vectors for some nodes and not for others, which is not possible with SC techniques.

Another graph-based approach to classification which is perhaps more related to ours is the work of Zhu et al. (2003) on binary classification with harmonic functions. Indeed,

the Gaussian field considered there is similar to the Potts model we obtain on the junction nodes. The approach of Zhu et al. (2003) is however just concerned by inference and not by learning, but their approach could be extended both to multi-class classification and to perform learning of the parameters.

8 EXPERIMENTS

We present in this section experiments on real data. Synthetic experiments on the core model of the CGMRF (without hidden layer) can be found in section 6 of the appendix.

In geographic information systems, data is often aggregated either on regular grid or on cells corresponding to abstract administrative boundaries, which do not necessarily reflect the structure of a city. A fairly natural type of representation for urban environment is based on graphs and in particular weighted graphs which can encode a distance information.

We consider a problem from geomatics in which this type of representation could be beneficial and which consists in predicting building use in urban and peri-urban environments from a few annotations and simple building shape characteristics that can be extracted easily from aerial images. More precisely, we consider the transductive learning problem of assigning city blocks to one category from $\{\textit{individual housing, collective housing, industrial/commercial area}\}$.

8.1 Building the city block continuous graph

A city can be divided into city blocks using its layout and road network as in Figure 8.1. Assuming that the blocks are given, we compute the Voronoi diagram of the block centroids and link together blocks with adjacent Voronoi cells. Edges are annotated with a proximity measure, in our case the distance between their respective closest buildings. This provides a continuous graph encapsulating the structure of the city. Each block is then annotated into one of three categories : individual residential, collective residential and industrial/commercial area. The blocks are annotated by hand using cadastral information, business registration codes, and resorting to Google street view images for ambiguous blocks (see Figure 8.1).

8.2 Data descriptors and learning setting

A block is then described by the weighted average of characteristics of the buildings it contains, each building counting with a weight proportional to its volume. We tested 10 different building descriptors, found that floor area and height were the most discriminative, and that adding more descriptors actually decreases the performance of all tested algorithms.

We use the example of Sevrans, a French city of 50 000 inhabitants north of Paris. We divided it into 461 blocks,

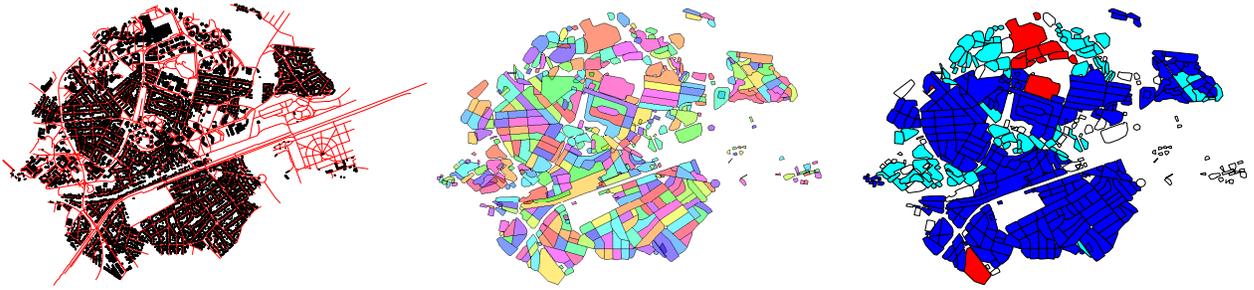

Figure 8.1: (left) Buildings and road network of Sevran. (middle) Division into city blocks. (right) City blocks with annotations. Blue: individual housing, cyan: collective housing, red: industrial/commercial area. (Best seen in color.)

400 of which can clearly be assigned one of three labels mentioned above and the rest being of insignificant size, ambiguous, or corresponding to other categories such as schools or hospitals.

We consider the transductive learning problem of predicting all block labels from a subset of labelled blocks. In our experiments, 7% of annotated labels, corresponding to 28 blocks, are used for training and the remaining are used for testing.

8.3 Competing algorithms

As baselines we consider two algorithms that do not take into account spatial information: a generative Gaussian mixture model and a logistic regression trained each using the 7% revealed labels. We also consider classical hidden MRFs, which cannot take into account the distance, and whose graph is either the same as for the CGMRF or a pruned graph in which all edges longer than a threshold (corresponding to the average city block radius) have been removed. The different graphs are illustrated on Figure 8.2. Note that the Gaussian mixture model does not take the graph structure into account, and can be interpreted as an edgeless MRF

In all Markov models, we use Gaussian emissions to model the distribution of the building descriptors given the block label, which can conveniently be optimized in closed form. To train the CGMRF and MRF models we learn the parameter θ with the maximum likelihood principle following the approach presented in section 6.5.

8.4 Results analysis

For each model, we construct a precision-coverage curve, obtained by sorting the probabilistic predictions by increasing values of their entropies, and reported on Figure 8.3. The confidence bands represented corresponds to one standard error for the estimation of the mean precision.

We can see that enriching the simple Gaussian mixture model by adding a graph structure significantly improves the overall performance. Building a MRF using all the edges from the Voronoi proximity or only retaining a fraction of the shorter edges yields similar results, on par with logistic regression. Building a CMRF using the edges annotated with a distance measure leads to a performance which is significantly above all others based on estimated standard errors.

When making prediction for all unlabeled points from the 7% of revealed annotations, the different algorithms yield the following average precisions (over the 300 resamplings): for the Gaussian mixture model 88.0%, for logistic regression 92.5%, the full MRF 92.4%, the pruned MRF 91.6% and our CGMRF 94.0%. Both pruned MRF and full MRF outperform the simple Gaussian mixture model, but not logistic regression, even though their precision at intermediate coverage is higher. The misclassification error of the CGMRF is 20% smaller than that of logistic regression, 21.5% smaller than for the best MRF model, and 50.2% smaller than for the Gaussian mixture. The gain in precision is not only obtained in average since the misclassification error in the CMRF was lower than MRF and logistic regression in respectively 193 and 293 out of 300 experiments. Wilcoxon signed rank tests assigns respectively p-values of $7 \cdot 10^{-26}$ and $3 \cdot 10^{-24}$ to the common median hypothesis.

In this experiment, with 461 nodes and 2718 edges the inference takes less than 0.1s on a CPU at 3.3GHz. Learning requires usually around 50 calls to the inference step for the MRF (5s total), while it is closer to 100 for the CGMRF (10s total).

8.5 Transfer learning on another city

We now consider the problem of predicting block labels on a new unannotated city using partial annotation from a given city. More precisely, we train our model with 15% of revealed labels from Sevran, and consider several

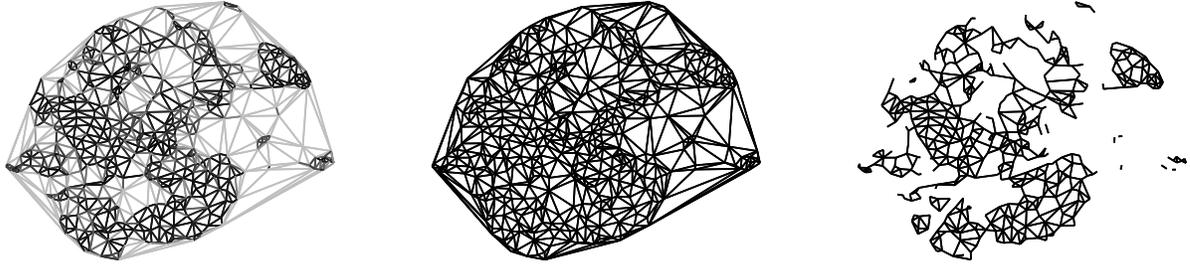

Figure 8.2: (left) continuous graph used to train the HCGMRF, the darker the edge the shorter the annotated distance, (middle) graph used for the HMRF including all edges or (right) with only edges shorter than a threshold.

schemes to make predictions on the neighboring urban area formed by Pierrefitte-sur-Seine together with Stains, for a total of 63000 inhabitants and 583 blocks, for which both graph and features are available but no labels are revealed. We consider logistic regression and the Gaussian mixture model trained from the annotated blocks from Sevran as baselines, and test for each of the CGMRF and MRF the models learnt as follows:

- θ and κ are learnt on data from Sevran
- idem followed by a single EM-step on κ alone (E-M2) on the graph of Pierrefitte+Stains
- idem followed by an EM-step on θ (E-M1) and then an EM-step on κ (E-M2).

We use the 359 labelled blocks (out of 583) of the Pierrefitte/Stains conglomeration as a testing set and construct the precision-coverage curves reported on Figure 8.4 (see the appendix for a figure comparing more approaches). We observe that the CGMRF setting is superior to its competitors, and that the relearning step improves the performance. The MRFs does not perform as well, which can be explained by the initial prediction being inferior, and relearning degrades its performance. The setting where only one E-M2 step is performed yields in both cases results comprised between the two other settings.

9 CONCLUSION

In this paper, we constructed a Potts model over a continuous graph and showed how to compute the likelihood of several of its variants as well as the corresponding gradients, for the purpose of learning.

Our experiments on a problem from geomatics show that this model outperforms regular MRFs, and compares favorably with logistic regression which although discriminative does not leverage unlabelled data. Finally, we showed that the model can be used to perform transfer learning from a first partially labelled graph towards a new completely unlabelled graph.

Efficient Inference of Gaussian-Process-Modulated Renewal Processes with Application to Medical Event Data

Thomas A. Lasko

Computational Medicine Laboratory, Department of Biomedical Informatics
Vanderbilt University School of Medicine
Nashville, TN 37203

Abstract

The episodic, irregular and asynchronous nature of medical data render them difficult substrates for standard machine learning algorithms. We would like to abstract away this difficulty for the class of time-stamped categorical variables (or *events*) by modeling them as a renewal process and inferring a probability density over non-parametric longitudinal intensity functions that modulate the process. Several methods exist for inferring such a density over intensity functions, but either their constraints prevent their use with our potentially bursty event streams, or their time complexity renders their use intractable on our long-duration observations of high-resolution events, or both. In this paper we present a new efficient and flexible inference method that uses direct numeric integration and smooth interpolation over Gaussian processes. We demonstrate that our direct method is up to twice as accurate and two orders of magnitude more efficient than the best existing method (thinning). Importantly, our direct method can infer intensity functions over the full range of bursty to memoryless to regular events, which thinning and many other methods cannot do. Finally, we apply the method to clinical event data and demonstrate a simple example application facilitated by the abstraction.

1 INTRODUCTION

One of the hurdles for identifying clinically meaningful patterns in medical data is the fact that much of that data is sparsely, irregularly, and asynchronously observed, rendering it a poor substrate for many pattern recognition algorithms.

A large class of this problematic data in medical records is time-stamped categorical data such as billing codes.

For example, an ICD-9 billing code with categorical label 714.0 (Rheumatoid Arthritis) gets attached to a patient record every time the patient makes contact with the health-care system for a problem or activity related to her arthritis. The activity could be an outpatient doctor visit, a laboratory test, a physical therapy visit, a discharge from an inpatient stay, or any other billable event. These events occur at times that are generally asynchronous with events for other conditions.

We would like to learn things from the patterns of these clinical contact events both within and between diseases, but their often sparse and irregular nature makes it difficult to apply standard learning algorithms to them. To abstract away this problem, we consider the data as streams of events, one stream per code or other categorical label. We model each stream as a modulated renewal process and use the process's modulation function as the abstract representation of the label's activity. The modulation function provides continuous longitudinal information about the intensity of the patient's contact with the healthcare system for a particular problem at any point in time. Our goal is to infer these functions, the renewal-process parameters, and the appropriate uncertainties from the raw event data.

We have previously demonstrated the practical utility of using a continuous function density to couple standard learning algorithms to sparse and irregularly observed continuous variables (Lasko et al., 2013). Unfortunately, the method of inferring such densities for continuous variables is not applicable to categorical variables. This paper presents a method that achieves the inference for categorical variables.

Our method models the log intensity functions nonparametrically as Gaussian processes, and uses Markov Chain Monte Carlo (MCMC) to infer a posterior distribution over intensity functions and model parameters given the events (Section 2).

There are several existing approaches to making this inference (Section 3), but all of the approaches we found have either flexibility or scalability problems with our clinical

data. For example, clinical event streams can be bursty, and some existing methods are unable to adapt to or adequately represent bursty event patterns.

In this paper we demonstrate using synthetic data that our approach is up to twice as accurate, up to two orders of magnitude more efficient, and more flexible than the best existing method (Section 4.1). We also demonstrate our method using synthetic data that mimics our clinical data, under conditions that no existing method that we know of is able to satisfactorily operate (Section 4.1). Finally, we use our method to infer continuous abstractions over real clinical data (Section 4.2), and as a simple application example we infer latent compound diseases from a complex patient record that closely correspond to its documented clinical problems.

2 MODULATED RENEWAL PROCESS EVENT MODEL

A renewal process models random events by assuming that the interevent intervals are independent and identically distributed (iid). A modulated renewal process model drops the iid assumption and adds a longitudinal intensity function that modulates the expected event rate with respect to time.

We consider a set of event times $T = \{t_0, t_1, \dots, t_n\}$ to form an event stream that can be modeled by a modulated renewal process. For this work we choose a modulated gamma process (Berman, 1981), which models the times T as

$$\mathbf{P}(T; a, \lambda(t)) = \frac{1}{\Gamma(a)^n} \prod_{i=1}^n \lambda(t_i) (\Lambda(t_i) - \Lambda(t_{i-1}))^{a-1} e^{-\Lambda(t_n)}, \quad (1)$$

where $\Gamma(\cdot)$ is the gamma function, $a > 0$ is the shape parameter, $\lambda(t) > 0$ is the modulating intensity function, and $\Lambda(t) = \int_0^t \lambda(u) du$.

Equation (1) is a generalization of the *homogeneous* gamma process $\gamma(a, b)$, which models the interevent intervals $x_i = t_i - t_{i-1}$, $i = 1 \dots n$ as positive iid random variables:

$$\gamma(x|a, b) = \mathbf{P}(x; a, b) = \frac{1}{\Gamma(a)b^a} x^{a-1} e^{-x/b}, \quad (2)$$

where b takes the place of a now-constant $1/\lambda(t)$, and can be thought of as the time scale of event arrivals.

The intuition behind (1) is that the function $\Lambda(t)$ warps the event times t_i into a new space where their interevent intervals become draws from the homogeneous gamma process of (2). That is, the warped intervals $w_i = \Lambda(t_i) - \Lambda(t_{i-1})$ are modeled by $w_i \sim \gamma(a, b)$.

For our purposes, a gamma process is better than the simpler and more common Poisson process because a gamma process allows us to model the relationship between neighboring events, instead of assuming them to be independent or memoryless. Specifically, parameterizing $a < 1$ models a bursty process, $a > 1$ models a more regular or refractory process, and $a = 1$ produces the memoryless Poisson process. Clinical event streams can behave anywhere from highly bursty to highly regular.

We model the log intensity function $\log \lambda(t) = f(t) \sim \mathcal{GP}(0, C)$ as a draw from a Gaussian process prior with zero mean and the squared exponential covariance function

$$C(t_i, t_j) = \sigma e^{-\left(\frac{t_i - t_j}{l}\right)^2}, \quad (3)$$

where σ sets the magnitude scale and l sets the time scale of the Gaussian process. We choose the squared exponential because of its smoothness guarantees that are relied upon by our inference algorithm, but other covariance functions could be used.

In our application the observation period generally starts at $t_{\min} < t_0$, and ends at $t_{\max} > t_n$, and no events occur at these endpoints. Consequently, we must add terms to (1) to account for these partially observed intervals. For efficiency in inference, we estimate the probabilities of these intervals by assuming that w_0 and w_{n+1} are drawn from a homogeneous $\gamma(1, 1)$ process in the warped space. The probability of the leading interval $w_0 = \Lambda(t_0) - \Lambda(t_{\min})$ is then approximated by $\mathbf{P}(w \geq w_0) = \int_{w_0}^{\infty} e^{-w} dw = e^{-w_0}$, which is equivalent to $w_0 \sim \gamma(1, 1)$. The trailing interval is treated similarly.

Our full generative model is as follows:

1. $l \sim \text{Exponential}(\alpha)$
 $\log \sigma \sim \text{Uniform}(\log \sigma_{\min}, \log \sigma_{\max})$
 $\log a \sim \text{Uniform}(\log a_{\min}, \log a_{\max})$
 $b = 1$
2. $f(t) \sim \mathcal{GP}(0, C)$ using (3)
3. $\lambda(t) = e^{f(t)}$
4. $\Lambda(t) = \int_0^t \lambda(u) du$
5. $w_0 \sim \gamma(1, 1)$; $w_{i>0} \sim \gamma(a, b)$
6. $t_i = t_{\min} + \Lambda^{-1}(\sum_{j=0}^i w_j)$

Step 1 places a prior on l that prefers smaller values, and uninformative priors on a and σ . We set $b = 1$ to avoid an identifiability problem. (Rao and Teh (2011) set $b = 1/a$ to avoid this problem. While that setting has some desirable properties, we've found that setting $b = 1$ avoids more degenerate solutions at inference time.)

2.1 INFERENCE

Given a set of event times T , we use MCMC to simultaneously infer posterior distributions over the intensity func-

tion $\lambda(T)$ and the parameters a , σ , and l (Algorithm 1). For simplicity we denote $g(T) = \{g(t) : t \in T\}$ for any function g that operates on event times. On each round we first use slice sampling with surrogate data (Murray and Adams, 2010, code publicly available) to compute new draws of $f(t)$, σ , and l using (1) as the likelihood function (with additional factors for the incomplete interval at each end). We then sample the gamma shape parameter a using Metropolis-Hastings updates.

One challenge of this direct inference is that it requires integrating $\Lambda(t) = \int_0^t \lambda(u) du$, which is difficult because $\lambda(t)$ does not have an explicit expression. Under certain conditions, the integral of a Gaussian process has a closed form (Rasmussen and Ghahramani, 2003), but we know of no closed form for the integral of a log Gaussian process. Instead, we compute the integral numerically (the trapezoidal rule works fine), relying on the smoothness guarantees provided by the covariance function (3) to provide high accuracy.

The efficiency bottleneck of the update is the $O(m^3)$ complexity of updating the Gaussian process f at m locations, due to a matrix inversion. Naively, we would compute f at all n of the observed t_i , with additional points as needed for accuracy of the integral. To improve efficiency, we do not directly update f at the t_i , but instead at k uniformly spaced points $\hat{T} = \{\hat{t}_j = t_{\min} + jd\}$, where $d = \frac{t_{\max} - t_{\min}}{k-1}$. We then interpolate the values $f(T)$ from the values of $f(\hat{T})$ as needed. We set the number of points k by the accuracy required for the integral. This is driven by our estimate of the smallest likely Gaussian process time scale l_{\min} , at which point we truncate the prior on l to guarantee $d \ll l_{\min} \leq l$. The efficiency of the resulting update is $O(k^3) + O(n)$, with k depending only on the ratio $l_{\min}/(t_{\max} - t_{\min})$.

It helps that the factor driving k is the time scale of changes in the intensity function $\lambda(t)$ instead of the time scale of interevent intervals, which is usually much smaller. In practice, we’ve found $k = 200$ to work well for nearly all of our medical data examples, regardless of the observation time span, resulting in an update that is linear in the number of observed points.

Additionally, the regular spacing in \hat{T} means that its covariance matrix generated by (3) is a symmetric positive definite Toeplitz matrix, which can be inverted or solved in a compact representation as fast as $O(k \log^2 k)$ (Martinson et al., 2005). We did not include this extra efficiency in our implementation, however.

3 RELATED WORK

There is a growing literature on finding patterns among clinical variables such as laboratory tests that have both a timestamp and a numeric value (Lasko et al., 2013), but we are not aware of any existing work exploring unsuper-

Algorithm 1 Intensity Function and Parameter Update

Input: Event times T , regular grid \hat{T} , current function f and parameters σ , l , and a

Output: Updated f , λ , Λ , σ , l , and a with likelihood p

- 1: Update $f(\hat{T})$, σ , l , using slice sampling
 - 2: Compute $f(T)$ by smooth interpolation of $f(\hat{T})$
 - 3: $\lambda(T \cup \hat{T}) \leftarrow e^{f(T \cup \hat{T})}$
 - 4: Compute $\Lambda(T)$ from $\lambda(\hat{T})$ numerically
 - 5: Compute $p = P(T; a, \lambda(T))$ using (1)
 - 6: Update a and p with Metropolis-Hastings and (1)
-

vised, data-driven abstractions of categorical clinical event streams that we address here.

There is much prior work on methods similar to ours that infer intensity functions for modulated renewal processes. The main distinction between these methods lies in the way they handle the form and integration of the intensity function $\lambda(t)$. Approaches include using kernel density estimation (Ramlau-Hansen, 1983), using parametric intensity functions (Lewis, 1972), using discretized bins within which the intensity is considered constant (Moller et al., 1998, Cunningham et al., 2008), or using a form of rejection sampling called *thinning* (Adams et al., 2009, Rao and Teh, 2011) that avoids the integration altogether.

The binned time approach is straightforward, but there is inherent information loss in the piecewise-constant intensity approximation that it must adopt. Moreover, when a Gaussian process is used to represent this intensity function, the computational complexity of inference is cubic with the number of bins in the interval of observation. For our data, with events at 1-day or finer time resolution over up to a 15 year observation period, this method is prohibitively inefficient. A variant of the binned-time approach that uses variable-sized bins (Gunawardana et al., 2011, Parikh et al., 2012) has been applied to medical data (Weiss and Page, 2013). This variant is very efficient, but is restricted to a Poisson process (fixed $a = 1$), and the inferred intensity functions are neither intended to nor particularly well suited to form an accurate abstraction over the raw events.

Thinning is a clever method, but it is limited by the requirement of a bounded hazard function, which prevents it from being used with bursty gamma processes. (Bursty gamma processes have a hazard function that is unbounded at zero). One thinning method has also adopted the use of Gaussian processes to modulate gamma processes (Rao and Teh, 2011). But in addition to not working with bursty events, it also rather inefficient; its time complexity is cubic in the number of events that would occur if the maximum event intensity were constant over the entire observation time span. For event streams with a small dynamic range of intensities, this is not a big issue, but our medical data

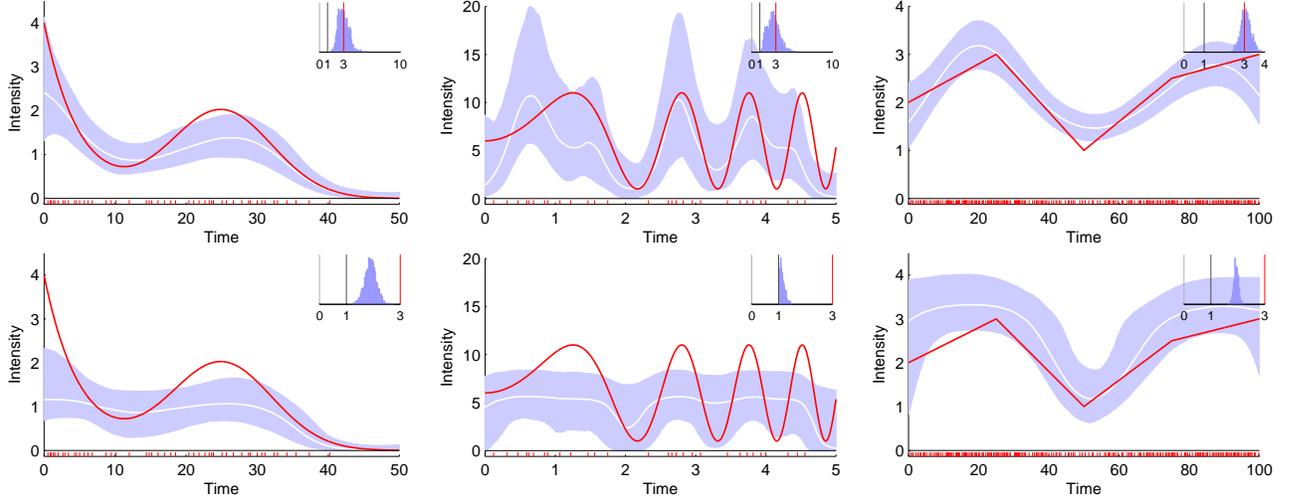

Figure 1: Our direct method (top) is more accurate than thinning (bottom) on parametric intensity functions λ_1 to λ_3 (left to right). Red line: true normalized intensity function $\lambda(t)/a$; White line: mean inferred normalized intensity function; Blue region: 95% confidence interval. Inset: inferred distribution of the gamma shape parameter a , with the true value marked in red. Grey bar at $a = 1$ for reference.

sequences can have a dynamic range of several orders of magnitude.

Our method therefore has efficiency and flexibility advantages over existing methods, and we will demonstrate in the experiments that it also has accuracy advantages.

4 EXPERIMENTS

In these experiments, we will refer to our inference method as the *direct method* because it uses direct numerical integration. A full implementation of our method and code to reproduce the results on the synthetic data is available at <https://github.com/ComputationalMedicineLab/egpmrp>.

We tested the ability of the direct method and the thinning method to recover known intensity functions and shape parameters from synthetic data. We then used the direct method to extract latent intensity functions from streams of clinical events, and we inferred latent compound conditions from the intensity functions for a complex patient record that accurately correspond to the dominant diseases documented in the record.

4.1 SYNTHETIC DATA

Our first experiments were with the three parametric intensity functions below, carefully following Adams et al. (2009) and Rao and Teh (2011). We generated all data using the warping model described in Section 2, with shape parameter $a = 3$.

1. $\lambda_1(t)/a = 2e^{-t/15} + e^{-((t-25)/10)^2}$ over the interval

$[0, 50]$, 48 events.

2. $\lambda_2(t)/a = 5 \sin(t^2) + 6$ on $[0, 5]$, 29 events.

3. $\lambda_3(t)/a$ is the piecewise linear curve shown in Figure 1, on the interval $[0, 100]$, 230 events.

We express these as normalized intensities $\lambda(t)/a$, which have units of “expected number of events per unit time”, because they are more interpretable than the raw intensities and they are comparable to the previous work done using Poisson processes, where $a = 1$.

We compared the direct method to thinning on these datasets, using the MATLAB implementation for thinning that was used by Rao and Teh (2011). Adams et al. (2009) compared thinning to the kernel smoothing and binned time methods (all assuming a Poisson process), and Rao and Teh (2011) compared thinning to binned time, assuming a gamma process with constrained $a > 1$. Both found thinning to be at least as accurate as the other methods in most tests.

We computed the RMS error of the true vs. the median normalized inferred intensity, the log probability of the data given the model, and the inference run time under 1000 burn-in and 5000 inference MCMC iterations.

On these datasets the direct method was more accurate than thinning for the recovery of both the intensity function and the shape parameter, and more efficient by up to two orders of magnitude (Figure 1 and Table 1). The results for thinning are consistent with those previously reported (Rao and Teh, 2011), with the exception that the shape parameter inference was more accurate in the earlier results.

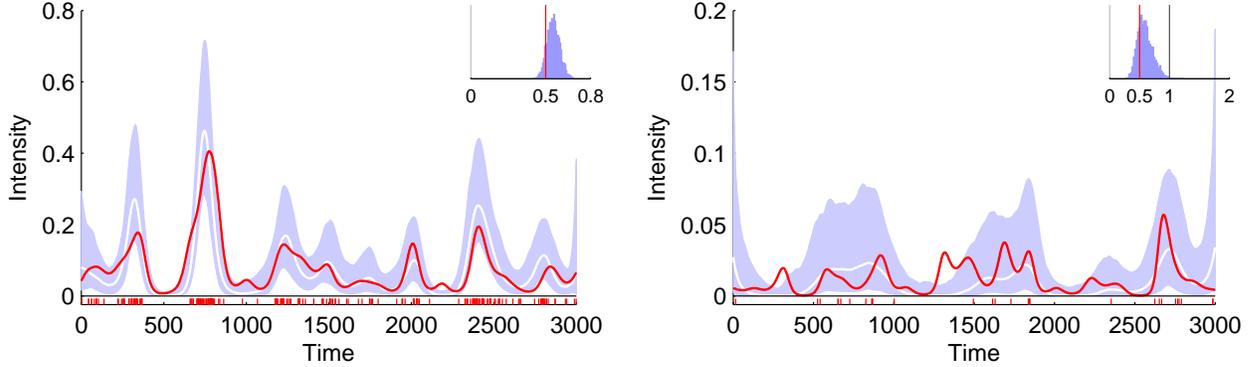

Figure 2: Accurate recovery of intensity function and parameters under conditions that would be prohibitive for any other method of which we are aware. Left panel presents results for high intensities and many events, right panel for low intensities and few events. While there is insufficient evidence in the right panel to recover the true intensity, the inferred intensity is reasonable given the evidence, and the inferred confidence intervals are accurate in that the true intensity is about 95% contained within them. Legend as in Figure 1.

The confidence intervals from the direct method are subjectively more accurate than from the thinning method. (That is, the 95% confidence intervals from the direct method contain the true function for about 95% of its length in each case). This is particularly important in the case of small numbers of events that may not carry sufficient information for any method to resolve a highly varying function.

As might be expected, we found the results for $\lambda_2(t)$ to be sensitive to the prior distribution on l , given the small amount of evidence available for the inference. Following Adams et al. (2009) and Rao and Teh (2011), we used a log-normal prior with a mode near $l = 0.2$, tuned slightly for each method to achieve the best results. We also allowed thinning to use a log-normal prior with appropriate modes for $\lambda_1(t)$ and $\lambda_3(t)$, to follow precedent in the previous work, although it may have conferred a small advantage to thinning. We used the weaker exponential prior on those datasets for the direct method.

Our next experiments were on synthetic data generated to resemble our medical data. We tested several configurations over wide ranges of parameters, including some that were not amenable to any known existing approach (such as the combination of $a < 1$, high dynamic range of in-

tensity, and high ratio of observation period to event resolution, Figure 2). The inferred intensities and gamma parameters were consistently accurate. Estimates of the confidence intervals were also accurate, including in cases with low intensities and few events (Figure 2, right panel).

4.2 CLINICAL DATA

We applied the direct method to sequences of billing codes representing clinical events. After obtaining IRB approval, we extracted all ICD-9 codes from five patient records with the greatest number of such codes in the deidentified mirror of our institution’s Electronic Medical Record. We arranged the codes from each patient record as streams of events grouped at the top (or *chapter*) level of the ICD-9 disease hierarchy (which collects broadly related conditions), as well as at the level of the individual disease.

For the streams of grouped events, we included an event if its associated ICD-9 code fell within the range of the given top-level division. For example, any ICD-9 event with a code in the range [390 – 459.81] was considered a *Cardiovascular* event. While intensity functions are only strictly additive for Poisson processes, we still find the curves of grouped events to be informative.

We inferred intensity functions for each of these event streams (for example, Figure 3). Each curve was generated using 2000 burn-in and 2000 inference iterations in about three minutes using unoptimized MATLAB code on a single desktop CPU. The results have good clinical face validity.

There is much underlying structure in these events that can now be investigated with standard learning methods applied to the inferred intensity functions. As a simple example, singular value decomposition (Strang, 2003) can infer the latent compound conditions (which we might as well

Table 1: Performance on Synthetic Data. RMS: root-mean-squared error; LP: log probability of data given the model; RT: run time in seconds. Best results for each measure are bolded.

	Direct			Thinning		
	RMS	LP	RT	RMS	LP	RT
λ_1	0.37	+12.1	453	0.66	-62.7	4816
λ_2	3.1	-228	511	3.4	-333	1129
λ_3	0.25	+1.21	385	0.53	-82.2	41291

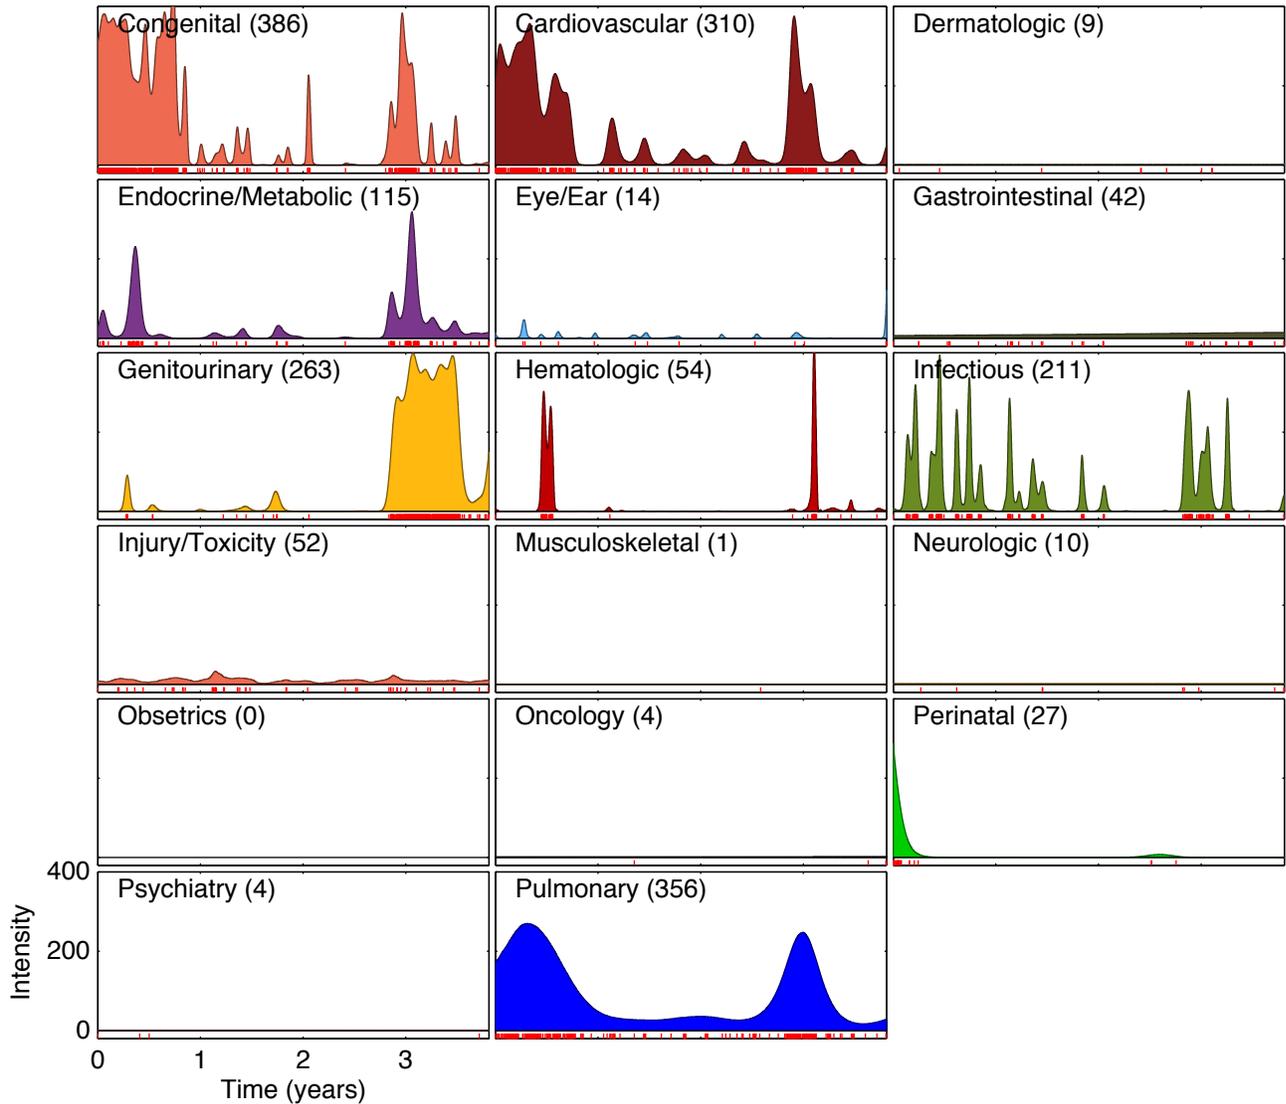

Figure 3: Inferred intensities for all top-level ICD-9 disease divisions of a very complicated patient’s record. Such a display may be clinically useful for getting a quick, broad understanding of a patient’s medical history, including quickly grasping which conditions have *not* been diagnosed or treated. Numbers in parentheses: total number of events in each division. For clarity, confidence intervals are not shown.

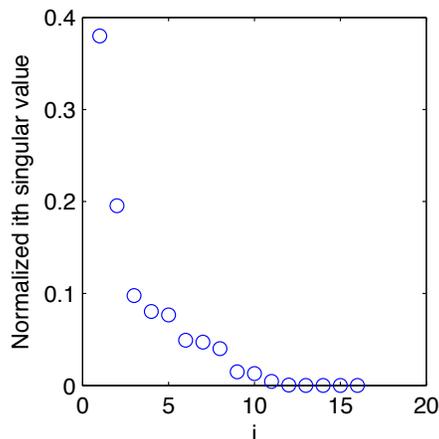

Figure 4: A small number of latent compound conditions (or *eigendiseases*) produce most of the activity captured by the patient record in Figure 3.

call *eigendiseases*) underlying the recorded clinical activity, taking into account the continuously changing, longitudinal time course of that activity. The singular values for the curves in Figure 3 reveal that about 40% of the patient’s activity relates to a single *eigendisease*, and about 70% is distributed among the top three (Figure 4). The inferred *eigendiseases* closely correspond to the dominant clinical problems described in the record (Figure 5).

5 DISCUSSION

We have made two contributions with this paper. First, we presented a direct numeric method to infer a distribution of continuous intensity functions from a set of episodic, irregular, and discrete events. This direct method has increased efficiency, flexibility, and accuracy compared to the best prior method. Second, we presented results using the direct method to infer a continuous function density as an abstraction over episodic clinical events, for the purposes of transforming the raw event data into a form more amenable to standard machine learning algorithms.

The clinical interpretation of these intensity functions is that increased intensity represents increased frequency of contact with the healthcare system, which usually means increased *instability* of that condition. In some cases, it may also mean increased *severity* of the condition, but not always. If a condition acutely increases in severity, this represents an instability and will probably generate a contact event. On the other hand, if a condition is severe but stably so, it may not necessarily require high-frequency medical contact.

The methods described here to represent categorically labeled events in time as continuous curves augment our

previously reported methods to construct similar curves from observations with both a time and a continuous value (Lasko et al., 2013). These two data types represent the majority of the information in a patient record (if we consider words and concepts in narrative text to be categorical variables), and opens up many possibilities for finding meaningful patterns in large medical datasets.

The practical motivation for this work is that once we have the continuous function densities, we can use them as inputs to a learning problem in the time domain (such as identifying trajectories that may be characteristic of a particular disease), or by aligning many such curves in time and looking for useful patterns in their cross-sections (which to our knowledge has not yet been reported). We presented a simple demonstration of inferring cross-sectional latent factors from the intensity curves of a single record. Discovering similar latent factors underlying a large population is a focus of future work.

We discovered incidentally that a presentation such as Figure 3 appears to be a promising representation for efficiently summarizing a complicated patient’s medical history and communicating that broad summary to a clinician. The presentation could allow drilling-down to the intensity plots of the specific component conditions and then to the raw source data. (The usual method of manually paging through the often massive chart of a patient to get this information can be a tedious and frustrating process.)

One could also imagine presenting the curves not of the raw ICD-9 codes, but of the inferred latent factors underlying them, and drilling down into the rich combinations of test results, medications, narrative text, and discrete billing events that comprise those latent factors.

We believe that these methods will facilitate *Computational Phenotype Discovery* (Lasko et al., 2013), or the data-driven search for population-scale clinical patterns in existing electronic medical records that may illuminate previously unknown disease variants, unanticipated medication effects, or emerging syndromes and infectious disease outbreaks.

Abstract

We study a sequential resource allocation problem involving a fixed number of recurring jobs. At each time-step the manager should distribute available resources among the jobs in order to maximise the expected number of completed jobs. Allocating more resources to a given job increases the probability that it completes, but with a cut-off. Specifically, we assume a linear model where the probability increases linearly until it equals one, after which allocating additional resources is wasteful. We assume the difficulty of each job is unknown and present the first algorithm for this problem and prove upper and lower bounds on its regret. Despite its apparent simplicity, the problem has a rich structure: we show that an appropriate optimistic algorithm can improve its learning speed dramatically beyond the results one normally expects for similar problems as the problem becomes resource-laden.

1 INTRODUCTION

Assume that there are K jobs and at each time-step t a learner must distribute the available resources with $M_{k,t} \geq 0$ going to job k , subject to a budget constraint,

$$\sum_{k=1}^K M_{k,t} \leq 1.$$

The probability that the k th job completes in time-step t is $\min\{1, M_{k,t}/\nu_k\}$, where the unknown cut-off parameter $\nu_k \in (0, \infty]$ determines the difficulty of job k . After every time-step the resources are replenished and all jobs are restarted regardless of whether or not they completed successfully in the previous time-step. The goal of the learner

is to maximise the expected number of jobs that successfully complete up to some known time horizon n .

Despite the simple model, the problem is surprisingly rich. Given its information structure, the problem belongs to the class of stochastic partial monitoring problems, which was first studied by [Agrawal et al. \[1989\]](#)¹, where in each time step the learner receives noisy information about a hidden “parameter” while trying to maximise the sum of rewards and both the information received and the rewards depend in a known fashion on the actions and the hidden parameter. While partial monitoring by now is relatively well understood, either in the stochastic or the adversarial framework when the action set is finite [[Bartók et al., 2011](#), [Foster and Rakhlin, 2012](#), [Bartók, 2013](#)], the case of continuous action sets has received only limited attention [[Broder and Rusmevichientong, 2012](#), and references therein]. To illustrate the difficulty of the problem, notice that over-assigning resources to a given job means that the job completes with certainty and provides little information about the job’s difficulty. On the other hand, if resources are under-assigned, then the information received allows one to learn about the payoff associated with all possible arms, which is reminiscent of bandit problems where the arms have “correlated payoffs” (e.g., [Filippi et al. 2010](#), [Russo and Roy 2013](#) and the references therein). Finally, allocating less resources yields high-variance estimates.

Our motivation to study this particular framework comes from the problem of cache allocation. In particular, data collected offline from existing and experimental allocation strategies showed a relatively good fit to the above parametric model. In this problem each job is a computer process, which is successful in a given time-step if there were no cache misses (cache misses are very expensive). Besides this specific resource allocation problem, we also envision other applications, such as load balancing in networked environments, or any other computing applications where some precious resource (bandwidth, radio spectrum, CPU, etc.) is to be subdivided amongst competing processes. In fact, we anticipate numerous extensions and adaptations for

*On sabbatical leave from the Department of Computing Science, University of Alberta, Canada

¹The name was invented later by (perhaps) [[Rustichini, 1999](#)].

specific applications, such as in the case of bandits (see, [Bubeck and Cesa-Bianchi \[2012\]](#) for an overview of this rich literature). Finally, let us point out that although our problem is superficially similar to the so-called budgeted bandit problems (or, budget limited bandit problems), there are some major differences: in budgeted bandits, the information structure is still that of bandit problems and the resources are not replenished. Either learning stops when the budget is exhausted (e.g., [Tran-Thanh et al. 2012](#), [Ding et al. 2013](#), [Badanidiyuru et al. 2013](#))², or performance is measured against the total resources consumed in an ongoing fashion (e.g., [György et al. 2007](#)).

The main contribution besides the introduction of a new problem is a new optimistic algorithm for this problem that is shown to suffer poly-logarithmic regret with respect to optimal omniscient algorithm that knows the parameters $(\nu_k)_k$ in advance. The structure of the bound depends significantly on the problem dynamics, ranging from a (relatively) easy full-information-like setting, corresponding to a resource-laden regime, to a bandit-like setting, corresponding to the resource-scant setting. Again, to contrast this work to previous works, note that the results we obtain for the full-information-like setting are distinct from those possible in the finite action case, where the full-information setting allows one to learn with finite regret [[Agrawal et al., 1989](#)]. On the technical side, we believe that our study and use of weighted estimators in situations where some samples are more informative than others might be of independent interest, too.

Problems of allocating resources to jobs were studied in the community of architecture and operating systems. [Liu et al. \[2004\]](#) build static profile-based allocation of L2-cache banks to different processes using their current miss rate data. [Suh et al. \[2002\]](#) proposed a hit-rate optimisation using hardware counters which used a model-based estimation of hit-rate vs allocated cache. However, they all assume the model is fully known and no learning is required. [Bitirgen et al. \[2008\]](#) used ANNs to predict individual program performance as a function of resources. Finally, [Ipek et al. \[2008\]](#) used reinforcement learning to allocate DRAM to multi-processors.

2 PRELIMINARIES

In each time-step t the learner chooses $M_{k,t} \geq 0$ subject to the constraint, $\sum_{k=1}^K M_{k,t} \leq 1$. Then all jobs are executed and $X_{k,t} \in \{0, 1\}$ indicates the success or failure of job k in time-step t and is sampled from a Bernoulli distribution with parameter $\beta(M_{k,t}/\nu_k) := \min\{1, M_{k,t}/\nu_k\}$. The goal is to maximise the expected number of jobs that successfully complete, $\sum_{k=1}^K \beta(M_{k,t}/\nu_k)$. We define the gaps $\Delta_{j,k} = \nu_j^{-1} - \nu_k^{-1}$. We assume throughout for conve-

²Besides [Badanidiyuru et al. \[2013\]](#), all works consider finite action spaces and unstructured reward functions.

nience, and without loss of generality, that $\nu_1 < \nu_2 < \dots < \nu_K$. It can be shown that the optimal allocation distributes the resources to jobs in increasing order of difficulty.

$$M_k^* = \min \left\{ 1 - \sum_{i=1}^{k-1} M_i^*, \nu_k \right\}.$$

We let ℓ be the number of jobs that are fully allocated under the optimal policy: $\ell = \max\{i : M_i^* = \nu_i\}$. The overflow is denoted by $S^* = M_{\ell+1}^*$, which we assume to vanish if $\ell = K$. The expected reward (number of completed jobs) when following the optimal allocation is

$$\sum_{k=1}^K \frac{M_k^*}{\nu_k} = \ell + \frac{S^*}{\nu_{\ell+1}},$$

where we define $\nu_{K+1} = \infty$ in the case that $\ell = K$. The (expected n -step cumulative) regret of a given allocation algorithm is the difference between the expected number of jobs that complete under the optimal policy and those that complete given the algorithm,

$$\begin{aligned} R_n &= \mathbb{E} \left[\sum_{t=1}^n r_t \right], \quad r_t = \sum_{k=1}^K \beta(M_k^*/\nu_k) - \sum_{k=1}^K \beta(M_{k,t}/\nu_k) \\ &= \left(\ell + \frac{S^*}{\nu_{\ell+1}} \right) - \sum_{k=1}^K \beta(M_{k,t}/\nu_k). \end{aligned}$$

Some proofs are omitted due to space constraints, but may be found in the supplementary material [[Lattimore et al., 2014](#)].

3 OVERVIEW OF ALGORITHM

We take inspiration from the optimal policy for known ν_k , which is to fully allocate the jobs with the smallest ν_k (easiest jobs) and allocate the remainder/overflow to the next easiest job. At each time-step t we replace the unknown ν_k by a high-probability lower bound $\underline{\nu}_{k,t-1} \leq \nu_k$. This corresponds to the optimistic strategy, which assumes that each job is as easy as reasonably possible. The construction of a confidence interval about ν_k is surprisingly delicate. There are two main challenges. First, the function $\beta(M_{k,t}/\nu_k)$ is non-differentiable at $M_{k,t} = \nu_k$, and for $M_{k,t} \geq \nu_k$ the job will always complete and little information is gained. This is addressed by always using a lower estimate of ν_k in the algorithm. The second challenge is that $M_{k,t}$ will vary with time, so the samples $X_{k,t}$ are not identically distributed. This would normally be unproblematic, since martingale inequalities can be applied, but the specific structure of this problem means that a standard sample average estimator is a little weak in the sense that its estimation accuracy can be dramatically improved. In particular, we will propose an estimator that is able to take advantage of the fact that the

variance of $X_{k,t}$ decreases to zero as $M_{k,t}$ approaches ν_k from below.

As far as the estimates are concerned, rather than estimate the parameters ν_k , it turns out that learning the reciprocal ν_k^{-1} is both more approachable and ultimately more useful for proving regret bounds. Fix k and let $M_{k,1}, \dots, M_{k,t} \leq \nu_k$ be a sequence of allocations with $M_{k,s} \leq \nu_k$ and $X_{k,s} \sim \text{Bernoulli}(M_{k,s}/\nu_k)$. Then a natural (unbiased) estimator of ν_k^{-1} is given by

$$\frac{1}{\hat{\nu}_{k,t}} := \frac{1}{t} \sum_{s=1}^t \frac{X_{k,s}}{M_{k,s}}.$$

The estimator has some interesting properties. First, the random variable $X_{k,s}/M_{k,s} \in [0, 1/M_{k,s}]$ has a large range for small $M_{k,s}$, which makes it difficult to control the error $\hat{\nu}_{k,t}^{-1} - \nu_k^{-1}$ via the usual Azuma/Bernstein inequalities. Secondly, if $M_{k,s}$ is close to ν_k , then the range of $X_{k,s}/M_{k,s}$ is small, which makes estimation easier. Additionally, the variance is greatly decreased for $M_{k,s}$ close to ν_k . This suggests that samples for which $M_{k,s}$ is large are more useful than those where $M_{k,s}$ is small, which motivates the use of the weighted estimator,

$$\frac{1}{\hat{\nu}_{k,t}} := \frac{\sum_{s=1}^t w_s X_{k,s}}{\sum_{s=1}^t w_s M_{k,s}},$$

where w_s will be chosen in a data-dependent way, but with the important characteristic that w_s is large for $M_{k,s}$ close to ν_k . The pseudo-code of the main algorithm is shown on Algorithm Listing 1. It accepts as input the horizon n , the number of jobs, and a set $\{\underline{\nu}_{k,0}\}_{k=1}^K$ for which $0 < \underline{\nu}_{k,0} \leq \nu_k$ for each k . In Section 7 we present a simple (and efficient) algorithm that relaxes the need for the lower bounds $\underline{\nu}_{k,0}$.

Remark 1. Later (in Lemma 6) we will show that with high probability $1 \leq w_{k,s} \leq O(s)$. By definition the confidence bounds $\underline{\nu}_{k,t}$ and $\bar{\nu}_{k,t}$ are non-decreasing/increasing respectively. These results are sufficient to guarantee that the new algorithm is numerically stable. It is also worth noting that the running time of Algorithm 1 is $O(1)$ per time step, since all sums can be computed incrementally.

4 UPPER BOUNDS ON THE REGRET

The regret of Algorithm 1 depends in a subtle way on the parameters ν_k . There are four natural cases, which will appear in our main result.

Case 1: Insufficient budget for any jobs. In this case $\ell = 0$ and the optimal algorithm allocates all available resources to the easiest task, which means $M_1^* = 1$. Knowing that $\ell = 0$, the problem can be reduced to a K -armed Bernoulli bandit by restricting the action space to $M_{k,t} = 1$ for all k . Then a bandit algorithm such as UCB1 [Auer et al.,

Algorithm 1 Optimistic Allocation Algorithm

- 1: **input:** $n, K, \{\underline{\nu}_{k,0}\}_{k=1}^K$
- 2: $\delta \leftarrow (nK)^{-2}$ and $\bar{\nu}_{k,0} = \infty$ for each k
- 3: **for** $t \in 1, \dots, n$ **do**
- 4: /* Optimistically choose $M_{k,t}$ using $\underline{\nu}_{k,t-1}$ */
- 5: $(\forall k \in 1, \dots, K)$ initialise $M_{k,t} \leftarrow 0$
- 6: **for** $i \in 1, \dots, K$ **do**
- 7: $k \leftarrow \arg \min_{k: M_{k,t}=0} \underline{\nu}_{k,t-1}$
- 8: $M_{k,t} \leftarrow \min \left\{ \underline{\nu}_{k,t-1}, 1 - \sum_{j=1}^K M_{j,t} \right\}$
- 9: **end for**
- 10: $(\forall k \in 1, \dots, K)$ observe $X_{k,t}$
- 11: $(\forall k \in 1, \dots, K)$ compute weighted estimates:

$$w_{k,t} \leftarrow \frac{1}{1 - \frac{M_{k,t}}{\bar{\nu}_{k,t-1}}} \quad \frac{1}{\hat{\nu}_{k,t}} \leftarrow \frac{\sum_{s=1}^t w_{k,s} X_{k,s}}{\sum_{s=1}^t w_{k,s} M_{k,s}}$$

- 12: $(\forall k \in 1, \dots, K)$ update confidence intervals:

$$R_{k,t} \leftarrow \max_{s \leq t} w_{k,s} \quad \hat{V}_{k,t}^2 \leftarrow \sum_{s \leq t} \frac{w_{k,s} M_{k,s}}{\underline{\nu}_{k,t-1}}$$

$$\tilde{\epsilon}_{k,t} \leftarrow \frac{f(R_{k,t}, \hat{V}_{k,t}^2, \delta)}{\sum_{s=1}^t w_{k,s} M_{k,s}}$$

$$\underline{\nu}_{k,t} \leftarrow \min \left\{ \frac{1}{\underline{\nu}_{k,t-1}}, \frac{1}{\hat{\nu}_{k,t}} + \tilde{\epsilon}_{k,t} \right\}$$

$$\frac{1}{\bar{\nu}_{k,t}} \leftarrow \max \left\{ \frac{1}{\bar{\nu}_{k,t-1}}, \frac{1}{\hat{\nu}_{k,t}} - \tilde{\epsilon}_{k,t} \right\}$$

- 13: **end for**

- 14: **function** $f(R, V^2, \delta)$

- 15: $\delta_0 \leftarrow \frac{\delta}{3(R+1)^2(V^2+1)^2}$

- 16: **return** $\frac{R+1}{3} \log \frac{2}{\delta_0}$
 $+ \sqrt{2(V^2+1) \log \frac{2}{\delta_0} + \left(\frac{R+1}{3}\right)^2 \log^2 \frac{2}{\delta_0}}$

- 17: **end function**
-

[2002] will achieve logarithmic (problem dependent) regret with some dependence on the gaps $\Delta_{1,k} = \frac{1}{\nu_1} - \frac{1}{\nu_k}$. In particular, the regret looks like $R_n \in O\left(\sum_{k=2}^K \frac{\log n}{\Delta_{1,k}}\right)$.

Case 2: Sufficient budget for all jobs. In this case $\ell = K$ and the optimal policy assigns $M_{k,t} = \nu_k$ for all k , which enjoys a reward of K at each time-step. Now Algorithm 1 will choose $M_{k,t} = \underline{\nu}_{k,t-1}$ for all time-steps and by Theorem 4 stated below we will have $\underline{\nu}_{k,t-1}/\nu_k \in O(1 - \frac{1}{t} \log n)$. Consequently, the regret may be bounded by $R_n \in O(\log^2 n)$ with *no dependence on the gaps*.

Case 3: Sufficient budget for all but one job. Now the algorithm must learn which jobs should be fully allocated. This introduces a weak dependence on the gaps $\Delta_{\ell,k}$ for

$k > \ell$, but choosing the overflow job is trivial. Again we expect the regret to be $O(\log^2 n)$, but with an additional modest dependence on the gaps.

Case 4: General case. In the completely general case even the choice of the overflow job is non-trivial. Ultimately it turns out that in this setting the problem decomposes into two sub-problems. Choosing the jobs to fully allocate, and choosing the overflow job. The first component is fast, since we can make use of the faster learning when fully allocating. Choosing the overflow reduces to the bandit problem as described in case 1.

Our main result is the following theorem bounding the regret of our algorithm.

Theorem 2. *Let δ be as in the algorithm, $\eta_k = \min\{1, \nu_k\} / \underline{\nu}_{k,0}$, $\tilde{\delta}_k = \frac{\delta}{48\eta_k^6 n^6}$, $c_{k,1} = 27 \log \frac{2}{\delta_k}$, $c_{k,2} = 6 \log \frac{2}{\delta_k}$, $u_{k,j} = \frac{c_{k,1}}{\underline{\nu}_{k,0} \Delta_{j,k}}$. Then Algorithm 1 suffers regret at most*

$$R_n \leq 1 + \sum_{k=1}^{\ell} c_{k,1} \eta_k (1 + \log n) + \mathbb{1}\{\ell < K\} \left[\sum_{k=\ell+2}^K \frac{c_{k,2}}{\underline{\nu}_{k,0} \Delta_{\ell+1,k}} + \sum_{k=1}^{\ell+1} c_{k,1} \eta_k (1 + \log n) + \sum_{k=\ell+2}^K c_{k,1} \eta_k (1 + \log u_{\ell+1,k}) + \sum_{k=\ell+1}^K c_{k,1} \eta_k (1 + \log u_{\ell,k}) \right].$$

If we assume $\eta_k \in O(1)$ for each k (reasonable as discussed in Section 7), then the regret bound looks like

$$R_n \in O\left(\ell \log^2 n + \sum_{k=\ell+1}^K \left(\log \frac{1}{\nu_k \Delta_{\ell,k}}\right) \log n + \sum_{k=\ell+2}^K \left(\log \frac{1}{\nu_k \Delta_{\ell+1,k}}\right) \log n + \sum_{k=\ell+1}^K \frac{\log n}{\Delta_{\ell+1,k}}\right), \quad (1)$$

where the first term is due to the gap between $\underline{\nu}_{k,t}$ and ν_k , the second due to discovering which jobs should be fully allocated, while the third and fourth terms are due to mistakes when choosing the overflow job.

The proof is broken into two components. In the first part we tackle the convergence of $\hat{\nu}_{t,k}$ to ν_k and analyse the width of the confidence intervals, which are data-dependent and shrink substantially faster when $M_{k,t}$ is chosen close to ν_k . In the second component we decompose the regret in terms of the width of the confidence intervals. While we avoided large constants in the algorithm itself, in the proof we focus on legibility. Optimising the constants would complicate an already long result.

5 ESTIMATION

We consider a single job with parameter ν and analyse the estimator and confidence intervals used by Algorithm 1.

We start by showing that the confidence intervals contain the truth with high-probability and then analyse the rate at which the intervals shrink as more data is observed. Somewhat surprisingly the rate has a strong dependence on the data with larger allocations leading to faster convergence.

Let $\{\mathcal{F}_t\}_{t=0}^{\infty}$ be a filtration and let M_1, \dots, M_n be a sequence of positive random variables such that M_t is \mathcal{F}_{t-1} -measurable. Define X_t to be sampled from a Bernoulli distribution with parameter $\beta(M_t/\nu)$ for some $\nu \in [\underline{\nu}_0, \infty]$ and assume that X_t is \mathcal{F}_t -measurable. Our goal is to construct a sequence of confidence intervals $\{\underline{\nu}_t, \bar{\nu}_t\}_{t=1}^n$ such that $\nu \in [\underline{\nu}_t, \bar{\nu}_t]$ with high probability and $\bar{\nu}_t - \underline{\nu}_t \rightarrow 0$ as fast as possible. We assume a known lower bound $\underline{\nu}_0 \leq \nu$ and define $\bar{\nu}_0 = \infty$. Recall that the estimator used by Algorithm 1 is defined by

$$w_s = \frac{1}{1 - \frac{M_t}{\bar{\nu}_{t-1}}}, \quad \frac{1}{\hat{\nu}_t} = \frac{\sum_{s=1}^t w_s X_s}{\sum_{s=1}^t w_s M_s}.$$

Fix a number $0 < \delta < 1$ and define $\tilde{\varepsilon}_t = f(R_t, \hat{\nu}_t^2, \delta) / \sum_{s=1}^t w_s M_s$, where the function f is defined in Algorithm 1, $R_t = \max_{s \leq t} w_s$ and $\hat{\nu}_t^2 = \sum_{s=1}^t \frac{w_s M_s}{\underline{\nu}_{t-1}}$. The lower and upper confidence bounds on ν^{-1} are defined by,

$$\frac{1}{\underline{\nu}_t} = \min \left\{ \frac{1}{\underline{\nu}_{t-1}}, \frac{1}{\hat{\nu}_t} + \tilde{\varepsilon}_t \right\}, \quad \frac{1}{\bar{\nu}_t} = \max \left\{ \frac{1}{\bar{\nu}_{t-1}}, \frac{1}{\hat{\nu}_t} - \tilde{\varepsilon}_t \right\}.$$

We define $\varepsilon_t = \underline{\nu}_t^{-1} - \bar{\nu}_t^{-1}$ to be the (decreasing) width of the confidence interval. Note that both $\underline{\nu}_t$ and $\bar{\nu}_t$ depend on δ , although this dependence is not shown to minimise clutter.

Theorem 3. *If M_s is chosen such that $M_s \leq \underline{\nu}_{s-1}$ for all s then $\mathbb{P}\{\exists s \leq t \text{ s.t. } \nu \notin [\underline{\nu}_s, \bar{\nu}_s]\} \leq t\delta$ holds for any $0 < \delta < 1$.*

Proof of Theorem 3. Let F_t be the event $F_t = \{\nu \in [\underline{\nu}_t, \bar{\nu}_t]\}$. Note that since $[\underline{\nu}_t, \bar{\nu}_t] \subset [\underline{\nu}_{t-1}, \bar{\nu}_{t-1}] \subset \dots \subset [\underline{\nu}_0, \bar{\nu}_0]$, $F_t \subset F_{t-1} \subset \dots \subset F_0$. Hence, $F_t = \cap_{s \leq t} F_s$ and it suffices to prove that $\mathbb{P}\{F_t^c\} \leq t\delta$.³

Define $Y_s = w_s X_s - \frac{w_s M_s}{\nu}$ and $S_t = \sum_{s=1}^t Y_s$ and $V_t^2 = \sum_{s=1}^t \text{Var}[Y_s | \mathcal{F}_{s-1}]$. We proceed by induction. Assume $\mathbb{P}\{F_{t-1}^c\} \leq (t-1)\delta$, which is trivial for $t = 1$. Now, on F_{t-1} ,

$$V_t^2 \stackrel{(a)}{=} \sum_{s=1}^t \text{Var}[Y_s | \mathcal{F}_{s-1}] \stackrel{(b)}{=} \sum_{s=1}^t \frac{w_s^2 M_s}{\nu} \left(1 - \frac{M_s}{\nu}\right) \stackrel{(c)}{=} \sum_{s=1}^t \frac{w_s M_s}{\nu} \left(\frac{1 - \frac{M_s}{\nu}}{1 - \frac{M_s}{\bar{\nu}_{s-1}}}\right) \stackrel{(d)}{\leq} \sum_{s=1}^t \frac{w_s M_s}{\nu} \stackrel{(e)}{\leq} \hat{\nu}_t^2,$$

³For an event E , we use E^c to denote its complement.

where (a) is the definition of V_t^2 , (b) follows since w_s is \mathcal{F}_{s-1} -measurable, (c) follows by substituting the definition of w_s , (d) and (e) are true since given F_{t-1} we know that $\underline{\nu}_{s-1} \leq \nu \leq \bar{\nu}_{s-1}$. Therefore $f(R_t, V_t^2, \delta) \leq f(R_t, \hat{V}_t^2, \delta)$, which follows since f is monotone increasing in its second argument. Therefore,

$$\begin{aligned} & \mathbb{P} \left\{ \left| \frac{1}{\hat{\nu}_t} - \frac{1}{\nu} \right| \geq \tilde{\varepsilon}_t \wedge F_{t-1} \right\} \\ = & \mathbb{P} \left\{ \left| \frac{\sum_{s=1}^t w_s X_s}{\sum_{s=1}^t w_s M_s} - \frac{1}{\nu} \right| \geq \frac{f(R_t, \hat{V}_t^2, \delta)}{\sum_{s=1}^t w_s M_s} \wedge F_{t-1} \right\} \\ \leq & \mathbb{P} \left\{ \left| \sum_{s=1}^t w_s X_s - \sum_{s=1}^t \frac{w_s M_s}{\nu} \right| \geq f(R_t, V_t^2, \delta) \wedge F_{t-1} \right\} \\ = & \mathbb{P} \{ |S_t| \geq f(R_t, V_t^2, \delta) \wedge F_{t-1} \}. \end{aligned} \quad (2)$$

By the union bound we have

$$\begin{aligned} & \mathbb{P} \{ |S_t| \geq f(R_t, \hat{V}_t^2, \delta) \vee F_{t-1}^c \} \\ \leq & \mathbb{P} \{ |S_t| \geq f(R_t, V_t^2, \delta) \wedge F_{t-1} \} + \mathbb{P} \{ F_{t-1}^c \} \\ \stackrel{(a)}{\leq} & \delta + \mathbb{P} \{ F_{t-1}^c \} \leq \delta + (t-1)\delta = t\delta, \end{aligned}$$

where (a) follows from a martingale version of Bernstein's inequality adapted from [Bernstein 1946](#) and [Freedman 1975](#). See the supplementary material for details. Therefore $\mathbb{P} \{ |S_t| \leq f(R_t, V_t^2, \delta) \wedge F_{t-1} \} \geq 1 - t\delta$ and so with probability at least $1 - t\delta$ we have that F_{t-1} and

$$\left| \frac{1}{\hat{\nu}_t} - \frac{1}{\nu} \right| \leq \frac{f(R_t, \hat{V}_t^2, \delta)}{\sum_{s=1}^t w_s M_s} = \tilde{\varepsilon}_t,$$

in which case

$$\frac{1}{\underline{\nu}_t} = \min \left\{ \frac{1}{\underline{\nu}_{t-1}}, \frac{1}{\hat{\nu}_t} + \tilde{\varepsilon}_t \right\} \geq \frac{1}{\nu},$$

and similarly $\frac{1}{\bar{\nu}_t} \leq \frac{1}{\nu}$, which implies F_t . Therefore $\mathbb{P} \{ F_t^c \} \leq t\delta$ as required. \square

We now analyse the width $\varepsilon_t \equiv \underline{\nu}_t^{-1} - \bar{\nu}_t^{-1}$ of the confidence interval obtained after t samples are observed. We say that a job is *fully allocated* at time-step s if $M_s = \underline{\nu}_{s-1}$. The first theorem shows that the width ε_t drops with order $O(1/T(t))$, where $T(t) = \sum_{s=1}^t \mathbb{1}\{M_s = \underline{\nu}_{s-1}\}$ is the number of fully allocated time-steps. The second theorem shows that for any $\alpha > 0$, the width ε_t drops with order $O(\sqrt{1/(\alpha U_\alpha(t))})$, where $U_\alpha(t) = \sum_{s=1}^t \mathbb{1}\{M_s \geq \alpha\}$. The dramatic difference in speeds is due to the low variance $\text{Var}[X_t | \mathcal{F}_{t-1}]$ when M_t is chosen close to ν . For the next results define $\eta = \min\{1, \nu\} / \underline{\nu}_0$ and $\tilde{\delta} = \frac{\delta}{48\eta^4 n^6}$.

Theorem 4. $\varepsilon_t \leq \frac{c_1}{\underline{\nu}_0(T(t) + 1)}$ where $c_1 = 27 \log \frac{2}{\delta}$.

Theorem 5. $\varepsilon_t \leq \sqrt{\frac{c_2}{\alpha \underline{\nu}_0 U_\alpha(t)}}$ where $c_2 = 6 \log \frac{2}{\delta}$.

The proofs are based on the following lemma that collects some simple observations:

Lemma 6. *The following hold for any $t \geq 1$:*

1. $w_t M_t \leq \frac{1}{\varepsilon_{t-1}}$, with equality if $M_t = \underline{\nu}_{t-1}$.
2. $1 \leq R_t \leq \frac{1}{\underline{\nu}_0 \varepsilon_{t-1}}$.
3. $\varepsilon_t \geq \frac{1}{t \min\{1, \nu\}}$.
4. $1 - \frac{\underline{\nu}_t}{\nu} \leq \underline{\nu}_t \varepsilon_t$.

Proof. Using the definition of w_s and the fact that M_s is always chosen to be smaller or equal to $\underline{\nu}_{s-1}$, we get

$$w_s \equiv \left(1 - \frac{M_s}{\bar{\nu}_{s-1}}\right)^{-1} \stackrel{(a)}{\leq} \left(1 - \frac{\underline{\nu}_{s-1}}{\bar{\nu}_{s-1}}\right)^{-1} = \frac{1}{\varepsilon_{s-1} \underline{\nu}_{s-1}}.$$

The first claim follows since the inequality (a) can be replaced by equality if $M_s = \underline{\nu}_{s-1}$. The second follows from the definition of R_t and the facts that $(\varepsilon_s)_s$ is non-increasing and $(\underline{\nu}_s)_s$ is non-decreasing. For the third claim we recall that $R_t = \max_{s \leq t} w_s$ and $M_s \leq \nu$. Therefore,

$$\begin{aligned} \varepsilon_t & \stackrel{(a)}{\geq} \min \left\{ \varepsilon_{t-1}, \frac{R_t}{\sum_{s=1}^t w_s M_s} \right\} \\ & \stackrel{(b)}{\geq} \min \left\{ \varepsilon_{t-1}, \frac{1}{t \min\{1, \nu\}} \right\}, \end{aligned}$$

where (a) follows from the definition of ε_t and naive bounding of the function f , (b) follows since $R_t \geq w_s$ for all $s \leq t$ and because $M_s \leq \min\{1, \nu\}$ for all s . Trivial induction and the fact that $\varepsilon_0 = \underline{\nu}_0^{-1} \geq \nu^{-1}$ completes the proof of the third claim. For the final claim we use the facts that $\underline{\nu}_t^{-1} \leq \nu^{-1} + \varepsilon_t$. Therefore, $1 - \frac{\underline{\nu}_t}{\nu} = \underline{\nu}_t \left(\frac{1}{\underline{\nu}_t} - \frac{1}{\nu} \right) \leq \underline{\nu}_t \varepsilon_t$. \square

Lemma 7. $\varepsilon_t \leq \frac{6R_t \log \frac{2}{\delta}}{\sum_{s=1}^t w_s M_s} + \sqrt{\frac{8 \log \frac{2}{\delta}}{\underline{\nu}_0 \sum_{s=1}^t w_s M_s}}$.

Proof. Let $\delta_t = \delta / (3(R_t + 1)^2 (\hat{V}_t^2 + 1)^2) < 1$. By the definition of ε_t ,

$$\begin{aligned} \varepsilon_t & \leq \frac{2f(R_t, \hat{V}_t^2, \delta)}{\sum_{s=1}^t w_s M_s} \\ & \stackrel{(a)}{\leq} \frac{\frac{4(R_t+1)}{3} \log \frac{2}{\delta_t} + 2\sqrt{2(\hat{V}_t^2 + 1)} \log \frac{2}{\delta_t}}{\sum_{s=1}^t w_s M_s} \\ & \stackrel{(b)}{\leq} \frac{6R_t \log \frac{2}{\delta_t} + \sqrt{\frac{8}{\underline{\nu}_0} \sum_{s=1}^t w_s M_s \log \frac{2}{\delta_t}}}{\sum_{s=1}^t w_s M_s} \\ & = \frac{6R_t \log \frac{2}{\delta_t}}{\sum_{s=1}^t w_s M_s} + \sqrt{\frac{8 \log \frac{2}{\delta_t}}{\underline{\nu}_0 \sum_{s=1}^t w_s M_s}}, \end{aligned}$$

where in (a) we used the definition of f , in (b) we substituted the definition of \hat{V}_t^2 and used the facts that $R_t \geq 1$

and $\nu_0 \leq \nu_{t-1}$ and we also used a naive bound. The proof is completed by proving $2/\delta_t \leq 2/\tilde{\delta}$. Indeed, by Lemma 6, $1 \leq R_t \leq \frac{1}{\varepsilon_{t-1}\nu_0} \leq \frac{1}{\varepsilon_t\nu_0}$. We also have $\hat{V}_t^2 \leq tR_t^2$. Thus,

$$\frac{2}{\delta_t} = \frac{6(R_t + 1)^2(\hat{V}_t^2 + 1)^2}{\delta} \leq \frac{6}{\delta} \left(\frac{16t^2}{(\varepsilon_t\nu_0)^4} \right) \stackrel{(a)}{\leq} \frac{2}{\tilde{\delta}},$$

where in (a) we used Lemma 6(3). \square

Proof of Theorem 4. By Lemma 7,

$$\varepsilon_t \leq \frac{6R_t \log \frac{2}{\delta}}{\sum_{s=1}^t w_s M_s} + \sqrt{\frac{8}{\nu_0 \sum_{s=1}^t w_s M_s} \log \frac{2}{\delta}}. \quad (3)$$

We proceed by induction. Assume that $\varepsilon_{s-1} \leq \frac{c_1}{\nu_0(T(s-1)+1)}$, which is trivial for $s = 1$. By Lemma 6(1),

$$\sum_{s=1}^t w_s M_s \geq \sum_{s=1}^{T(t)} \frac{s\nu_0}{c_1} = \frac{\nu_0 T(t)(T(t)+1)}{2c_1}. \quad (4)$$

Therefore,

$$\sqrt{\frac{8}{\nu_0 \sum_{s=1}^t w_s M_s} \log \frac{2}{\delta}} \stackrel{(a)}{\leq} \frac{1}{\nu_0 T(t)} \sqrt{4c_1 \log \frac{2}{\delta}}. \quad (5)$$

Now we work on the first term in (3). If $\varepsilon_{t-1} \leq \frac{c_1}{\nu_0(T(t)+1)}$, then we are done, since ε_s is non-increasing. Otherwise, we use Lemma 6(2) to obtain,

$$\begin{aligned} \frac{6R_t}{\sum_{s=1}^t w_s M_s} \log \frac{2}{\delta} &\leq \frac{6}{\nu_0 \varepsilon_{t-1} \sum_{s=1}^t w_s M_s} \log \frac{2}{\delta} \\ &\stackrel{(a)}{\leq} \frac{3}{\nu_0 T(t)} \log \frac{2}{\delta}, \end{aligned} \quad (6)$$

where in (a) we used (4) and the lower bound on ε_{t-1} . Substituting (5) and (6) into (3) we have

$$\varepsilon_t \leq \frac{1}{\nu_0 T(t)} \sqrt{4c_1 \log \frac{2}{\delta}} + \frac{3}{\nu_0 T(t)} \log \frac{2}{\delta}.$$

Choosing $c_1 = 27 \log \frac{2}{\delta}$ leads to

$$\begin{aligned} \varepsilon_t &\leq \frac{1}{\nu_0 T(t)} \sqrt{4 \cdot 27 \log^2 \frac{2}{\delta}} + \frac{3}{\nu_0 T(t)} \log \frac{2}{\delta} \\ &\leq \frac{27}{\nu_0 (T(t)+1)} \log \frac{2}{\delta} = \frac{c_1}{\nu_0 (T(t)+1)}, \end{aligned}$$

which completes the induction and proof. \square

Proof of Theorem 5. Firstly, by Lemma 7,

$$\varepsilon_t \leq \frac{6R_t}{\sum_{s=1}^t w_s M_s} \log \frac{2}{\delta} + \sqrt{\frac{8}{\nu_0 \sum_{s=1}^t w_s M_s} \log \frac{2}{\delta}}.$$

The second term is easily bounded by using the fact that $w_s \geq 1$ and the definition of $U_\alpha(t)$,

$$\sqrt{\frac{8}{\nu_0 \sum_{s=1}^t w_s M_s} \log \frac{2}{\delta}} \leq \sqrt{\frac{8}{\nu_0 U_\alpha(t) \alpha} \log \frac{2}{\delta}}.$$

For the first term we assume $\varepsilon_{t-1} \geq \sqrt{\frac{c_2}{\nu_0 U_\alpha(t) \alpha}}$, since otherwise we can apply monotonicity of ε_t . Therefore

$$\begin{aligned} \frac{6R_t}{\sum_{s=1}^t w_s M_s} \log \frac{2}{\delta} &\leq \frac{6}{\nu_0 \varepsilon_{t-1} \sum_{s=1}^t w_s M_s} \log \frac{2}{\delta} \\ &\leq \sqrt{\frac{U_\alpha(t) \alpha \nu_0}{c_2}} \cdot \frac{6 \log \frac{2}{\delta}}{\nu_0 U_\alpha(t) \alpha} \leq 6 \sqrt{\frac{1}{c_2 \alpha \nu_0 U_\alpha(t)}} \log \frac{2}{\delta}. \end{aligned}$$

Now choose $c_2 = 6 \log \frac{2}{\delta}$ to complete the result. \square

6 PROOF OF THEOREM 2

We are now ready to use the results of Section 5 to bound the regret of Algorithm 1. The first step is to decompose the regret into two cases depending on whether or not the confidence intervals contain the truth. The probability that they do not is low, so this contributes negligibly to the regret. When the confidence intervals are valid we break the problem into two components. The first is the selection of the processes to fully allocation, which leads to the $O(\log^2 n)$ part of the bound. The second component involves analysing the selection of the overflow process, where the approach is reminiscent of the analysis for the UCB algorithm for stochastic bandits [Auer et al., 2002].

Let $F_{k,t}$ denote the event when none of the confidence intervals underlying job k fail up to time t :

$$F_{k,t} = \{\forall s \leq t : \nu \in [\underline{\nu}_{k,s}, \bar{\nu}_{k,s}]\}.$$

The algorithm uses $\delta = (nK)^{-2}$, which is sufficient by a union bound and Theorem 3 to ensure that,

$$\mathbb{P}\{G^c\} \leq \frac{1}{nK}, \quad \text{where } G = \bigcap_{k=1}^K F_{k,n}. \quad (7)$$

The regret can be decomposed into two cases depending on whether G holds:

$$\begin{aligned} R_n &= \mathbb{E} \sum_{t=1}^n r_t \stackrel{(a)}{=} \mathbb{E} \mathbb{1}\{G^c\} \sum_{t=1}^n r_t + \mathbb{E} \mathbb{1}\{G\} \sum_{t=1}^n r_t \quad (8) \\ &\stackrel{(b)}{\leq} \mathbb{E} \mathbb{1}\{G^c\} nK + \mathbb{E} \mathbb{1}\{G\} \sum_{t=1}^n r_t \stackrel{(c)}{\leq} 1 + \mathbb{E} \mathbb{1}\{G\} \sum_{t=1}^n r_t, \end{aligned}$$

where (a) follows from the definition of expectation, (b) is true by bounding $r_t \leq K$ for all t , and (c) follows from (7). For the remainder we assume G holds and use Theorems 4

and 5 combined with the definition of the algorithm to control the second term in (8). The first step is to decompose the regret in round t :

$$r_t = \ell^* + \frac{S^*}{\nu_{\ell+1}} - \sum_{k=1}^K \beta \left(\frac{M_{k,t}}{\nu_k} \right).$$

By the assumption that G holds we know for all $t \leq n$ and k that $\bar{\nu}_{k,t}^{-1} \leq \nu_k^{-1} \leq \underline{\nu}_{k,t}^{-1}$. Therefore $M_{k,t} \leq \underline{\nu}_{k,t-1} \leq \nu_k$, which means that $\beta(M_{k,t}/\nu_k) = M_{k,t}/\nu_k$. Define $\pi_t(i) \in \{1, \dots, K\}$ such that $\underline{\nu}_{\pi_t(i),t-1} \leq \underline{\nu}_{\pi_t(i+1),t-1}$. Also let

$$\begin{aligned} A_t &= \{k : M_{k,t} = \underline{\nu}_{k,t-1}\}, \\ A_t^{\leq j} &= A_t \cap \{\pi_i(t) : 1 \leq i \leq j\}, \\ T_k(t) &= \sum_{s=1}^t \mathbb{1}\{k \in A_s\} \quad \text{and} \quad B_t = \pi_t(\ell + 1). \end{aligned}$$

Informally, A_t is the set of jobs that are fully allocated at time-step t , $A_t^{\leq j}$ is a subset of A_t containing the j jobs believed to be easiest, $T_k(t)$ is the number of times job k has been fully allocated at time-step t , and B_t is the $(\ell + 1)$ th easiest job at time-step t (this is only defined if $\ell < K$ and will only be used in that case).

Lemma 8. *For all t , $|A_t| \geq \ell$ and if $|A_t| = \ell$, then $M_{B_t,t} \geq S^*$.*

Proof. $|A_t| = \max \left\{ j : \sum_{i=1}^j \underline{\nu}_{\pi_t(i),t-1} \leq 1 \right\}$. But $\underline{\nu}_{k,t-1} \leq \nu_k$ for all k and t , so $\sum_{i=1}^{\ell} \underline{\nu}_{\pi_t(i),t-1} \leq \sum_{k=1}^{\ell} \underline{\nu}_{k,t-1} \leq \sum_{k=1}^{\ell} \nu_k \leq 1$. Therefore $|A_t| \geq \ell$. If $|A_t| = \ell$, then $B_t \notin A_t$ is the overflow job and so $M_{B_t,t} = 1 - \sum_{k \in A_t} \underline{\nu}_{k,t-1} \geq 1 - \sum_{k \in A^*} \underline{\nu}_{k,t-1} \geq 1 - \sum_{k \in A^*} \nu_k \equiv S^*$ \square

We now decompose the regret, while still assuming that G holds:

$$\begin{aligned} \sum_{t=1}^n r_t &= \sum_{t=1}^n \left(\ell + \frac{S^*}{\nu_{\ell+1}} - \sum_{k=1}^K \frac{M_{k,t}}{\nu_k} \right) \\ &\leq \sum_{t=1}^n \sum_{k \in A_t^{\leq \ell}} \left(1 - \frac{M_{k,t}}{\nu_k} \right) \\ &\quad + \mathbb{1}\{\ell < K\} \sum_{t=1}^n \left(\frac{S^*}{\nu_{\ell+1}} - \frac{M_{B_t,t}}{\nu_{B_t}} \right). \end{aligned} \quad (9)$$

Let us bound the first sum:

$$\begin{aligned} &\sum_{t=1}^n \sum_{k \in A_t^{\leq \ell}} \left(1 - \frac{M_{k,t}}{\nu_k} \right) \\ &= \sum_{t=1}^n \sum_{k=1}^K \mathbb{1}\{k \in A_t^{\leq \ell}\} \left(1 - \frac{\underline{\nu}_{k,t-1}}{\nu_k} \right) \end{aligned}$$

$$\begin{aligned} &\stackrel{(a)}{\leq} \sum_{t=1}^n \sum_{k=1}^K \mathbb{1}\{k \in A_t^{\leq \ell}\} \underline{\nu}_{k,t-1} \varepsilon_{k,t-1} \\ &\stackrel{(b)}{\leq} \sum_{t=1}^n \sum_{k=1}^K \mathbb{1}\{k \in A_t^{\leq \ell}\} \frac{c_{k,1} \underline{\nu}_{k,t-1}}{\underline{\nu}_{k,0} T_k(t)}, \end{aligned} \quad (11)$$

where (a) follows by Lemma 6 and (b) by Theorem 4.

Lemma 9. *If $k > j$, then*

$$\sum_{t=1}^n \mathbb{1}\{k \in A_t^{\leq j}\} \leq \frac{c_{k,1}}{\underline{\nu}_{k,0} \Delta_{j,k}} =: u_{j,k}.$$

Proof. Assume $k \in A_t^{\leq j}$. Therefore $\underline{\nu}_{k,t-1} \leq \nu_j$. But if $u_{j,k} < \sum_{s=1}^t \mathbb{1}\{k \in A_s^{\leq j}\} \leq T_k(t-1) + 1$, then

$$\begin{aligned} \frac{1}{\underline{\nu}_{k,t-1}} &\leq \frac{1}{\nu_k} + \varepsilon_{k,t-1} = \frac{1}{\nu_j} + \varepsilon_{k,t-1} - \Delta_{j,k} \\ &\stackrel{(a)}{\leq} \frac{1}{\nu_j} + \frac{c_{k,1}}{\underline{\nu}_{k,0}(T_k(t-1) + 1)} - \Delta_{j,k} < \frac{1}{\nu_j}, \end{aligned}$$

where (a) follows from Theorem 4. Therefore $k \in A_t^{\leq j}$ implies that $\sum_{s=1}^t \mathbb{1}\{k \in A_s^{\leq j}\} \leq u_{j,k}$ and so $\sum_{t=1}^n \mathbb{1}\{k \in A_t^{\leq j}\} \leq u_{j,k}$ as required. \square

Continuing (11) by applying Lemma 9 with $j = \ell$:

$$\begin{aligned} &\sum_{t=1}^n \sum_{k=1}^K \mathbb{1}\{k \in A_t^{\leq \ell}\} \frac{c_{k,1} \underline{\nu}_{k,t-1}}{\underline{\nu}_{k,0} T_k(t)} \\ &= \sum_{t=1}^n \sum_{k \in A^*} \mathbb{1}\{k \in A_t^{\leq \ell}\} \frac{c_{k,1} \underline{\nu}_{k,t-1}}{\underline{\nu}_{k,0} T_k(t)} \\ &\quad + \sum_{t=1}^n \sum_{k \notin A^*} \mathbb{1}\{k \in A_t^{\leq \ell}\} \frac{c_{k,1} \underline{\nu}_{k,t-1}}{\underline{\nu}_{k,0} T_k(t)} \\ &\stackrel{(a)}{\leq} \sum_{k \in A^*} \sum_{t=1}^n \frac{c_{k,1} \eta_k}{t} + \sum_{k \notin A^*} \sum_{t=1}^{u_{\ell,k}} \frac{c_{k,1} \eta_k}{t} \\ &\leq \sum_{k=1}^{\ell} c_{k,1} \eta_k (1 + \log n) + \sum_{k=\ell+1}^K c_{k,1} \eta_k (1 + \log u_{\ell,k}), \end{aligned} \quad (12)$$

where (a) follows by Lemma 9 and the fact that $k \in A_t^{\leq \ell}$ implies that $\frac{\underline{\nu}_{k,t-1}}{\underline{\nu}_{k,0}} \leq \eta_k$. Now if $\ell = K$, then the second term in (9) is zero and the proof is completed by substituting the above result into (9) and then into (8). So now we assume $\ell > K$ and bound the second term in (9) as follows:

$$\begin{aligned} &\sum_{t=1}^n \left(\frac{S^*}{\nu_{\ell+1}} - \frac{M_{B_t,t}}{\nu_{B_t}} \right) \leq \sum_{t=1}^n \mathbb{1}\{B_t \in A_t\} \left(1 - \frac{\underline{\nu}_{B_t,t-1}}{\nu_{B_t}} \right) \\ &\quad + \sum_{t=1}^n \mathbb{1}\{B_t \notin A_t\} \left(\frac{S^*}{\nu_{\ell+1}} - \frac{S^*}{\nu_{B_t}} \right), \end{aligned} \quad (13)$$

where we used Lemma 8 and $S^* \leq 1$ and that if $B_t \in A_t$, then $M_{B_t,t} = \underline{\nu}_{B_t,t-1}$. Bounding each term separately:

$$\begin{aligned}
& \sum_{t=1}^n \mathbb{1}\{B_t \in A_t\} \left(1 - \frac{\underline{\nu}_{B_t,t-1}}{\nu_{B_t}}\right) \\
\stackrel{(a)}{\leq} & \sum_{k=1}^K \sum_{t=1}^n \mathbb{1}\{k \in A_t^{\leq \ell+1}\} \left(1 - \frac{\underline{\nu}_{k,t-1}}{\nu_k}\right) \\
\stackrel{(b)}{\leq} & \sum_{k=1}^K \sum_{t=1}^n \mathbb{1}\{k \in A_t^{\leq \ell+1}\} \underline{\nu}_{k,t-1} \varepsilon_{k,t-1} \\
\stackrel{(c)}{\leq} & \sum_{k=1}^K \sum_{t=1}^n \mathbb{1}\{k \in A_t^{\leq \ell+1}\} \frac{c_{k,1} \underline{\nu}_{k,t-1}}{\underline{\nu}_{k,0} T_k(t)} \\
\stackrel{(d)}{\leq} & \sum_{k=1}^{\ell+1} c_{k,1} \eta_k (1 + \log n) + \sum_{k=\ell+2}^K c_{k,1} \eta_k (1 + \log u_{\ell+1,k}),
\end{aligned} \tag{14}$$

where (a) follows since $B_t \in A_t$ implies that $B_t \in A_t^{\leq \ell+1}$, (b) follows from Lemma 6(4), (c) by Theorem 4, and (d) follows from Lemma 9 and the same analysis as (12). For the second term we need the following lemma, which uses Theorem 5 and a reasoning analogues to that of Auer et al. [2002] to bound the regret of the UCB algorithm for stochastic bandits:

Lemma 10. Let $U_k(t) = \sum_{s=1}^t \mathbb{1}\{M_{k,s} \geq S^*\}$ and $k > \ell + 1$. If $U_k(t) \geq \frac{c_{k,2}}{S^* \underline{\nu}_{k,0} \Delta_{\ell+1,k}^2} =: v_k$, then $k \neq B_t$.

Proof. If $\underline{\nu}_{k,t-1} > \nu_{\ell+1}$, then $k \neq B_t$. Furthermore, if $U_k(t) > v_k$, then

$$\begin{aligned}
\frac{1}{\underline{\nu}_{k,t-1}} & \leq \frac{1}{\nu_k} + \varepsilon_{k,t-1} = \frac{1}{\nu_{\ell+1}} - \Delta_{\ell+1,k} + \varepsilon_{k,t-1} \\
& \stackrel{(a)}{\leq} \frac{1}{\nu_{\ell+1}} - \Delta_{\ell+1,k} + \sqrt{\frac{c_{k,2}}{\underline{\nu}_{k,0} S^* U_k(t)}} < \frac{1}{\nu_{\ell+1}},
\end{aligned}$$

where (a) follows from Theorem 5. \square

Therefore

$$\begin{aligned}
& \sum_{t=1}^n \mathbb{1}\{B_t \notin A_t\} \left(\frac{S^*}{\nu_{\ell+1}} - \frac{S^*}{\nu_{B_t}}\right) \\
\stackrel{(a)}{\leq} & S^* \sum_{k=1}^K \sum_{t=1}^n \mathbb{1}\{k = B_t \notin A_t\} \Delta_{\ell+1,k} \\
\stackrel{(b)}{\leq} & S^* \sum_{k=\ell+2}^K \sum_{t=1}^n \mathbb{1}\{k = B_t \notin A_t\} \Delta_{\ell+1,k} \\
\stackrel{(c)}{\leq} & S^* \sum_{k=\ell+2}^K \sum_{t=1}^n \mathbb{1}\{k = B_t \wedge M_{k,t} \geq S^*\} \Delta_{\ell+1,k} \\
\stackrel{(d)}{\leq} & \sum_{k=\ell+2}^K S^* \Delta_{\ell+1,k} v_k \stackrel{(e)}{=} \sum_{k=\ell+2}^K \frac{c_{k,2}}{\underline{\nu}_{k,0} \Delta_{\ell+1,k}}, \tag{15}
\end{aligned}$$

where (a) follows from the definition of $\Delta_{\ell+1,k}$ and the fact that if $B_t \notin A_t$, then $|A_t| = \ell$, (b) follows since $\Delta_{\ell+1,k}$ is negative for $k \leq \ell + 1$, (c) by Lemma 8, (d) by Lemma 10, and (e) by the definition of v_k . Substituting (14) and (15) into (13) we have

$$\begin{aligned}
& \sum_{t=1}^n \left(\frac{S^*}{\nu_{\ell+1}} - \frac{M_{B_t,t}}{\nu_{B_t}}\right) \leq \sum_{k=1}^{\ell+1} c_{k,1} \eta_k (1 + \log n) \\
& + \sum_{k=\ell+2}^K c_{k,1} \eta_k (1 + \log u_{\ell+1,k}) + \sum_{k=\ell+2}^K \frac{c_{k,2}}{\underline{\nu}_{k,0} \Delta_{\ell+1,k}}.
\end{aligned}$$

We then substitute this along with (12) into (9) and then (8) to obtain

$$\begin{aligned}
R_n & \leq 1 + \sum_{k=1}^{\ell} c_{k,1} \eta_k (1 + \log n) \\
& + \mathbb{1}\{\ell < K\} \left[\sum_{k=\ell+2}^K \frac{c_{k,2}}{\underline{\nu}_{k,0} \Delta_{\ell+1,k}} + \sum_{k=1}^{\ell+1} c_{k,1} \eta_k (1 + \log n) \right. \\
& \left. + \sum_{k=\ell+2}^K c_{k,1} \eta_k (1 + \log u_{\ell+1,k}) + \sum_{k=\ell+1}^K c_{k,1} \eta_k (1 + \log u_{\ell,k}) \right].
\end{aligned}$$

7 INITIALISATION

Previously we assumed a known lower bound $\underline{\nu}_{k,0} \leq \nu_k$ for each k . In this section we show that these bounds are easily obtained using a halving trick. In particular, the following algorithm computes a lower bound $\underline{\nu}_0 \leq \nu$ for a single job with unknown parameter ν .

Algorithm 2 Initialisation of $\underline{\nu}_0$

- 1: **for** $t \in 1, \dots, \infty$ **do**
 - 2: Allocate $M_t = 2^{-t}$ and observe X_t
 - 3: **if** $X_t = 0$ **then return** $\underline{\nu}_0 \leftarrow 2^{-t}$.
 - 4: **end for**
-

A naive way to eliminate the need for the lower bounds $(\underline{\nu}_{k,0})_k$ is simply to run Algorithm 2 for each job sequentially. Then the following proposition (proven in supplementary material) shows that $\eta \in O(1)$ is reasonable, which justifies the claim made in (1) that the η_k terms appearing in Theorem 2 are $O(1)$.

Proposition 11. If $\eta = \frac{\min\{1, \nu\}}{\underline{\nu}_0}$, then $\mathbb{E}\eta \leq 4$.

The problem with the naive method is that the expected running time of Algorithm 2 is $O(\log \frac{1}{\nu})$, which may be arbitrary large for small ν and lead to a high regret *during the initialisation period*. Fortunately, the situation when ν is small is easy to handle, since the amount of resources required to complete such a job is also small. The trick is to run K offset instances of Algorithm 2 alongside a modified version of Algorithm 1. First we describe the parallel

implementations of Algorithm 2. For job k , start Algorithm 2 in time-step k , which means that the total amount of resources used by the parallel copies of Algorithm 2 in time-step t is bounded by

$$\sum_{k=1}^K \mathbb{1}\{t \geq k\} 2^{k-t-1} \leq \min\{1, 2^{K-t}\}. \quad (16)$$

Job	$M_{k,1}$	$M_{k,2}$	$M_{k,3}$	$M_{k,4}$
1	1/2	1/4	1/8	1/16
2	0	1/2	1/4	1/8
3	0	0	1/2	1/4
$\sum_{k=1}^K M_{k,t}$	1/2	3/4	7/8	7/16

Algorithm 1 is implemented starting from time-step 1, but only allocates resources to jobs for which the initialisation process has completed. Estimates are computed using only the samples for which Algorithm 1 chose the allocation, which ensures that they are based on allocations with $M_{k,t} \leq \nu_k$. Note that the analysis of the modified algorithm does not depend on the order in which the parallel processes are initialised. The regret incurred by the modified algorithm is given in order notation in (1). The proof is omitted, but relies on two observations. First, that the expected number of time-steps that a job is not (at least) fully allocated while it is being initialised is 2. The second is that the resources available to Algorithm 1 at time-step t converges exponentially fast to 1 by (16).

8 MINIMAX LOWER BOUNDS

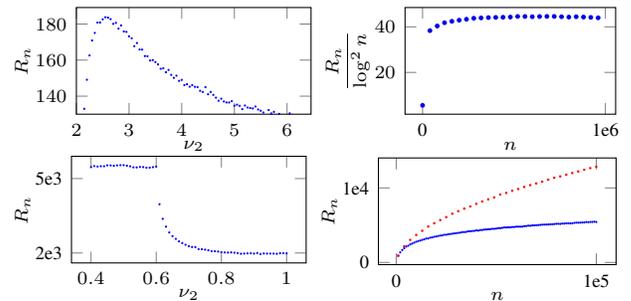

Despite the continuous action space, the techniques used when proving minimax lower bounds for standard stochastic bandits [Auer et al., 1995] can be adapted to our setting. The proof is included in the supplementary material.

Theorem 12. *Given fixed n and $8n \geq K \geq 2$ and an arbitrary algorithm, there exists an allocation problem for which the expected regret satisfies $R_n \geq \frac{\sqrt{nK}}{16\sqrt{2}}$.*

9 EXPERIMENTS

All code and data is available in the supplementary material. Data points were generated using the modified algorithm described in Section 7 and by taking the mean of 300 samples. With this many samples the standard error is relatively low (and omitted for readability). We should note that the variance in the regret of the modified algorithm is reasonably large, because the regret depends linearly on the random η_k . For known lower bounds the variance is extremely low. To illustrate the behaviour of the algorithm we performed four experiments on synthetic data with $K = 2$, which are plotted below as TL (top left), TR, BL, BR (bottom right) respectively. In TL we fixed $n = 10^4$, $\nu_1 = 2$ and plotted the regret as a function of $\nu_2 \in [2, 10]$. The experiment shows the usual bandit-like dependence on the gap $1/\Delta_{1,2}$. In TR we fixed $\nu_1 = 4/10$, $\nu_2 = 6/10$ and plotted $R_n / \log^2 n$ as a function of n . The experiment lies within case 2 described in Section 4 and shows that the algorithm suffers regret $R_n \approx 45 \log^2 n$ as predicted by Theorem 2. In BL we fixed $n = 10^5$, $\nu_1 = 4/10$ and plotted the regret as a function of $\nu_2 \in [4/10, 1]$. The results show

the algorithm suffering $O(\log^2 n)$ regret for both processes until the critical point when $\nu_2 > 6/10$ when the second process can no longer be fully allocated, which is quickly learned and the algorithm suffers $O(\log^2 n)$ regret for only one process. In BR we fixed $\nu_1 = 4/10$ and $\nu_2 = 6/10$ and plotted the regret as a function of n for two algorithms. The first algorithm (solid blue) is the modified version of Algorithm 1 as described in Section 7. The second (dotted red) is the same, but uses the unweighted estimator $w_{k,t} = 1$ for all k and t . The result shows that both algorithms suffer sub-linear regret, but that the weighted estimator is a significant improvement over the unweighted one.

10 CONCLUSIONS

We introduced the linear stochastic resource allocation problem and a new optimistic algorithm for this setting. Our main result shows that the new algorithm enjoys a (squared) logarithmic problem-dependent regret. We also presented a minimax lower bound of $\Omega(\sqrt{nK})$, which is consistent with the problem-dependent upper bound. The simulations confirm the theory and highlight the practical behaviour of the new algorithm. There are many open questions and possibilities for future research. Most important is whether the $\log^2 n$ can be reduced to $\log n$. Problem-dependent lower bounds would be interesting. The algorithm is not anytime (although a doubling trick presumably works in theory). Developing and analysing algorithms when the horizon is not known, and have high-probability bounds are both of interest. We also wonder if Thompson sampling can be efficiently implemented for some reasonable prior, and if it enjoys the same practical and theoretical guarantees in this domain as it does for bandits. Other interesting extensions are when resources are not replenished, or the state of the jobs follow a Markov process. Finally, we want to emphasise that we have made just the first steps towards developing this new and interesting setting. We hope to see significant activity extending and modifying the model/algorithm for specific problems.

Abstract

We consider the problem of selecting informative observations in Gaussian graphical models containing both cycles and nuisances. More specifically, we consider the subproblem of quantifying conditional mutual information measures that are *nonlocal* on such graphs. The ability to efficiently quantify the information content of observations is crucial for resource-constrained data acquisition (adaptive sampling) and data processing (active learning) systems. While closed-form expressions for Gaussian mutual information exist, standard linear algebraic techniques, with complexity cubic in the network size, are intractable for high-dimensional distributions. We investigate the use of embedded trees for computing nonlocal pairwise mutual information and demonstrate through numerical simulations that the presented approach achieves a significant reduction in computational cost over inversion-based methods.

1 INTRODUCTION

In resource-constrained inferential settings, uncertainty can be efficiently minimized with respect to a resource budget by acquiring or processing the most informative subset of observations – a problem known as *active inference* (Krause and Guestrin, 2005; Williams et al., 2007). Yet despite the myriad recent advances in both understanding and streamlining inference through probabilistic graphical models (Koller and Friedman, 2009), there does not exist a comparable wealth of knowledge regarding how information measures propagate on these graphs. This paper considers the problem of efficiently quantifying a measure of informativeness across nonlocal pairings in a loopy Gaussian graphical model.

This paper assumes a model has been provided, and the ensuing goal is to interpret relationships within this model

in the context of informativeness. This assumption is motivated by the hypothesis that, regardless of the specific sensing modalities or communication platforms used in an information collection system, the underlying phenomena can be described by *some* stochastic process structured according to a probabilistic graphical model. The sparsity of that model determines the efficiency of inference procedures. In contrast to methods for estimating information measures directly from raw data (e.g., Kraskov et al., 2004), the approach of this paper does not require the prior enumeration of interaction sets that one wishes to quantify, and the presented algorithm computes *conditional* information measures that account for statistical redundancy between observations.

This paper specifically addresses the common issue of nuisances in the model – variables that are not of any extrinsic importance, but act as intermediaries between random variables that are either observable or of inferential interest. Marginalization of nuisances can be both computationally expensive and detrimental to the sparsity of the graph, which, in the interest of efficient model utilization, one wishes to retain. Ignoring nuisances by treating them as relevant can result in observation selectors fixated on reducing uncertainty in irrelevant portions of the underlying distribution (Levine and How, 2013). In terms of information quantification, nuisances can induce nonlocality in the sense that observations and relevant latent variables are not adjacent in the graph, motivating the study of how information measure propagate through graphical models.

In this paper, we investigate the use of embedded trees (Sudderth et al., 2004) for efficiently quantifying nonlocal mutual information in loopy Gaussian graphs. The formal problem statement and a characterization thereof is described in Section 2. Some preliminary material and prior algorithmic technologies are reviewed in Section 3. Our method for quantify mutual information using embedded trees, ET-MIQ, is described in Section 4 and demonstrated through experimental results in Section 5. A discussion of ET-MIQ in comparison to alternative methods and in anticipation of future extensions is provided in Section 6.

2 PROBLEM STATEMENT

Let $\mathbf{x} = (x_1, \dots, x_N)$ be a collection of N random variables (or disjoint subvectors) with joint distribution $p_{\mathbf{x}}(\cdot)$. Let index set $\mathcal{V} = \{1, \dots, N\}$ be partitioned such that $\mathcal{V} = \mathcal{U} \cup \mathcal{S}$, where $\mathcal{U} \subset \mathcal{V}$ indexes latent (unobservable) variables, and where $\mathcal{S} \subset \mathcal{V}$ indexes observable variables, whose realizations $\mathbf{x}_{\mathcal{S}} = x_s, s \in \mathcal{S}$ may be obtained by expending some resource. Let $c : 2^{\mathcal{S}} \rightarrow \mathbb{R}_{\geq 0}$ be the cost function that maps subsets of observable variables to a resource cost, and let $\beta \in \mathbb{R}_{\geq 0}$ be a resource budget. Given a subset $\mathcal{R} \subseteq \mathcal{U}$ of *relevant latent variables*, which are of inferential interest and about which one wishes to reduce uncertainty, the general *focused active inference* problem (Levine and How, 2013) is

$$\begin{aligned} & \text{maximize}_{\mathcal{A} \subseteq \mathcal{S}} && I(\mathbf{x}_{\mathcal{R}}; \mathbf{x}_{\mathcal{A}}) \\ & \text{s.t.} && c(\mathcal{A}) \leq \beta, \end{aligned} \quad (1)$$

where $I(\cdot, \cdot)$ is the mutual information measure (cf. Section 3.3).

It is well known that (1) is **NP-hard** (Ko et al., 1995; Krause and Guestrin, 2009). Despite this, suboptimal heuristics such as greedy selection have been analyzed in the context of submodularity (Nemhauser et al., 1978), leading to various performance bounds (Golovin and Krause, 2010; Krause and Guestrin, 2005; Williams et al., 2007). In the focused case, where there are nuisances $\mathcal{U} \setminus \mathcal{R}$ in the problem, the objective in (1) is in general not submodular (Krause et al., 2008), although online-computable performance bounds can be established through submodular relaxations (Levine and How, 2013).

However, efficient computation of the mutual information objective in (1) has remained elusive for all but simple models – symmetric discrete distributions (Choi et al., 2011) and Gaussian trees (Levine and How, 2013). Just as covariance analysis in the Kalman filtering framework can be used to anticipate the uncertainty evolution in a linear-Gaussian state space model, which is Markov to a minimal tree-shaped Gaussian graph, this paper aims to provide a general *preposterior analysis* of uncertainty reduction in nontree Gaussian systems.

This paper specifically considers the class of Gaussian distributed vectors $\mathbf{x} \sim \mathcal{N}^{-1}(\mathbf{0}, J)$ with inverse covariance matrices J , each of which is Markov to an undirected graph with cycles. For large N , evaluating the MI objective in (1) via matrix inversion is cubic in N , which may be prohibitively expensive. The aim of this paper is explicating an iterative algorithm for computing MI whose complexity per iteration is linear in N , and whose convergence is often subquadratic in N , leading to a relative asymptotic efficiency over naïve linear algebraic techniques.

3 BACKGROUND

3.1 MARKOV RANDOM FIELDS

A graph $\mathcal{G} = (\mathcal{V}, \mathcal{E})$, with vertex set \mathcal{V} and edge set \mathcal{E} linking pairs of vertices, can be used to represent the conditional independence structure of a joint distribution $p_{\mathbf{x}}(\cdot)$ over a collection $\mathbf{x} = (x_1, \dots, x_N)$ of N random variables (or disjoint random subvectors). This paper considers the class of distributions represented by undirected graphs, also known as Markov random fields (MRFs).

The topology of an MRF can be characterized, in part, by its set of paths. A path is a sequence of distinct adjacent vertices (v_1, \dots, v_m) where $\{v_k, v_{k+1}\} \in \mathcal{E}, k = 1, \dots, m - 1$. If for any two distinct vertices $s, t \in \mathcal{V}$ there is more than one path joining s to t , then \mathcal{G} contains a cycle. A graph without cycles is called a *tree* (or, if it is disconnected, a *forest*).

An MRF can represent conditional independences of the form given by the global Markov condition: For disjoint subsets $A, B, C \subset \mathcal{V}$, $\mathbf{x}_A \perp\!\!\!\perp \mathbf{x}_B \mid \mathbf{x}_C$ iff A and B are graph-separated by C (all paths between a vertex in A and a vertex in B must pass through C). The edge set \mathcal{E} satisfies the pairwise Markov property: For all $i, j \in \mathcal{V}$, $\{i, j\} \notin \mathcal{E}$ iff $\mathbf{x}_i \perp\!\!\!\perp \mathbf{x}_j \mid \mathbf{x}_{\mathcal{V} \setminus \{i, j\}}$. A distribution is said to be Markov with respect to a graph \mathcal{G} if it satisfies the conditional independences implied by \mathcal{G} .

3.2 INFERENCE ON GAUSSIAN MRFS

A multivariate Gaussian distribution in the information form $p_{\mathbf{x}}(\mathbf{x}) \propto \exp\{-\frac{1}{2}\mathbf{x}^T J \mathbf{x} + \mathbf{h}^T \mathbf{x}\}$, with (symmetric, positive definite) *precision* or *inverse covariance matrix* J and potential vector \mathbf{h} , is Markov with respect to a Gaussian MRF (GMRF; Speed and Kiiveri, 1986) if J satisfies the sparsity pattern of \mathcal{E} : $(J)_{i,j} = (J)_{j,i}^T \neq \mathbf{0} \Leftrightarrow \{i, j\} \in \mathcal{E}$. The parameters of the information form are related to the covariance $P = J^{-1}$ and mean $J^{-1}\mathbf{h}$. Thus, estimating the mean of a Gaussian is equivalent to solving the system of equations

$$J\hat{\mathbf{x}} = \mathbf{h}. \quad (2)$$

Assume without loss of generality¹ that each component x_i of \mathbf{x} is a subvector of dimension $d \in \mathbb{N}^+$, whereby $J \in \mathbb{R}^{Nd \times Nd}$ can be partitioned into an $N \times N$ grid of $d \times d$ block submatrices. Solving (2) by inverting J requires $\mathcal{O}((Nd)^3)$ operations, which can be prohibitively expensive for large N . If the graph contains no cycles, then Gaussian belief propagation (GaBP) (Pearl, 1988; Weiss and Freeman, 2001) can be used to compute the conditional mean, as well as marginal variances, in $\mathcal{O}(Nd^3)$, providing a significant computational savings for large N . For graphs

¹Extension to the case of varying subvector dimensions with $d \triangleq \max_{i \in \mathcal{V}} \dim(\mathbf{x}_i)$ is straightforward.

with cycles, various estimation procedures have been recently developed to exploit available sparsity in the graph (cf. Sections 3.4 and 3.5).

Marginalization and conditioning can be conceptualized as selecting submatrices of P and J , respectively. Let disjoint sets A and B form a partition of $\mathcal{V} = \{1, \dots, N\}$. The marginal distribution $p_{\mathbf{x}_A}(\cdot)$ over \mathbf{x}_A is parameterized by covariance matrix $(P)_{A,A}$, the block submatrix of P corresponding to the rows and columns indexed by A . Similarly, the conditional distribution $p_{\mathbf{x}_A|\mathbf{x}_B}(\cdot|\mathbf{x}_B)$ of \mathbf{x}_A conditioned on $\mathbf{x}_B := \mathbf{x}_B$ is parameterized by the $(J)_{A,A}$ block submatrix of J . In the inferential setting, one has access to J and not P .

3.3 MUTUAL INFORMATION

Mutual information (MI) is an information-theoretic measure of dependence between two (sets of) random variables. Its interpretation as a measure of entropy reduction appeals to its use in uncertainty mitigation (Caselton and Zidek, 1984). For disjoint subsets $A, B, C \subset \mathcal{V}$ (with C possibly empty), conditional mutual information is defined as

$$I(\mathbf{x}_A; \mathbf{x}_B | \mathbf{x}_C) \triangleq h(\mathbf{x}_A | \mathbf{x}_C) - h(\mathbf{x}_A | \mathbf{x}_B, \mathbf{x}_C), \quad (3)$$

where, for continuous random variables $\mathbf{x}_\mathcal{V}$, $h(\cdot)$ is the differential entropy functional

$$h(q_{\mathbf{x}}(\cdot)) = - \int_{\mathcal{X}} q_{\mathbf{x}}(x) \log q_{\mathbf{x}}(x) dx.$$

Note that MI is always nonnegative and is symmetric with respect to its first two arguments. For convenience, we will often use only the index sets (and not the random variables they index) as the arguments of mutual information.

Let $P_{A|C}$ denote the (marginal) covariance of \mathbf{x}_A given \mathbf{x}_C . For multivariate Gaussians, the conditional MI (Cover and Thomas, 2006) is

$$I(A; B | C) = \frac{1}{2} \log \frac{\det(P_{A|C}) \det(P_{B|C})}{\det(P_{A \cup B | C})}. \quad (4)$$

Computing the marginal covariance matrices needed in (4) via matrix inversion (or taking Schur complements) of $J_{A \cup B | C}$ generally requires $\mathcal{O}((Nd)^3)$ operations, even if one is computing *pairwise* MI (i.e., $|A| = |B| = 1$). For Gaussian trees, an efficient algorithm exist for reducing pairwise MI complexity to $\mathcal{O}(Nd^3)$, i.e., linear in the number of vertices (Levine and How, 2013). The main objective of this paper is providing a similar reduction in complexity for loopy Gaussian graphical models.

3.4 EMBEDDED TREES

The embedded trees (ET) algorithm was introduced in (Sudderth, 2002; Wainwright et al., 2000) to iteratively

compute both conditional means and marginal error variances in Gaussian graphical models with cycles. Although the algorithm requires only the identification of subgraphs on which inference is tractable, and extensions to, for example, embedded polygons (Delouille et al., 2006) and embedded hypergraphs (Chandrasekaran et al., 2008) have been considered, this paper will focus for clarity of discussion on embedded trees.

Let $\mathbf{x} \sim \mathcal{N}^{-1}(\mathbf{0}, J)$ be a Gaussian distributed random vector Markov to an undirected graph $\mathcal{G} = (\mathcal{V}, \mathcal{E})$ that contains cycles. Consider an alternatively distributed random vector $\mathbf{x}_\mathcal{T} \sim \mathcal{N}^{-1}(\mathbf{0}, J_\mathcal{T})$ that is of the same dimension as \mathbf{x} but is instead Markov to a cycle-free subgraph $\mathcal{G}_\mathcal{T} = (\mathcal{V}, \mathcal{E}_\mathcal{T})$ of \mathcal{G} (in the sense that $\mathcal{E}_\mathcal{T} \subset \mathcal{E}$). The tree-shaped (and symmetric, positive definite) inverse covariance matrix $J_\mathcal{T}$ can be decomposed as $J_\mathcal{T} = J + K_\mathcal{T}$, where $K_\mathcal{T}$ is any symmetric *cutting matrix* that enforces the sparsity pattern of $J_\mathcal{T}$ by zeroing off-diagonal elements of J corresponding to cut edges $\mathcal{E} \setminus \mathcal{E}_\mathcal{T}$. Since many cutting matrices $K_\mathcal{T}$ will result in a tree-shaped inverse covariance $J_\mathcal{T}$ Markov to $\mathcal{G}_\mathcal{T}$, attention will be restricted to so-called *regular* cutting matrices, whose nonzero elements are constrained to lie at the intersection of the rows and columns corresponding to the vertices incident to cut edges. Note that $K_\mathcal{T}$ can always be chosen such that $\text{rank}(K_\mathcal{T})$ is at most $\mathcal{O}(Ed)$, where $E \triangleq |\mathcal{E} \setminus \mathcal{E}_\mathcal{T}|$ will be used to denote the number of cut edges.

3.4.1 Conditional Means

Given an initial solution $\hat{\mathbf{x}}^{(0)}$ to (2), the single-tree Richardson iteration (Young, 1971) induced by embedded tree $\mathcal{G}_\mathcal{T}$ with cutting matrix $K_\mathcal{T}$ and associated inverse covariance $J_\mathcal{T} = J + K_\mathcal{T}$ is

$$\hat{\mathbf{x}}^{(n)} = J_\mathcal{T}^{-1} \left(K_\mathcal{T} \hat{\mathbf{x}}^{(n-1)} + \mathbf{h} \right). \quad (5)$$

Thus, each update $\hat{\mathbf{x}}^{(n)}$ is the solution of a synthetic inference problem (2) with precision matrix $\tilde{J} = J_\mathcal{T}$ and potential vector $\tilde{\mathbf{h}} = K_\mathcal{T} \hat{\mathbf{x}}^{(n-1)} + \mathbf{h}$. This update requires a total of $\mathcal{O}(Nd^3 + Ed^2)$ operations, where $\mathcal{O}(Nd^3)$ is due to solving $\tilde{J} \hat{\mathbf{x}}^{(n)} = \tilde{\mathbf{h}}$ with a tree-shaped graph, and where $\mathcal{O}(Ed^2)$ with $E = |\mathcal{E} \setminus \mathcal{E}_\mathcal{T}|$ is due to forming $\tilde{\mathbf{h}}$. In the case that E is at most $\mathcal{O}(N)$, the overall complexity *per iteration* is $\mathcal{O}(Nd^3)$. Letting $\rho(D) \triangleq \max_{\lambda \in \{\lambda_i(D)\}} |\lambda|$ denote the spectral radius of a square matrix D , the asymptotic convergence rate of the single-tree iteration (5) is

$$\rho(J_\mathcal{T}^{-1} K_\mathcal{T}) = \rho(I - J_\mathcal{T}^{-1} J), \quad (6)$$

with convergence to $\hat{\mathbf{x}}$ guaranteed (regardless of $\hat{\mathbf{x}}^{(0)}$) if and only if $\rho(J_\mathcal{T}^{-1} K_\mathcal{T}) < 1$. Inherent in (5) and (6) is a tradeoff in the choice of embedded structure between the tractability of solving $J_\mathcal{T} \hat{\mathbf{x}}^{(n)} = \tilde{\mathbf{h}}$ and the approximation strength of $J_\mathcal{T} \approx J$ for fast convergence.

The ET algorithm (Sudderth et al., 2004) is conceptualized as a nonstationary Richardson iteration with multiple matrix splittings of J . Let $\{G_{\mathcal{T}_n}\}_{n=1}^{\infty}$ be a sequence of embedded trees within \mathcal{G} , and let $\{K_{\mathcal{T}_n}\}_{n=1}^{\infty}$ be a sequence of cutting matrices such that $J_{\mathcal{T}_n} = J + K_{\mathcal{T}_n}$ is Markov to $\mathcal{G}_{\mathcal{T}_n}$ for $n = 1, \dots, \infty$. The nonstationary Richardson update is then

$$\hat{\mathbf{x}}^{(n)} = J_{\mathcal{T}_n}^{-1} \left(K_{\mathcal{T}_n} \hat{\mathbf{x}}^{(n-1)} + \mathbf{h} \right), \quad (7)$$

with error $e^{(n)} \triangleq \hat{\mathbf{x}}^{(n)} - \hat{\mathbf{x}}$ that evolves according to

$$e^{(n)} = J_{\mathcal{T}_n}^{-1} K_{\mathcal{T}_n} e^{(n-1)}. \quad (8)$$

The criterion for convergence is when the normalized residual error $\|K_{\mathcal{T}_n}(\hat{\mathbf{x}}^{(n)} - \hat{\mathbf{x}}^{(n-1)})\|_2 / \|\mathbf{h}\|_2$ falls below a specified tolerance $\epsilon > 0$. The sparsity of $K_{\mathcal{T}_n}$ permits the efficient computation of this residual.

When $\{G_{\mathcal{T}_n}, K_{\mathcal{T}_n}\}_{n=1}^{\infty}$ is periodic in n , a convergence rate analysis similar to (6) is given in (Sudderth et al., 2004). It is also demonstrated that using multiple embedded trees can significantly improve the convergence rate. Online adaptive selection of the embedded tree was explored in (Chandrasekaran et al., 2008) by scoring edges according to single-edge walk-sums and forming a maximum weight spanning tree in $\mathcal{O}(|\mathcal{E}| \log |N|)$.

3.4.2 Marginal Variances

Given that $\text{rank}(K_{\mathcal{T}}) \leq 2Ed$ (Sudderth, 2002), where $E = |\mathcal{E} \setminus \mathcal{E}_{\mathcal{T}}|$, an additive rank-one decomposition

$$K_{\mathcal{T}} = \sum_i w_i u_i u_i^T, \quad u_i \in \mathbb{R}^{Nd} \quad (9)$$

can be substituted in the fixed-point equation (Sudderth et al., 2004)

$$P = J_{\mathcal{T}}^{-1} + J_{\mathcal{T}}^{-1} K_{\mathcal{T}} P, \quad (10)$$

yielding

$$P = J_{\mathcal{T}}^{-1} + \sum_i w_i (J_{\mathcal{T}}^{-1} u_i) (P u_i)^T. \quad (11)$$

Solving for the vertex-marginal covariances $P_i = (P)_{i,i}$, $i \in \mathcal{V}$, which are the block-diagonal entries of P , requires:

- solving for the block-diagonal entries of $J_{\mathcal{T}}^{-1}$, with one-time complexity $\mathcal{O}(Nd^3)$ via GaBP;
- solving the synthetic inference problems $J_{\mathcal{T}} z_i = u_i$, for all $\mathcal{O}(Ed)$ vectors u_i of $K_{\mathcal{T}}$ in (9), with one-time total complexity $\mathcal{O}(Nd^3 \cdot Ed) = \mathcal{O}(NEd^4)$ via GaBP;
- solving the synthetic inference problems $J z_i = u_i$, for all $\mathcal{O}(Ed)$ vectors u_i of $K_{\mathcal{T}}$ in (9), with *per iteration* total complexity of $\mathcal{O}(NEd^4)$ operations via ET conditional means (7);

- and assembling the above components via (11).

Note that there exists a decomposition, alternative to (9), of $K_{\mathcal{T}}$ into $\mathcal{O}(Wd)$ rank-one matrices using a cardinality- W vertex cover of $\mathcal{E} \setminus \mathcal{E}_{\mathcal{T}}$ (where $W \leq E$ for any minimal vertex cover); this alternative decomposition requires solving a symmetric quadratic eigenvalue problem (Sudderth et al., 2004).

3.5 COMPETING METHODS

Other methodologies have been proposed to perform inference in loopy graphs. Loopy belief propagation (LBP) is simply parallel belief propagation performed on graphs with cycles; if it converges, it does so to the correct mean but, in general, to incorrect variances (Weiss and Freeman, 2001). Extended message passing augments the original BP messages and provides for convergence to the correct variances, but its complexity is $\mathcal{O}(NL^2)$ in the scalar case, where L is the number of vertices incident to any cut edge, and it requires the full message schedule to be executed to produce an estimate (Plarre and Kumar, 2004). Linear response algorithms can be used to compute pairwise marginal distributions for nonadjacent pairs of vertices, but at a complexity of $\mathcal{O}(N|\mathcal{E}|d^3)$, which may be excessive for large N and $|\mathcal{E}| = \mathcal{O}(N)$ given that conditional MI requires only very specific pairwise marginals (Welling and Teh, 2004).

It is also possible to perform efficient inference if it is known that removal of a subset of \mathcal{V} , called a feedback vertex set (FVS), will induce a tree-shaped subgraph (Liu et al., 2012). The resulting belief propagation-like inference algorithm, called feedback message passing, has complexity $\mathcal{O}(Nk^2)$ for scalar networks, where k is the size of the FVS. If the topological structure of the graphical model is well known *a priori*, or if the graph is learned by an algorithm oriented towards forming FVSs (Liu and Willsky, 2013), then identification of an FVS is straightforward. However, if the graphical model is provided without such identification, it may be computationally expensive to form an FVS of reasonable size, whereas finding a spanning tree (as the ET algorithm does) is comparatively simple.

Various graph sparsification methods have been pursued to find useful substructures that can precondition linear systems of equations (e.g., support graph theory (Bern et al., 2006)). Notably, Spielman and Teng (2011) present a spectral sparsification method for the graph Laplacian (which has scalar edge weights) that permits the solution of diagonally dominant linear systems in near-linear time. In contrast, this paper analyzes the ET sparsifier, which operates on edges with potentially *vectoral* weights and does *not* assume diagonal dominance (which would, for example, guarantee the convergence of LBP (Weiss and Freeman, 2001)).

4 ET MUTUAL INFORMATION QUANTIFICATION (ET-MIQ)

This section describes the application of embedded trees to efficient iterative computation of nonlocal mutual information measures on loopy Gaussian graphs.

It is typically intractable to enumerate all possible selection sets $\mathcal{A} \in 2^{\mathcal{V}}$ and evaluate the resulting MI objective $I(\mathcal{R}; \mathcal{A})$. Often, one balances tractability with performance by using suboptimal selection heuristics with either a priori or online-computable performance bounds (Krause and Guestrin, 2005; Levine and How, 2013). Starting from an empty selection $\mathcal{A} \leftarrow \emptyset$, the greedy heuristic

$$a \leftarrow \underset{\{y \in \mathcal{S} \setminus \mathcal{A} : c(y) \leq \beta - c(\mathcal{A})\}}{\operatorname{argmax}} I(\mathcal{R}; y | \mathcal{A}) \quad (12)$$

$$\mathcal{A} \leftarrow \mathcal{A} \cup \{a\}$$

selects one unselected observable variable with the highest marginal increase in objective and continues to do so until the budget is expended. By comparison to (4), the MI evaluations needed to perform a greedy update are of the form

$$I(\mathcal{R}; y | \mathcal{A}) = \frac{1}{2} \log \frac{\det(P_{\mathcal{R}|\mathcal{A}}) \det(P_{\{y\}|\mathcal{A}})}{\det(P_{\mathcal{R} \cup \{y\}|\mathcal{A}})} \quad (13)$$

While inverse covariance matrices obey specific sparsity patterns, covariance matrices are generally dense. Thus two of the determinants in (13) require $\mathcal{O}(|\mathcal{R}|^3 d^3)$ operations to compute. If $|\mathcal{R}|$ is $\mathcal{O}(N)$ (e.g., the graph represents a regular pattern, a constant fraction of which is to be inferred), then such determinants would be intractable for large N . One instead fixes some ordering R over the elements of \mathcal{R} , denoting by r_k its k th element, $R_k = \cup_{i=1}^k \{r_i\}$ its first k elements, and appeal to the chain rule of mutual information:

$$I(\mathcal{R}; y | \mathcal{A}) = I(r_1; y | \mathcal{A}) + I(r_2; y | \mathcal{A} \cup R_1) + \dots + I(r_{|\mathcal{R}|}; y | \mathcal{A} \cup R_{|\mathcal{R}|-1}). \quad (14)$$

The advantage of this expansion is twofold. Each term in the summation is a pairwise mutual information term. Given an efficient method for computing marginal covariance matrices (the focus of the remainder of this section), the determinants in (4) can be evaluated in $\mathcal{O}(d^3)$ operations. More pressingly, conditioning in an undirected graphical model removes paths from the graph (by the global Markov property), potentially simplifying the structure over which one must perform the quantification. Therefore, the chain rule converts the problem of evaluating a set mutual information measure $I(\mathcal{R}; y | \mathcal{A})$ into $|\mathcal{R}|$ separate pairwise MI computations that *decrease* in difficulty as the conditioning set expands.

It suffices to describe how to compute *one* of the $|\mathcal{R}|$ terms in the summation (14); the template will be repeated for the

other $|\mathcal{R}|-1$ terms, but with a modified conditioning set. In the remainder of this section, it is shown how to efficiently compute $I(r; y | C)$ for all $y \in \mathcal{S} \setminus C$ provided some $r \in \mathcal{R}$ and conditioning set $C \subset \mathcal{V} \setminus \{r\}$. Since conditioning on C can be performed by selecting the appropriate submatrix of J corresponding to $\mathcal{V} \setminus C$, it is assumed for clarity of presentation and without loss of generality² that either $C = \emptyset$ or that one is always working with a J resulting from a larger J' that has been conditioned on C . The resulting MI terms, in further simplification of (13), are of the form

$$I(r; y) = \frac{1}{2} \log \frac{\det(P_{\{r\}}) \det(P_{\{y\}})}{\det(P_{\{r,y\}})}, \quad (15)$$

where $P_{\{r\}} = (P)_{r,r}$ and $P_{\{y\}} = (P)_{y,y}$ are the $d \times d$ marginal covariances on the diagonal, and where $P_{\{r,y\}}$ is the $2d \times 2d$ block submatrix of the (symmetric) covariance $P = J^{-1}$:

$$P_{\{r,y\}} = \begin{bmatrix} (P)_{r,r} & (P)_{r,y} \\ (P)_{y,r} & (P)_{y,y} \end{bmatrix}.$$

In addition to the marginal covariances on the diagonal, the $d \times d$ off-diagonal cross-covariance term $(P)_{r,y} = (P)_{y,r}^T$ is needed to complete $P_{\{r,y\}}$. If it were possible to efficiently estimate the d columns of P corresponding to r , all such cross-covariance terms $(P)_{r,y}, \forall y \in \mathcal{S}$, would be available. Therefore, let P be partitioned into columns $\{p_i\}_{i=1}^{Nd}$ and assume without loss of generality that r corresponds to p_1, \dots, p_d . Let e_i be the i th Nd -dimensional axis vector (with a 1 in the i th position). Then $p_i \equiv P e_i, i = 1, \dots, d$, can be estimated using the synthetic inference problem

$$J p_i = e_i. \quad (16)$$

Thus, by comparison to (2) and (7), the first d columns of P can be estimated with a complexity of $\mathcal{O}(Nd^4)$ per ET iteration.

Using the results of Section 3.4.2, the marginal variances can be estimated in $\mathcal{O}(NEd^4)$ per iteration, where $E = |\mathcal{E} \setminus \mathcal{E}_{\mathcal{T}_n}|$ is the number of cut edges. One can subsequently form each matrix $P_{\{r,y\}}, y \in \mathcal{S}$ in $\mathcal{O}(d^2)$ and take its determinant in $\mathcal{O}(d^3)$. Since $|\mathcal{S}| < N$, the ET-MIQ procedure outlined in the section can be used to iteratively estimate the set $\{I(r; y)\}_{y \in \mathcal{S}}$ with total complexity $\mathcal{O}(NEd^4)$ operations per iteration. Returning to the greedy selection of (12) and the chain rule of (14), given a subset $\mathcal{A} \subset \mathcal{S}$ of previous selections, the set of marginal gains $\{I(\mathcal{R}; y | \mathcal{A})\}_{y \in \mathcal{S} \setminus \mathcal{A}}$ can be estimated in $\mathcal{O}(N|\mathcal{R}|Ed^4)$ operations per iteration.

²Alternatively, the unconditioned J can be used by treating conditioned vertices as blocked (not passing messages) and by zeroing the elements of \mathbf{h} and $\hat{\mathbf{x}}^{(n)}$ in (5) corresponding to C .

5 EXPERIMENTS

5.1 ALTERNATIVE METHODS

In order to demonstrate the comparative performance of the ET-MIQ procedure of Section 4, alternative methods for computing mutual information in Gaussian graphs – two based on matrix inversion, and one based exclusively on estimating columns of P – are briefly described.

5.1.1 Naïve Inversion

Whenever a mutual information term of the form $I(A; B|C)$ is needed, the `NaïveInversion` procedure conditions J on C and computes the marginal covariance matrices $P_{A \cup B|C}$, $P_{A|C}$, and $P_{B|C}$ of (4) using standard matrix inversion, which is $\mathcal{O}(N^3 d^3)$. A greedy selection update, which requires computing marginal information gain scores $\{I(\mathcal{R}; y|\mathcal{A})\}_{y \in \mathcal{S} \setminus \mathcal{A}}$, thereby requires $\mathcal{O}(N^3 |\mathcal{S}| d^3)$ operations using this procedure.

5.1.2 Block Inversion

Intuitively, the `NaïveInversion` procedure appears wasteful even for an inversion-based method, as it repeats many of the marginalization operations needed to form $\{I(\mathcal{R}; y|\mathcal{A})\}_{y \in \mathcal{S} \setminus \mathcal{A}}$. The `BlockInversion` procedure attempts to rectify this. Given a previous selection set \mathcal{A} , `BlockInversion` conditions J on \mathcal{A} and marginalizes out nuisances $\mathcal{U} \setminus \mathcal{R}$ (along with infeasible observation selections $\{y \in \mathcal{S} \setminus \mathcal{A} \mid c(y) > \beta - c(\mathcal{A})\}$) using Schur complements. The complexity of this approach, for each greedy update, is $\mathcal{O}(|\mathcal{S}|^4 + |\mathcal{R}||\mathcal{S}|^3 + |\mathcal{R}|^3|\mathcal{S}| + N^3)$. `BlockInversion` has the same worst-case asymptotic complexity of $\mathcal{O}(N^3 |\mathcal{S}| d^3)$ as `NaïveInversion` but may achieve a significant reduction in computation depending on how $|\mathcal{R}|$ and $|\mathcal{S}|$ scale with N .

5.1.3 ColumnET

The `ColumnET` procedure uses nonstationary embedded tree estimation of specific columns of P to compute all information measures. That is to say, no marginal error variance terms are computed (cf. Section 3.4.2). Given a previous selection set \mathcal{A} , and an ordering R over \mathcal{R} , the columns of $P_{\cdot|\mathcal{A} \cup R_{k-1}}$ corresponding to $\{r_k\} \cup \mathcal{S} \setminus \mathcal{A}$ are estimated via (7) and (16). The complexity of a greedy update using `ColumnET` is $\mathcal{O}(N|\mathcal{R}||\mathcal{S}|d^4)$ operations per ET iteration.

5.2 “HOOP-TREE” EXAMPLES

To investigate the performance benefits of ET-MIQ, we consider a subclass of scalar ($d = 1$) loopy graphs containing m simple cycles (achordal “hoops”) of length l , where cycles may share vertices but no two cycles may share edges. The structure of this graph resembles a macro-tree

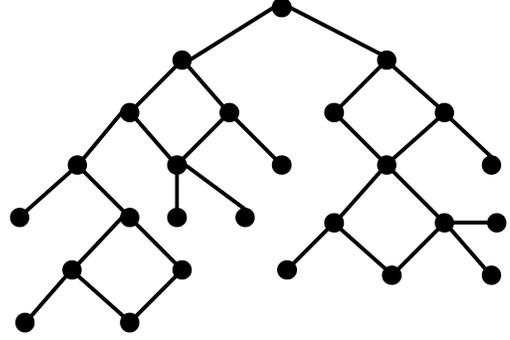

Figure 1: Example of a hoop-tree with 4-vertex cycles.

over hoop subcomponents (a “hoop-tree”; see Figure 1). Any embedded tree on this graph must only cut m edges ($E = m$), one for each l -cycle. This class of graphs is useful for benchmarking purposes, as it permits randomization without requiring the subsequent enumeration of loops via topological analysis, which may be computationally expensive and thus inefficient for testing.

For each problem *instance*, we generate a random hoop-tree $\mathcal{G} = (\mathcal{V}, \mathcal{E})$ of size $|\mathcal{V}| = N$. To generate a corresponding inverse covariance J , we sample $(J)_{i,j} \sim \text{uniform}([-1, 1])$ for each $\{i, j\} \in \mathcal{E}$, and sample $(J)_{i,i} \sim \text{Rayleigh}(1)$, with the diagonal rescaled to enforce the positive definiteness of J . We then randomly label vertices in \mathcal{V} as belonging to \mathcal{S} or \mathcal{U} (or neither), set a budget $\beta \propto |\mathcal{S}|$, and sample an integer-valued additive cost function $c(\cdot)$ such that $c(s) \sim \text{uniform}([1, \gamma\beta])$ for some $\gamma \in [0, 1]$ and all $s \in \mathcal{S}$, and such that $c(\mathcal{A}) = \sum_{a \in \mathcal{A}} c(a)$ for all $\mathcal{A} \subseteq \mathcal{S}$.

Let $\mathcal{G}_{\mathcal{T}_1}$ and $K_{\mathcal{T}_1}$ be the embedded subtree and associated regular cutting matrix formed by cutting the edge of each l -cycle with the highest absolute precision parameter $|(J)_{i,j}|$. Guided by the empirical results of Sudderth et al. (2004), the second embedded tree $\mathcal{G}_{\mathcal{T}_2}$ is selected such that in every l -cycle, $K_{\mathcal{T}_2}$ cuts the edge farthest from the corresponding cut edge in the $\mathcal{G}_{\mathcal{T}_1}$ (modulo some tie-breaking for odd l).

Figure 2 summarizes a comparison of ET-MIQ against `NaïveInversion`, `BlockInversion`, and `ColumnET` in terms of the mean runtime to complete a full greedy selection. Random networks of size N were generated, with $|\mathcal{R}| = 5$ and $|\mathcal{S}| = 0.3N$. The alternative methods were suppressed when they began to take prohibitively long to simulate (e.g., $N = 1200$ for `BlockInversion` and `ColumnET`).

The runtime of ET-MIQ, which vastly outperforms the alternative methods for this problem class, appears to grow superlinearly, but subquadratically, in N (approximately, bounded by $o(N^{1.7})$). The growth rate is a confluence of three factors: the $\mathcal{O}(N|\mathcal{R}|Ed^4)$ complexity per Richardson iteration of updating $\{I(\mathcal{R}; y|\mathcal{A})\}_{y \in \mathcal{S} \setminus \mathcal{A}}$; the number

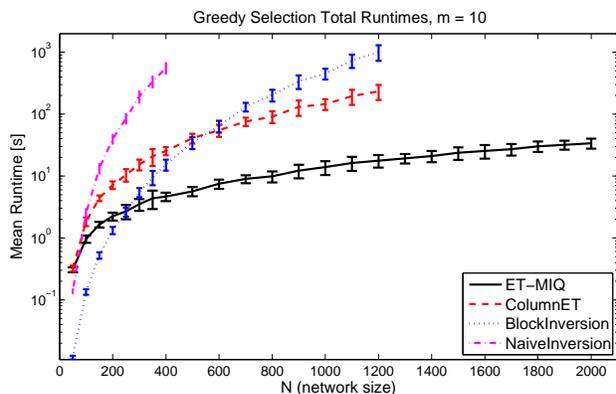

Figure 2: Mean runtime of the full greedy selection as a function of the network size N for randomized loopy graphs with $m = 10$ simple cycles of length $l = 4$.

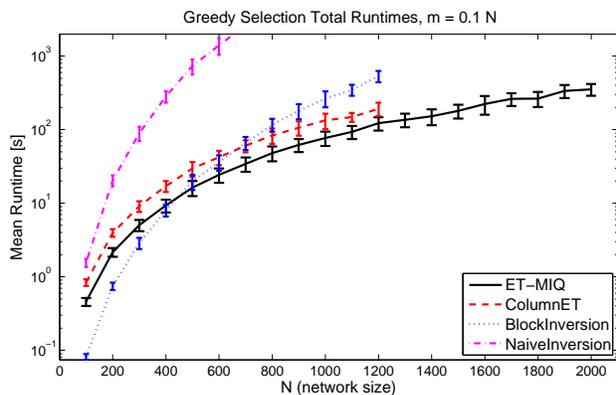

Figure 3: Mean runtime of the full greedy selection as a function of the network size N for randomized loopy graphs with $m = 0.1N$ simple cycles of length $l = 4$. As predicted, in the case where $m = \mathcal{O}(N)$, the ET-based algorithms have the same asymptotic complexity; ET-MIQ has a lower constant factor.

of Richardson iterations until the normalized residual error converges to a fixed tolerance of $\epsilon = 10^{-10}$; and the growth rate of $|\mathcal{S}|$ as a function of N , which indirectly affects the runtime through the budget β by permitting larger selection sets, and hence more rounds of greedy selection. To better disambiguate the second and third factors, we studied how the number of Richardson iterations to convergence (for a random input \mathbf{h} ; cf. (2)) varies as a function of N and found no significant correlation in the case where m is constant (not a function of N). The median iteration count was 7, with standard deviation of 0.6 and range 5-9 iterations.

We also considered the effect of letting m , the number of cycles in the graph, vary with N . A runtime comparison for $m = 0.1N$ is shown in Figure 3. Given that $E = m = \mathcal{O}(N)$ and $|\mathcal{R}| = \mathcal{O}(1)$, ET-MIQ has an asymptotic complexity of $\mathcal{O}(N|\mathcal{R}|E d^4) = \mathcal{O}(N^2)$. Similarly, the complexity of `ColumnET` is $\mathcal{O}(N|\mathcal{R}||\mathcal{S}|d^4) = \mathcal{O}(N^2)$. Fig-

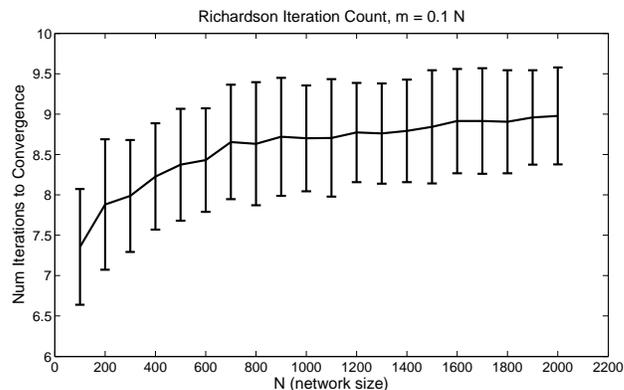

Figure 4: Number of Richardson iterations until convergence, for $m = 0.1N$ cycles.

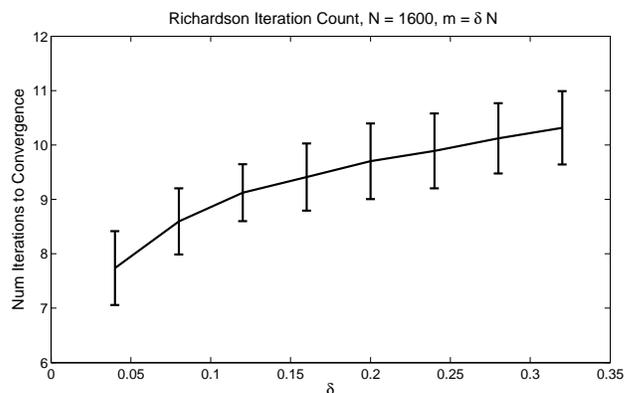

Figure 5: Number of Richardson iterations until convergence, for $N = 1600$ vertices, $m = \delta N$ cycles.

ure 3 confirms this agreement of asymptotic complexity, with ET-MIQ having a lower constant factor.

We repeated the convergence study for $m = 0.1N$ and varying $N \in [100, 2000]$ (see Figure 4). The mean iteration count appears to grow sublinearly in N ; the *actual* increase in iteration count over N is quite modest.

The relationship between the convergence and the problem structure was more clearly illustrated when we fixed a network size of $N = 1600$ and varied the number of 4-vertex cycles $m = \delta N$, for $\delta \in [0.04, 0.32]$ (see Figure 5). The cycle fraction δ is strongly correlated with the iteration count – and even slightly more correlated with its log – suggesting an approximately linear (and perhaps marginally sublinear) relationship with δ , albeit with a very shallow slope.

6 DISCUSSION

This paper has presented a method of computing nonlocal mutual information in Gaussian graphical models containing both cycles and nuisances. The base computations are

iterative and performed using trees embedded in the graph. We assess the proposed algorithm, ET-MIQ, and its alternatives (cf. Sections 3.5 and 5.1) in terms of the asymptotic complexity of performing a greedy update. For ET-MIQ, per-iteration complexity is $\mathcal{O}(N|\mathcal{R}|Ed^4)$, where N is the number of vertices in the network, $\mathcal{R} \subset \mathcal{V}$ is set of relevant latent variables that are of inferential interest, E is the number of edges cut to form the embedded tree, and d is the dimension of each random vector indexed by a vertex of the graph. Let κ denote the expected number of Richardson iterations to convergence of ET-MIQ, which is a direct function of the eigenproperties of the loopy precision matrix and its embedded trees and an indirect function of the other instance-specific parameters (number of cycles, network size, etc.). The experimental results of Section 5 suggest that the proposed algorithm, ET-MIQ, achieves significant reduction in computation over inversion-based methods, which have a total complexity of $\mathcal{O}(N^3|\mathcal{S}|d^3)$, where $\mathcal{S} \subset \mathcal{V}$ is the set of observable vertices that one has the option of selecting to later realize.

Based on the asymptotic complexities, we expect ET-MIQ would continue to achieve a significant reduction in computation for large networks whenever $|\mathcal{R}|Ed\kappa = o(N^2|\mathcal{S}|)$. Typically, the vertex dimension d is not a function of the network size. For dense networks ($|\mathcal{E}| = \mathcal{O}(N^2)$), we would not expect significant performance improvements using ET-MIQ; however, it is often the case that \mathcal{E} is sparse in the sense that the number of cut edges $E = \mathcal{O}(N)$. With $|\mathcal{S}| = \mathcal{O}(N)$ (the number of available observations growing linearly in the network size), asymptotic benefits would be apparent for $|\mathcal{R}|\kappa = o(N^2)$. Since we suspect κ grows sublinearly (and very modestly) in N , and whichever system utilizing the graphical model is free to choose \mathcal{R} , we expect that ET-MIQ would be beneficial for efficiently quantifying information in a wide class of active inference problems on Gaussian graphs.

The methods described in this paper are exact in the sense that all mutual information measures are estimated to within a specified tolerance. If the computational cost of quantifying mutual information were constrained (e.g., in a distributed estimation framework with communication costs), it may be of interest to develop algorithms for allowing prioritized approximation depending on how sensitive the overall information reward is to these conditional mutual information terms. In addition to algorithms for adaptively selecting embedded trees to hasten convergence, Chandrasekaran et al. (2008) propose methods for choosing and updating only a subset of variables in each Richardson iteration. If, in an essentially dual problem to (1), the cost of sensor selections were to be minimized subject to a quota constraint on the minimum amount of collected information, the ability to truncate information quantification when a subset of the graph falls below an informativeness threshold would be of potential interest, which we intend

to explore in future work.

Abstract

The term “CoRE kernel” stands for *correlation-resemblance kernel*. In many real-world applications (e.g., computer vision), the data are often high-dimensional, sparse, and non-binary. We propose two types of (nonlinear) CoRE kernels for non-binary sparse data and demonstrate the effectiveness of the new kernels through a classification experiment. CoRE kernels are simple with no tuning parameters. However, training nonlinear kernel SVM can be costly in time and memory and may not be always suitable for truly large-scale industrial applications (e.g., search). In order to make the proposed CoRE kernels more practical, we develop basic probabilistic hashing (approximate) algorithms which transform nonlinear kernels into linear kernels.

1 INTRODUCTION

The use of high-dimensional data has become popular in practice, especially in search, natural language processing (NLP), and computer vision. For example, Winner of 2009 PASCAL image classification challenge [27] used 4 million (non-binary) features. [5, 25, 28] mentioned datasets with billions or even trillions of features.

For text data, the use of extremely high-dimensional representations (e.g., n -grams) is the standard practice. In fact, binary representations for text data could be sufficient if the order of n -grams is high enough. On the other hand, in current practice of computer vision, it is still more common to use non-binary feature representations, for example, *local coordinate coding (LCC)* [29, 27]. It is often the case that in practice high-dimensional non-binary features might be appropriately sparsified without hurting the performance of subsequent tasks (e.g., classification). However simply binarizing the features will often incur loss of accuracies, sometimes significantly so. See Table 1 for an illustration of such a phenomenon.

Our contribution in this paper is the proposal of two types of (nonlinear) “CoRE” kernels, where “CoRE” stands for “correlation-resemblance”, for non-binary sparse data. Interestingly, using CoRE kernels leads to improvement in classification accuracies (in some cases significantly so) on a variety of datasets (see Table 2).

For practical large-scale applications, naive implementations of nonlinear kernels may be too costly (in time and/or memory), while linear learning methods (e.g., linear SVM or logistic regression) are extremely popular in industry. The proposed CoRE kernels would be facing the same challenge. To address this critical issue, we also develop basic hashing algorithms which approximate the CoRE kernels by linear kernels. These new hashing algorithms allow us to take advantage of highly efficient (batch or stochastic) linear learning algorithms, e.g., [15, 24, 1, 8].

In the rest of this section, we first review the definitions of correlation and resemblance, then we provide an experimental study to illustrate the loss of classification accuracies when sparse data are binarized.

1.1 Correlation

We assume a data matrix of size $n \times D$, i.e., n observations in D dimensions. Consider, without loss of generality, two data vectors $u, v \in \mathbb{R}^D$. The correlation is simply the normalized inner product defined as follows

$$\rho = \rho(u, v) = \frac{\sum_{i=1}^D u_i v_i}{\sqrt{\sum_{i=1}^D u_i^2 \sum_{i=1}^D v_i^2}} = \frac{A}{\sqrt{m_1 m_2}}, \quad (1)$$

$$\text{where } A = \sum_{i=1}^D u_i v_i, \quad m_1 = \sum_{i=1}^D u_i^2, \quad m_2 = \sum_{i=1}^D v_i^2$$

It is well-known that $\rho(u, v)$ constitutes a positive definite and linear kernel, which is one of the reasons why correlation is very popular in practice.

1.2 Resemblance

For binary data, the resemblance is commonly used:

$$R = R(u, v) = \frac{a}{f_1 + f_2 - a}, \quad (2)$$

$$\text{where } f_1 = \sum_{i=1}^D 1\{u_i \neq 0\}, \quad f_2 = \sum_{i=1}^D 1\{v_i \neq 0\},$$

$$a = \sum_{i=1}^D 1\{u_i \neq 0\}1\{v_i \neq 0\}$$

It was shown in [22] that the resemblance defines a type of positive definite (nonlinear) kernel. In this study, we will combine correlation and resemblance to define two new types of nonlinear kernels.

1.3 Linear SVM Experiment

Table 1 lists the datasets, which are non-binary and sparse. The table also presents the test classification accuracies using linear SVM on both the original (non-binary) data and the binarized data. The results in the table illustrate the noticeable drop of accuracies by using only binarized data.¹

Available at the UCI repository, *Youtube* is a multi-view dataset, and we choose the largest set of features (audio) for our experiment. *M-Basic*, *M-Rotate*, and *MNIST10k* were used in [18] for testing *abc-logitboost* and *abc-mart* [17] (and comparisons with deep learning [16]). For *RCV1*, we use a subset of the original testing examples (to facilitate efficient kernel computation later needed in the paper).

Table 1: Classification accuracies using linear SVM (LIBLINEAR [8]) on sparse non-binary data. As we always normalize data to unit norm, the correlation kernel ρ is naturally used in our study. We experiment with the l_2 -regularized linear SVM (with a regularization parameter “ C ”) and report the best test accuracies from a wide range of C values. Using binarized data (i.e., the last column), the test accuracies drop very noticeably in most datasets.

Dataset	#Train	#Test	Linear	Lin. Bin.
M-Basic	12,000	50,000	90.0%	88.9%
MNIST10k	10,000	60,000	90.0%	88.8%
M-Rotate	12,000	50,000	48.0%	44.4%
RCV1	20,242	60,000	96.3%	95.6%
USPS	7,291	2,007	91.8%	87.4%
Youtube	11,930	97,934	47.6%	46.5%

Figure 1 provides more detailed classification accuracy results for a wide range of C values, where C is the usual l_2 -regularization parameter in linear SVM.

¹For all datasets except *USPS*, we used “0” as the threshold to binarize the data. For *USPS*, since it contains many very small entries, we used a threshold which is slightly different from zero.

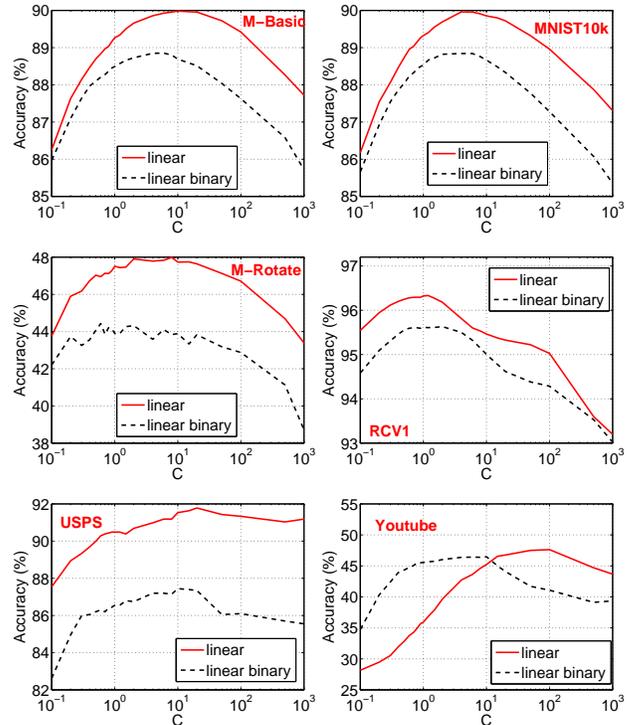

Figure 1: Test classification accuracies for both the original (non-binary, solid) and the binarized (dashed) data, using l_2 -regularized linear SVM with a regularization parameter C . We present results for a wide range of C values. The best (highest) values are summarized in Table 1.

While linear SVM is extremely popular in industrial practice, it is often not as accurate. Our proposed CoRE kernels will be able to produce noticeably more accurate results.

2 CORE KERNELS

We propose two types of CoRE kernels, which combine resemblance with correlation, for sparse non-binary data. Both kernels are positive definite. We will demonstrate the effectiveness of the two CoRE kernels using the same datasets in Table 1 and Figure 1.

2.1 CoRE Kernel, Type 1

The first type of CoRE kernel is basically the product of correlation ρ and the resemblance R , i.e.,

$$K_{C,1} = K_{C,1}(u, v) = \rho R \quad (3)$$

Later in the paper we will express $K_{C,1}$ as an (expectation of) inner product, i.e., $K_{C,1}$ is obviously positive definite.

If the data are fully dense (i.e., no zero entries), then $R = 1$ and $K_{C,1} = \rho$. On the other hand, if the data are binary, then $\rho = \frac{a}{\sqrt{f_1 f_2}}$ and $K_{C,1} = \frac{a}{\sqrt{f_1 f_2} f_1 + f_2 - a}$. See (2) for the definitions of f_1, f_2, a .

2.2 CoRE Kernel, Type 2

The second type of CoRE kernel perhaps appears less intuitive than the first type:

$$K_{C,2} = K_{C,2}(u, v) = \rho \frac{\sqrt{f_1 f_2}}{f_1 + f_2 - a} = \frac{\rho R}{a/\sqrt{f_1 f_2}} \quad (4)$$

If the data are binary, then $K_{C,2} = R$. We will, later in the paper, also write $K_{C,2}$ as an expectation of inner product to confirm it is also positive definite.

2.3 Kernel SVM Experiment

Figure 2 presents the classification accuracies on the same 6 datasets as in Figure 1 and Table 1, using nonlinear kernel SVM with three different kinds of kernels: CoRE Type 1, CoRE Type 2, and resemblance. We can see that resemblance (which only uses binary information of the data) does not perform as well as CoRE kernels.

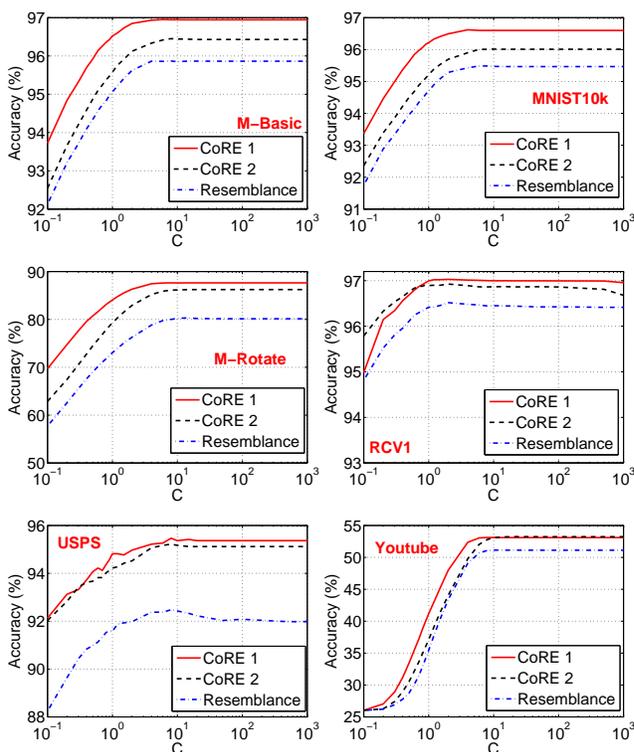

Figure 2: Test classification accuracies using nonlinear kernel SVM and three types of kernels: CoRE Type 1, CoRE Type 2, and resemblance. We use the LIBSVM pre-computed kernel functionality. Compared with the results of linear SVM in Figure 1, we can see CoRE kernels and resemblance kernel perform better (or much better, especially on *M-Rotate* dataset). The best results (highest points on the curves) are summarized in Table 2.

The best results in Figure 2 are summarized in Table 2. It is interesting to compare them with the test accuracies of linear SVM in Table 1 and Figure 1. We can see that CoRE kernels perform very well, without using additional

tuning parameters. In fact, if we compare the best results in [16, 18] (e.g., RBF SVM, abc-boosting, or deep learning) on MNIST10k, M-Rotate, and M-Basic, we will see that CoRE kernels (with no tuning parameters) can achieve the same (or similar) performance.

Table 2: Best test classification accuracies (in %) for five different kernels. The first two columns (i.e., “linear” and “linear binary”) are already shown in Table 1.

Dataset	Lin.	Lin. Bin.	Res.	CoRE1	CoRE2
M-Basic	90.0	88.9	95.9	97.0	96.5
MNIST10k	90.0	88.8	95.5	96.6	96.0
M-Rotate	48.0	44.4	80.3	87.6	86.2
RCV1	96.3	95.6	96.5	97.0	96.9
USPS	91.8	87.4	92.5	95.5	95.2
Youtube	47.6	46.5	51.1	53.1	53.2

We shall mention that our experiments can be fairly easily reproduced because all datasets are public and we use standard SVM packages (LIBSVM and LIBLINEAR) without any modifications. We also provide the results for a wide range of C values in Figure 1 and Figure 2. Note that, because we use pre-computed kernel functionality of LIBSVM (which consumes very substantial memory to store the kernel matrix), we only experiment with training data of moderate sizes, to ensure repeatability (by other researchers without access to machines with large memory).²

2.4 Challenges with Nonlinear Kernel SVM

[2, Section 1.4.3] mentioned three main computational issues of kernels summarized as follows:

1. *Computing kernels is very expensive.*
2. *Computing a full kernel matrix is wasteful, because not all pairwise kernel values are used during training.*
3. *The kernel matrix does not fit in memory.* The cost of storing the full kernel matrix in the memory is $O(n^2)$, which is not realistic for most PCs even for merely 10^5 , while the industry has used training data with billions of examples. Thus, kernel evaluations are often conducted *on the fly*, which means the computational cost is dominated by kernel evaluations.

In fact, evaluating kernels on-demand would encounter another serious (and often common) issue if the dataset itself is too big for the memory.

All these crucial issues motivate us to develop hashing algorithms to approximate CoRE kernels by linear kernels.

²At the time this paper was written, the implementation of LIBSVM restricted the maximum size of the kernel matrix. The LIBSVM team recently has made effort on this issue and it is expected such a restriction will be removed in the new release. We highly appreciate Dr. Chih-Jen Lin and his team for the efforts.

2.5 Benefits of Hashing

Our goal is to develop good probabilistic hashing algorithms to (approximately) transform our proposed nonlinear CoRE kernels into linear kernels. Once we have the new data representations (i.e., the hashed data), we can use highly efficient batch or stochastic linear methods for training SVM (or logistic regression) [15, 24, 1, 8].

Another benefit of hashing would be in the context of approximate near neighbor search because probabilistic hashing provides a (often good) strategy for space partitioning (i.e., bucketing) which will help reduce the search time (i.e., no need to scan all data points). Our proposed hashing methods can be modified to become an instance of *locality sensitive hashing (LSH)* [13] in the space of CoRE kernels.

At this stage, we will focus on developing hashing algorithms for CoRE kernels based on the standard *random projection* and *minwise hashing* methods. There will be plenty of room for improvement which we leave for future work.

We first provide a review of the two basic building blocks.

3 REVIEW OF RANDOM PROJECTIONS AND MINWISE HASHING

Typically, the method of random projections is used for dense high-dimensional data, while the method of minwise hashing is very useful for sparse (often binary) data. The proposed hashing algorithms for CoRE kernels combine random projections and minwise hashing.

3.1 Random Projections

Consider two vectors $u, v \in \mathbb{R}^D$. The idea of random projection is simple. We first generate a random vector of i.i.d. entries $r_i, i = 1$ to D , and then compute the inner products as the hashed values:

$$P(u) = \sum_{i=1}^D u_i r_i, \quad P(v) = \sum_{i=1}^D v_i r_i \quad (5)$$

For the convenience of theoretical analysis, we adopt the choice of $r_i \sim N(0, 1)$, which is a typical choice in the literature. Several variants of random projections like [21, 28] are essentially equivalent, as analyzed in [22].

In this study, we always assume the data are normalized, i.e., $\sum_{i=1}^D u_i^2 = \sum_{i=1}^D v_i^2 = 1$. Note that computing the l_2 norms of all the data points only requires scanning the data once which is anyway needed during data collection/processing. For normalized data, it is known that $E[P(u)P(v)] = \rho$. In order to estimate ρ , we need to use k random projections to generate $P_j(u), P_j(v), j = 1$ to k , and estimate ρ by $\frac{1}{k} \sum_{j=1}^k P_j(u)P_j(v)$, which is also an inner product. This means we can directly use the projected data to build a linear classifier.

3.2 Minwise Hashing

The method of minwise hashing [3] is very popular for computing set similarities, especially for industrial applications, for example, [3, 9, 12, 26, 14, 7, 11, 23, 4].

Consider the space of the column numbers: $\Omega = \{1, 2, 3, \dots, D\}$. We assume a random permutation $\pi : \Omega \rightarrow \Omega$ and apply π on the coordinates of both vectors u and v . For example, consider $D = 4, u = [0, 0.45, 0.89, 0]$ and $\pi : 1 \rightarrow 3, 2 \rightarrow 1, 3 \rightarrow 4, 4 \rightarrow 2$. Then the permuted vector becomes $\pi(u) = [0.45, 0, 0, 0.89]$. In this example, the first nonzero column of $\pi(u)$ is 1, and the corresponding value of the coordinate is 0.45. For convenience, we introduce the following notation:

$$L(u) = \text{location of first nonzero entry of } \pi(u) \quad (6)$$

$$V(u) = \text{value of first nonzero entry of } \pi(u) \quad (7)$$

In this example, we have $L(u) = 1$ and $V(u) = 0.45$.

The well-known *collision probability*

$$\Pr(L(u) = L(v)) = R(u, v) = R \quad (8)$$

can be used to estimate the resemblance R . To do so, we need to generate k permutations $\pi_j, j = 1$ to k .

4 HASHING CORE KERNELS

The goal is to develop unbiased linear estimators of CoRE Kernels $K_{C,1}$ and $K_{C,2}$. Linear estimators can be written as inner products. We assume that we have already conducted random projections and minwise hashing k times. In other words, for each data vector u , we have the hashed values $P_j(u), L_j(u), V_j(u), j = 1$ to k . Recall the definitions of P_j, L_j, V_j in (5), (6), and (7), respectively.

4.1 Hashing Type 1 CoRE Kernel

Our proposed estimator of $K_{C,1}$ is

$$\hat{K}_{C,1}(u, v) = \sum_{j=1}^k P_j(u)P_j(v)1\{L_j(u) = L_j(v)\} \quad (9)$$

The following Theorem 1 shows $\hat{K}_{C,1}$ is an unbiased estimator and provides its variance.

Theorem 1

$$E\left(\hat{K}_{C,1}\right) = K_{C,1} \quad (10)$$

$$\text{Var}\left(\hat{K}_{C,1}\right) = \frac{1}{k} \{(1 + 2\rho^2)R - \rho^2 R^2\} \quad (11)$$

Proof: See Appendix A. □

A simple argument can show that $\hat{K}_{C,1}$ could be written as an inner product and hence $K_{C,1}$ is positive definite. Although this fact is obvious since $K_{C,1}$ is a product of two positive definite kernels, we would like to present a constructive proof because the construction is basically the same procedure for expanding the hashed data before feeding them to a linear SVM solver.

Recall, L_j is the location of the first nonzero after minwise hashing. Basically, we can view $L_j(u)$ equivalently as a vector of length D whose coordinates are all zero except the $L_j(u)$ -th coordinate. The value of the only nonzero coordinate will be $P_j(u)$. For example, suppose $D = 4$, $L_j(u) = 2$, $P_j(u) = 0.1$. Then the equivalent vector would be $[0, 0.1, 0, 0]$. With k projections and k permutations, we can have k such vectors. This way, we can write $\hat{K}_{C,1}$ as an inner product of two $D \times k$ -dimensional sparse vectors.

Note that the input data format of standard SVM packages is the sparse format. For linear SVM, the cost is essentially determined by the number of nonzeros (in this case, k), not much to do with the dimensionality (unless it is too high). If D is too high, then we can adopt the standard trick of *b-bit minwise hashing* [22] by only using the lowest b bits of $L_j(u)$. This will lead to an efficient implementation.

4.2 Hashing Type 2 CoRE Kernel

Our proposed estimator for Type 2 CoRE Kernel is

$$\hat{K}_{C,2} = \frac{\sqrt{f_1 f_2}}{k} \sum_{j=1}^k V_j(u) V_j(v) 1\{L_j(u) = L_j(v)\} \quad (12)$$

Recall that we always assume the data (u, v) are normalized. For example, if the data are binary, then we have $u_i = \frac{1}{\sqrt{f_1}}$, $v_i = \frac{1}{\sqrt{f_2}}$. Hence the values $V_j(u)$ and $V_j(v)$ are small (and we need the term $\sqrt{f_1 f_2}$).

This estimator is again unbiased. Theorem 2 proves the mean the variance of $\hat{K}_{C,2}$.

Theorem 2

$$E(\hat{K}_{C,2}) = K_{C,2} \quad (13)$$

$$\begin{aligned} \text{Var}(\hat{K}_{C,2}) & \quad (14) \\ &= \frac{1}{k} \frac{f_1 f_2}{f_1 + f_2 - a} \left(\sum_{i=1}^D u_i^2 v_i^2 - \frac{(\sum_{i=1}^D u_i v_i)^2}{(f_1 + f_2 - a)} \right) \end{aligned}$$

Proof: See Appendix B. \square

Once we understand how to express $\hat{K}_{C,1}$ as an inner product, it should be easy to see that $\hat{K}_{C,2}$ can also be written as an inner product. Again, suppose $D = 4$, $L_j(u) = 2$, and $V_j(u) = 0.05$. We can consider an equivalent vector

$[0, 0.05\sqrt{f_1}, 0, 0]$. In other words, the difference between $\hat{K}_{C,1}$ and $\hat{K}_{C,2}$ is what value we should put in the nonzero location. Compared to $\hat{K}_{C,1}$, one advantage of $\hat{K}_{C,2}$ is that it only requires the permutations and thus eliminates the cost for conducting random projections.

As one would expect, the variance of $\hat{K}_{C,2}$ would be large if the data are heavy-tailed. However, when the data are appropriately normalized (e.g., via the TF-IDF transformation, or simply binarized), $\text{Var}(\hat{K}_{C,2})$ is actually quite small. Consider the extreme case when the data are binary, i.e., $u_i = \frac{1}{\sqrt{f_1}}$, $v_i = \frac{1}{\sqrt{f_2}}$, we have $\text{Var}(\hat{K}_{C,2}) = \frac{1}{k} (R - R^2)$, which is (considerably) smaller than $\text{Var}(\hat{K}_{C,1}) = \frac{1}{k} \{(1 + 2\rho^2) R - \rho^2 R^2\}$.

4.3 Experiment for Validation

To validate the theoretical results in Theorem 1 and Theorem 2, we provide a set of experiments in Figure 3. Two pairs of word vectors are selected: “A–THE” and “HONG–KONG”, from a chunk of web crawls. For example, the vector “HONG” is a vector whose i -th entry is the number of occurrences of the word “HONG” in the i -th document. For each pair, we apply the two proposed hashing algorithms to estimate $K_{C,1}$ and $K_{C,2}$. With sufficient repetitions (i.e., k), we can empirically compute the mean square errors ($\text{MSE} = \text{Var} + \text{Bias}^2$), which should match the theoretical variances if the estimators are indeed unbiased and the variance formulas, (11) and (14), are correct.

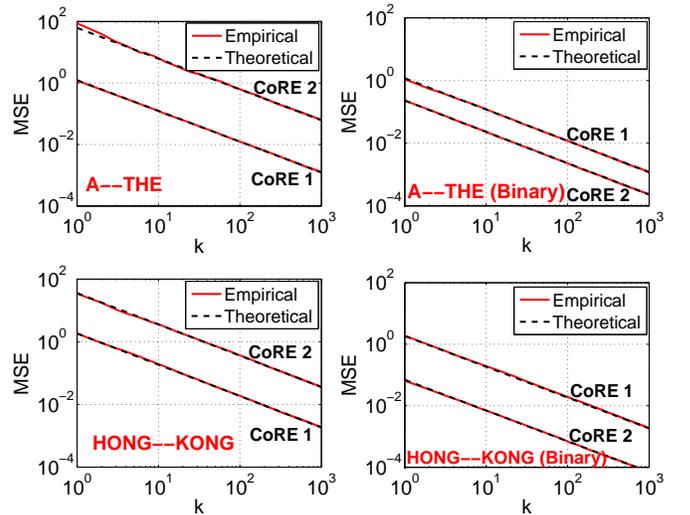

Figure 3: Mean square errors ($\text{MSE} = \text{Var} + \text{Bias}^2$) on two pairs of word vectors for validating Theorems 1 and 2. The empirical MSEs (solid curves) essentially overlap the theoretical variances (dashed curves), (11) and (14). When using the raw counts (left panels), the MSEs of $\hat{K}_{C,2}$ is significantly higher than the MSEs of $\hat{K}_{C,1}$. However, when using binarized data (right panels), the MSEs of $\hat{K}_{C,2}$ become noticeably smaller, as expected.

The number of word occurrences is a typical example of highly heavy-tailed data. Usually when text data are used in machine learning tasks, they have to be appropriately weighted (e.g., TF-IDF) or simply binarized. Figure 3 presents the results on the original data (raw counts) as well as the binarized data, to verify the formulas in Theorem 1 and Theorem 2, for $k = 1$ to 1000.

Indeed, the plots show that the empirical MSEs essentially overlap the theoretical variances. In addition, the MSEs of $\hat{K}_{C,2}$ is significantly larger than the MSEs of $\hat{K}_{C,1}$ on the raw data, as expected. Once the data are binarized, the MSEs of $\hat{K}_{C,2}$ become smaller, also as expected.

5 HASHING CORE KERNELS FOR SVM

In this section, we provide a set of experiments for using the hashed data as input for a linear SVM solver (LIBLINEAR). Our goal is to approximate the (nonlinear) CoRE kernels with linear kernels. In Section 4, we have explained how to express the estimators $\hat{K}_{C,1}$ and $\hat{K}_{C,2}$ as inner products by expanding the hashed data. With k permutations and k random projections, the number of nonzeros of the expanded data is precisely k . To reduce the dimensionality, we use only the lowest b bits of the locations [22]. In this study, we experiment with $b = 1, 2, 4, 8$.

Figure 4 presents the results on the **M-Rotate** dataset. As shown in Figure 1 and Table 1, using linear kernel can only achieve a test accuracy of 48%. This means, if we use random projections (or the variants, e.g., [21, 28]), which approximate inner products, then the best accuracy we can achieve would be about 48%. For this dataset, the performance of CoRE kernels (and resemblance kernel) is astonishing, as shown in Figure 2 and Table 2. Thus, we choose this dataset to demonstrate our proposed hashing algorithms combined with linear SVM can also approach the performance of (nonlinear) CoRE kernels.

To explain the procedure, we use the same examples as in Section 4. Suppose we apply k minwise hashing and k random projections on the data and we consider without loss of generality the data vector u . For the j -th projection and j -th minwise hashing, suppose $L_j(u) = 2, V_j(u) = 0.05, P_j(u) = 0.1$. Recall L_j and V_j are, respectively, the location and the value of the first nonzero entry after minwise hashing. P_j is the projected value obtained from random projection.

In order to use linear SVM to approximate kernel SVM with Type 1 CoRE kernel, for the above example, we expand the j -th hashed data as a vector $[0, 0.1, 0, 0]$ if $b = 2$, or $[0, 0.1]$ if $b = 1$. We then concatenate k such vectors to form a vector of length $2^b \times k$ (with exactly k nonzeros). Before we feed the expanded hashed data to LIBLINEAR, we normalize the vectors to have unit norm. The experimental results are presented in the left panels of Figure 4.

To approximate Type 2 CoRE kernel, we expand the j -th hashed data of u as $[0, 0.05\sqrt{f_1}, 0, 0]$ if $b = 2$, or $[0, 0.05\sqrt{f_1}]$ if $b = 1$, where f_1 is the number of nonzero entries in the original data vector u . Again, we concatenate k such vectors. The experimental results are presented in the middle panels of Figure 4.

To approximate resemblance kernel, we expand the j -th hashed data of u as $[0, 1, 0, 0]$ if $b = 2$ or $[0, 1]$ if $b = 1$ and we concatenate k such vectors.

The results in Figure 4 are exciting because linear SVM on the original data can only achieve an accuracy of 48%. Our proposed hashing methods + linear SVM can achieve $> 86\%$. In comparison, using only the original b -bit minwise hashing, the accuracy can still reach about 80%. Again, we should mention that other hashing algorithms which aim at approximating the inner product (such as random projections and variants) can at most achieve the same result as using linear SVM on the original data. This is the significant advantage of CoRE kernels.

6 DISCUSSIONS

There is a line of related work called *Conditional Random Sampling (CRS)* [19, 20] which was also designed for sparse non-binary data. Basically, the idea of CRS is to keep the first (smallest) k nonzero entries after applying one permutation on the data. [19, 20] developed the trick to construct an (essentially) equivalent random sample for each pair. CRS is naturally applicable to non-binary data and is capable of estimating any (linear) summary statistics, in static as well as dynamic (streaming) settings. In fact, the estimators developed for CRS can be (substantially) more accurate than the estimator for minwise hashing.

The major drawback of CRS is that the samples are not appropriately aligned. Consequently, CRS is not suitable for training linear SVM (or other applications which require the input data to be in a metric space). Our method has overcome this drawback. Of course, CRS can still be used in important scenarios such as estimating similarities during the re-ranking stage in LSH.

Why do we need to two types of CoRE kernels? While hashing Type 2 CoRE kernel is simpler because it requires only the random permutations, Table 2 shows that Type 1 CoRE kernel can often achieve better results than Type 2 CoRE kernel. Therefore, we develop hashing methods for both CoRE kernels, to provide users with more choices.

There are many promising extensions. For example, we can construct new kernels based on CoRE kernels (which currently do not have tuning parameters), by using the exponential function and introducing an additional tuning parameter γ , just like RBF kernel. This will allow more flexibility and potentially further improve the performance.

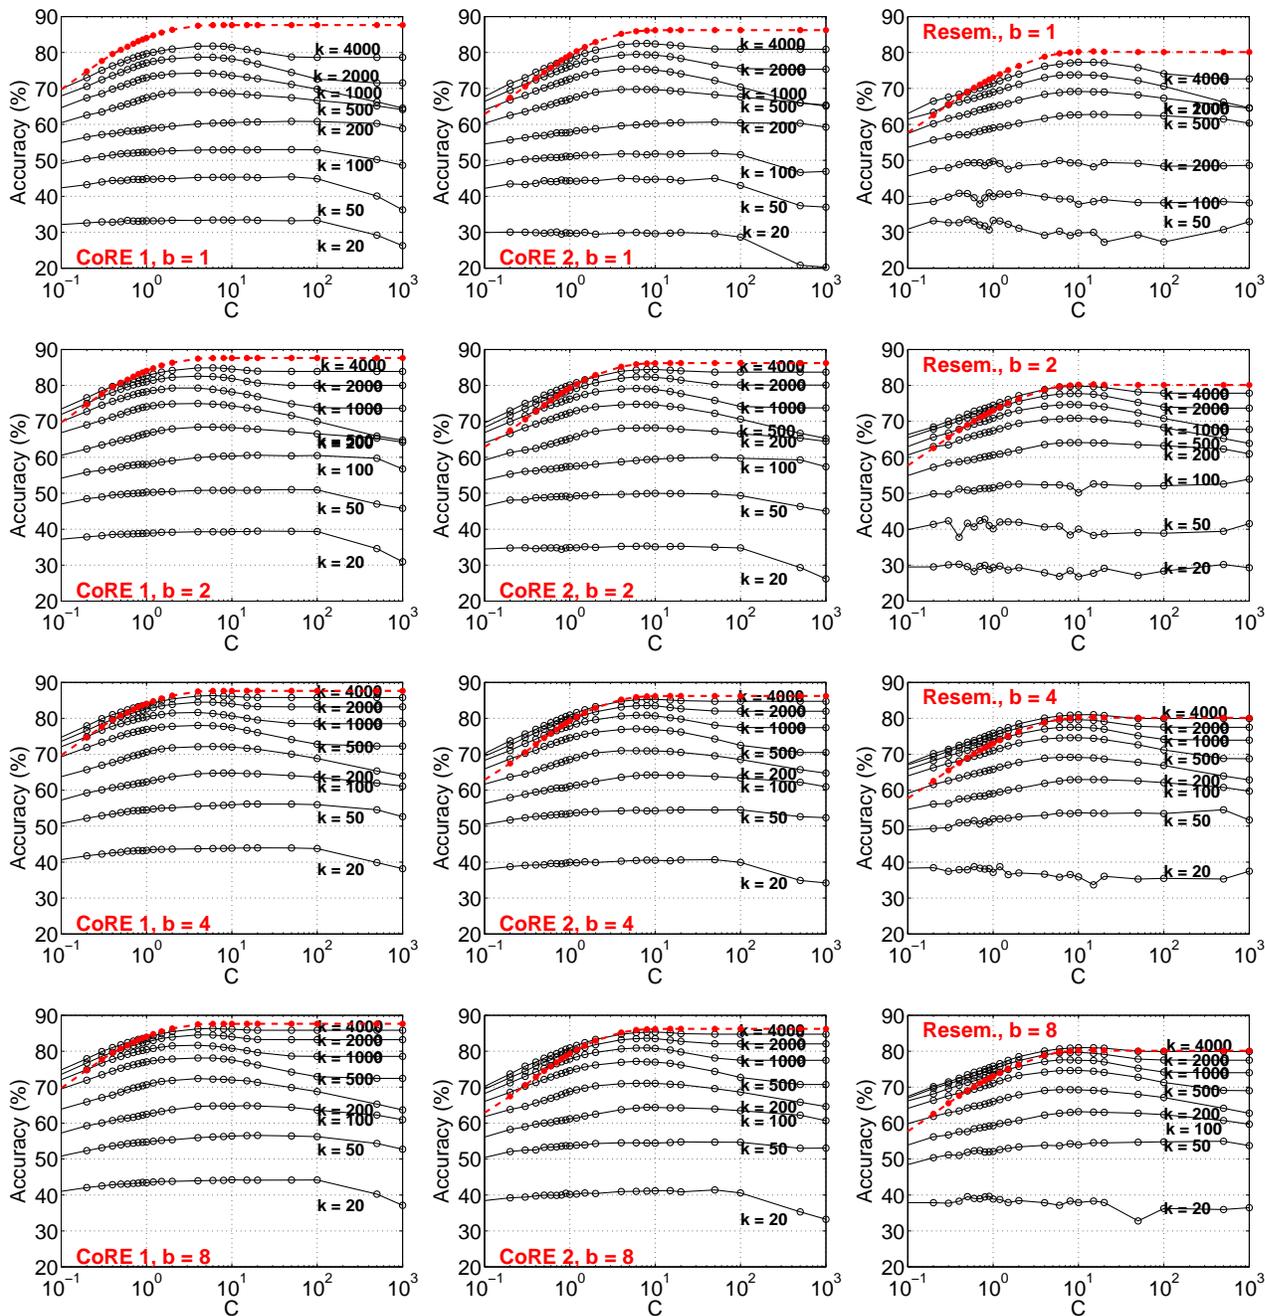

Figure 4: Test classification accuracies on the *M-Rotate* dataset using our proposed hashing methods and linear SVM (LIBLINEAR). The red (if color is available) dot curves are the results of kernel SVM on the original data (i.e., the same curves from Figure 2), using Type 1 CoRE kernel (left panels), Type 2 CoRE kernel (middle panels), and resemblance kernel (right panels), respectively. We apply both b -bit minwise hashing (with $b = 1, 2, 4, 8$) and random projections k times and feed the (expanded) hashed data to linear SVM.

Another interesting line of extensions would be applying other hashing algorithms on top of our generated hashed data. This is possible again because we can view our estimators as inner products and hence we can apply other hashing algorithms which approximate inner products on top of our hashed data. The advantage is the potential further data compression. Another advantage would be in the context of sublinear time approximate near neighbor search (when the target similarity is the CoRE kernels).

For example, we can apply another layer of random projections on top of the hashed data and then store the signs of the new projected data [6, 10]. These signs, which are bits, provide good indexing & space partitioning capability to allow sublinear time approximate near neighbor search under the framework of *locality sensitive hashing (LSH)* [13]. This way, we can search for near neighbors in the space of CoRE kernels (instead of the space of inner products).

In addition, we expect that our work will inspire new research on the development of more efficient (b -bit) minwise hashing methods when the size of the space (i.e., D) is not too large and the data are not necessarily extremely sparse. Traditionally, minwise hashing has been used as a data size/dimensionality reduction tool, typically for very large D (e.g., 2^{64}). Readers perhaps have noticed that, in our paper, (b -bit) minwise hashing could be utilized as a *data expansion* tool in order to apply efficient linear algorithms. When D is not very large, many aspects of the algorithms such as pseudo-random number generation would be quite different and new research may be necessary.

7 CONCLUSION

Current popular hashing methods, such as random projections and variants, often focus on approximating inner products and large-scale linear classifiers (e.g., linear SVM). However, linear kernels often do not achieve good performance. In this paper, we propose two types of nonlinear CoRE kernels which outperform linear kernels, sometimes by a large margin, on sparse non-binary data (which are common in practice). Because CoRE kernels are nonlinear, we accordingly develop basic hash methods to approximate CoRE kernels with linear kernels. The hashed data can be fed into highly efficient linear classifiers. Our experiments confirm the findings. We expect this work will inspire a new line of research on kernel learning, hashing algorithms, and large-scale learning.

A Proof of Theorem 1

To compute the expectation and variance of the estimator $\hat{K}_{C,1} = \frac{1}{k} \sum_{j=1}^k P_j(u)P_j(v)1\{L_j(u) = L_j(v)\}$, we need the first two moments of $P_j(u)P_j(v)1\{L_j(u) = L_j(v)\}$. The first moment is

$$\begin{aligned} & E [P_j(u)P_j(v)1\{L_j(u) = L_j(v)\}] \\ &= E [P_j(u)P_j(v)] \Pr(L_j(u) = L_j(v)) = \rho R \end{aligned}$$

which implies that $E(\hat{K}_{C,1}) = K_{C,1} = \rho R$. The second moment is

$$\begin{aligned} & E [P_j^2(u)P_j^2(v)1\{L_j(u) = L_j(v)\}] \\ &= E [P_j^2(u)P_j^2(v)] \Pr(L_j(u) = L_j(v)) \\ &= (1 + 2\rho^2) \rho R \end{aligned}$$

Here, we have used the result in the prior work [21]: $E [P_j^2(u)P_j^2(v)] = 1 + 2\rho^2$. Therefore, the variance is

$$\text{Var}(\hat{K}_{C,1}) = \frac{1}{k} \{(1 + 2\rho^2) R - \rho^2 R^2\}$$

This completes the proof.

B Proof of Theorem 2

We need the first two moments of the estimator $\hat{K}_{C,2} = \frac{1}{k} \sum_{j=1}^k V_j(u)V_j(v)1\{L_j(u) = L_j(v)\}\sqrt{f_1 f_2}$

Because

$$\begin{aligned} & E [V_j(u)V_j(v)1\{L_j(u) = L_j(v)\}] \\ &= E [V_j(u)V_j(v)1\{L_j(u) = L_j(v)\} | L_j(u) = L_j(v)] \\ &\quad \times \Pr(L_j(u) = L_j(v)) \\ &= \frac{\sum_{i=1}^D u_i v_i}{a} R = \rho \frac{1}{f_1 + f_2 - a} \end{aligned}$$

we know

$$E(\hat{K}_{C,2}) = \frac{1}{k} \sum_{j=1}^k \rho \frac{\sqrt{f_1 f_2}}{f_1 + f_2 - a} = K_{C,2}$$

and

$$\begin{aligned} & E [V_j^2(u)V_j^2(v)1\{L_j(u) = L_j(v)\}] \\ &= E [V_j^2(u)V_j^2(v)] \Pr(L_j(u) = L_j(v)) \\ &= \frac{\sum_{i=1}^D u_i^2 v_i^2}{a} R = \frac{\sum_{i=1}^D u_i^2 v_i^2}{f_1 + f_2 - a} \end{aligned}$$

Therefore,

$$\begin{aligned} & \text{Var}(\hat{K}_{C,2}) \\ &= \frac{1}{k} \frac{f_1 f_2}{f_1 + f_2 - a} \left(\sum_{i=1}^D u_i^2 v_i^2 - \frac{(\sum_{i=1}^D u_i v_i)^2}{(f_1 + f_2 - a)} \right) \end{aligned}$$

This completes the proof.

Abstract

The main shortcoming of sparse recovery with a convex regularizer is that it is a biased estimator and therefore will result in a suboptimal performance in many cases. Recent studies have shown, both theoretically and empirically, that non-convex regularizer is able to overcome the biased estimation problem. Although multiple algorithms have been developed for sparse recovery with non-convex regularization, they are either computationally demanding or not equipped with the desired properties (i.e. optimal recovery error, selection consistency and oracle property). In this work, we develop an algorithm for efficient sparse recovery based on proximal gradient descent. The key feature of the proposed algorithm is introducing adaptive non-convex regularizers whose shrinking threshold vary over iterations. The algorithm is compatible with most popular non-convex regularizers, achieves a geometric convergence rate for the recovery error, is selection consistent, and most importantly has the oracle property. Based on the proposed framework, we suggest to use a so-called ACCQ regularizer, which is equivalent to zero proximal projection gap adaptive hard-thresholding. Experiments with both synthetic data sets and real images verify both the efficiency and effectiveness of the proposed method compared to the state-of-the-art methods for sparse recovery.

1 INTRODUCTION

Inspired by the seminal work of compressive sensing (Candès et al., 2006), numerous algorithms have been

Ming Lin and Changshui Zhang are from State Key Laboratory on Intelligent Technology and Systems, Tsinghua National Laboratory for Information Science and Technology (TNList), Department of Automation, Tsinghua University, Beijing, P.R. China 100084.

developed to recover a sparse vector from its linear low dimensional measurement. Most of these algorithms can be classified into two categories: greedy methods and optimization-based methods. Greedy methods aggressively select the support set as they recover the target sparse vector ((Tropp and Wright, 2010) and references therein). Although they are computationally efficient, the greedy methods are usually sensitive to noise especially when the target signal is not exactly sparse. Optimization-based methods, on the other hand, are known to be more robust to noise but at the price of a higher computational cost (Zou and Hastie, 2005; Rosenbaum and Tsybakov, 2010; Xu et al., 2010).

Most optimization-based methods cast sparse recovery into convex optimization problems. The most well known algorithms in this category are LASSO (Tibshirani, 1996; Efron et al., 2004) and Dantzig selector (Candes and Tao, 2007). A main drawback of convex optimization based methods for sparse recovery is that they are biased estimators, i.e. the solutions found by the convex optimization based methods do not have the *oracle property* (Fan and Li, 2001; Zhang and Zhang, 2011), which is sometime referred to as *Lasso bias* (Zhang and Zhang, 2011). We note that there are two different versions of oracle property used in the literature: the asymptotical one that examines the oracle property with the number of measurements going to infinity (Fan and Li, 2001) and the finite sample one (Zhang and Zhang, 2011) that examines the oracle property with a finite number of measurements. In this study, we will use the finite sample version of oracle property.

It was first suggested in (Fan and Li, 2001) that the Lasso bias can be corrected by a non-convex regularizer. Several theory and algorithms have been developed recently for sparse recovery using concave regularizers (Zhang and Zhang, 2011; Zhang, 2012; Loh and Wainwright, 2013), and their effectiveness for sparse recovery has been verified empirically by several recent studies (Xiang et al., 2013; Gong et al., 2013a; Ochs et al., 2013). Despite the appealing result, it remains to be challenging as how to efficiently solve the optimization problem with non-convex regular-

izer.

Zhang (2012) proposed a multi-stage algorithm that relaxes a non-convex optimization problem into a sequence of convex optimization problems with weighted ℓ_1 regularizers. Besides the recovery error, the author also showed in (Zhang, 2012) that the solution found by multi-stage algorithm satisfies the oracle property when the non-zero entries in the target sparse vector are sufficiently large. The main shortcoming of the multi-stage algorithm is its potentially high computational cost as it needs to solve a sequence of ℓ_1 regularized optimization problems. (Zhaoran Wang, 2013) relax this problem by computing approximate solution at each stage, but still require multiple stages thus is not very efficient. Several proximal gradient descent methods have been proposed for non-convex regularizers (Gong et al., 2013b; Loh and Wainwright, 2013) that enjoy higher computational efficiency than the multi-stage algorithm. However, it is unclear if the solutions found by these algorithms will be unbiased estimators and have the oracle property, the key reason for using a non-convex regularizer.

In this work, we propose an algorithm for sparse recovery using adaptive non-convex regularizer to develop efficient algorithms with all the desired properties above. The proposed framework, on one hand, enjoys the high computational efficiency and achieves a linear convergence rate in the recovery error as some of the proximal gradient descent methods do. On the other hand, like the multi-stage algorithm, the proposed framework is able to find a sparse solution with optimal recovery error, selection consistency, and oracle property under appropriate conditions. The key feature introduced by the proposed framework is introducing *adaptive concave regularizers* whose shrinking-threshold vary over iterations. It is the introduction of the adaptive concave regularizer that allows us to effectively remove the noise and identify the support set, leading to high computational efficiency and a solution with optimal recovery error and oracle property.

Although the proposed algorithm is compatible with most popular non-convex regularizers, via a more deep examination, we find that the type of non-convex regularizer is not important at all. What really matters is the so-called *proximal projection gap* that will be defined later. This gap determines the bias of regularizer in sparse estimation. Based on this discovery, we propose to use a so-called ACCQ regularizer, whose proximal projection gap is zero. From optimization viewpoint, the ACCQ regularizer is equivalent to one kind of hard-thresholding algorithms with adaptive threshold. The ACCQ regularizer is the only regularizer whose projection gap is zero, thus is superior than other alternatives.

The rest of this paper is organized as following. Section 2 reviews the related work. Section 3 describes the proposed algorithm for sparse recovery. Section 4 analyzes theoretic

cal properties. Experimental results with both synthesized and real data sets are summarized in Section 5. Section 6 encloses our study with open questions.

2 RELATED WORK

We briefly review the related work on sparse recovery, with focus on non-convex regularizer. More complete references on the related subject can be found in (Tropp and Wright, 2010), (Davenport et al., 2011) and (Zhang and Zhang, 2011).

Most sparse recovery methods are based on ℓ_1 regularization. The most well algorithm is LASSO (Tibshirani, 1996; Efron et al., 2004). Numerous algorithms have been developed to solve LASSO related optimization problem efficiently (Beck and Teboulle, 2009; Foucart, 2012). It has been shown that ℓ_1 regularization can be solved efficiently with a linear convergence (up to stochastic tolerance) (Xiao and Zhang, 2012; Agarwal et al., 2012). A main problem with LASSO is that it is a biased estimator. In particular, LASSO is unable to perfectly recover the solution of oracle Least Square Estimation (LSE), a property that is usually referred to as *oracle property*. We emphasize that the LASSO bias is not an artifact of analysis, and it does show up noticeably in the recovery error, according to our empirical study as well as others (Zhang, 2012; Zou, 2006). It was pointed out in (Fan and Li, 2001; Zhang and Zhang, 2011) that LASSO bias also exists in other convex regularizers.

Multiple non-convex regularizers have been proposed to address the bias of convex regularizers, including Geman Penalty (GP) (Geman and Yang, 1995; Trzasko and Manduca, 2009), SCAD (Fan and Li, 2001), Log Sum Penalty (LSP) (Candes et al., 2008), ℓ_q norm (Foucart and Lai, 2009), Minimax Concave Penalty (MCP) (Zhang, 2010a), Capped- ℓ_1 norm (Loh and Wainwright, 2013). Various algorithms have been developed to find local optimal for non-convex regularizers (Zhang and Zhang, 2011) and references therein). It is however unclear if the local solutions found by these algorithms have the desired properties (i.e. the optimal recovery error and the oracle property). Only a handful algorithms that achieve the desired properties, including the multi-stage algorithm (Zhang, 2010b), adaptive LASSO (Zou, 2006) that can be shown as a special case of multi-stage algorithm and achieve the asymptotical oracle property, and the forward and backward regression scheme (FOBA) (Zhang, 2011), based on adaptive regularization, also finds the solutions with all the desired properties. FOBA is guaranteed to terminate within $O(s)$ iterations, where s is the sparsity. The main limitation of FOBA is that it is unclear if the oracle property recovery error of their algorithm can achieve a linear convergence rate. Each iteration of FOBA is an optimization problem therefore is not efficient. Ji Liu (2013) propose an variant of FOBA but

they still suffer the same problem. The FOBA and its variants make different assumptions that is complementary to our analysis. Although the multi-stage algorithm achieves a linear convergence, it requires to solve a weighted ℓ_1 regularization problem that can be computationally costly when the dimension of data is high.

3 SPARSE RECOVERY BY ADAPTIVE NON-CONVEX REGULARIZER

In this section, we first introduce the background materials and notations for sparse recovery. We then present our algorithm and its main theoretical property. The sketch of proofs is given at the end of this section.

3.1 BACKGROUNDS AND NOTATIONS

Let A be an $n \times d$ design matrix and $\mathbf{y} \in \mathbb{R}^n$ be response vector satisfying

$$\mathbf{y} = A\mathbf{x}_* + \mathbf{z}, \quad (1)$$

where $\mathbf{x}_* \in \mathbb{R}^d$ is the s -sparse vector to be recovered and $\mathbf{z} \in \mathbb{R}^n$ is a noise vector. We assume that each element $[A^\top \mathbf{z}]_i$ follows a subgaussian distribution with $\|[A^\top \mathbf{z}]_i\|_{\psi_2} \leq \sigma\sqrt{n}, i = 1, \dots, d$, where σ indicates the noise level in \mathbf{z} and $\|\cdot\|_{\psi_2}$ is Orlicz norm (Koltchinskii, 2011). Using the property of subgaussianity, we have, with a high probability $(1 - d^{-3})$,

$$\|[A\mathbf{z}]_i\|_\infty \leq 2\sigma\sqrt{n \log d} \quad (2)$$

For the rest of the paper, we will simply assume condition (2) holds.

Following (Candes and Tao, 2005), we assume A satisfies *Restricted Isometric Property* (R.I.P.) defined as follows.

Definition 1 (*Restricted Isometric Property*). *A matrix A satisfies δ_s -R.I.P. condition, if there exists a positive constant δ_s such that for all s -sparse vector \mathbf{x} ,*

$$(1 - \delta_s) \|\mathbf{x}\|_2^2 \leq \frac{1}{n} \|A\mathbf{x}\|_2^2 \leq (1 + \delta_s) \|\mathbf{x}\|_2^2. \quad (3)$$

A is called $\delta_{s,s}$ -restricted orthogonal, if there exists a positive constant $\delta_{s,s}$ such that for any two s -sparse vector \mathbf{u}, \mathbf{v} whose support sets are disjoint,

$$\frac{1}{n} |\langle A\mathbf{u}, A\mathbf{v} \rangle| \leq \delta_{s,s} \|\mathbf{u}\|_2 \|\mathbf{v}\|_2. \quad (4)$$

Small δ_s and $\delta_{s,s}$ indicate that A is approximately isometric on sparse subspace and any two set of s columns are approximately orthogonal if they are disjoint. In the rest of this paper, we will say A is δ -R.I.P. when both (3) and (4) are satisfied with $\delta = \max\{\delta_{2s}, \delta_{s,s}\}$.

Algorithm 1 Proximal Gradient Descent With Adaptive Capped Concave Quadratic (ACCQ) Regularizer

Input: the size of target vector $R \geq \|\mathbf{x}_*\|_2$, design matrix A , measurements \mathbf{y} , threshold θ , shrinking parameter $q \in (0, 1)$, and number of iterations T

- 1: **Initialization:** $\mathbf{x}_1 = 0$
- 2: **for** $t = 1$ to T **do**
- 3: Compute τ_t by $\tau_t = Rq^{t-1} + \theta$
- 4: Compute $\hat{\mathbf{x}}_{t+1}$ by $\hat{\mathbf{x}}_{t+1} = \mathbf{x}_t - \nabla L(\mathbf{x}_t)$
- 5: Update \mathbf{x}_{t+1} using (8)
- 6: **end for**

Output: \mathbf{x}_{T+1}

There are other alternative conditions for sparse recovery which are more general than R.I.P, such as restricted eigenvalue condition (Bickel et al., 2009). A complete list of conditions for sparse recovery and their comparison can be found (Van De Geer and Bühlmann, 2009). We choose R.I.P condition due to its simplicity, and extension to more general cases will be studied in the future. From now on we will assume that A is δ -R.I.P.. In experiments we generate A from random Gaussian distribution, which is widely known to obey the R.I.P. with a high probability.

To recover the sparse vector \mathbf{x}_* , a common approach is to minimize the regularized empirical loss

$$\min_{\mathbf{x}} \frac{1}{2n} \|\mathbf{y} - A\mathbf{x}\|_2^2 + \Omega(\mathbf{x}), \quad (5)$$

where $\Omega(\mathbf{x})$ is a regularizer that controls the sparsity of the solution. To remove the LASSO bias, a non-convex regularizer is used for $\Omega(\mathbf{x})$, leading to a non-convex optimization problem that is not only difficult to solve numerically and but also challenging to analyze the theoretical properties for the found solution.

The following notation will be used throughout this paper. For a vector \mathbf{x} , we denote by $[\mathbf{x}]_i$ the i -th entry of \mathbf{x} , by $|\mathbf{x}|_i$ the absolute value of $[\mathbf{x}]_i$, by $[\mathbf{x}]_A$ the subvector of \mathbf{x} that only includes the elements in the index set $A \subseteq [d]$, and by $\lambda_{\min}(\mathbf{x})$ the minimum absolute value of the non-zero entries in \mathbf{x} . We will use $\text{supp}(\mathbf{x})$ for the support set for a vector \mathbf{x} . We will use $\|\mathbf{x}\|_2$, $\|\mathbf{x}\|_1$, and $\|\mathbf{x}\|_\infty$ to represent the ℓ_2 , ℓ_1 , and ℓ_∞ norm of vector \mathbf{x} . We will denote by S_* the support set of \mathbf{x}_* and by S_t the support set for \mathbf{x}_t .

3.2 PROXIMAL GRADIENT DESCENT USING ADAPTIVE CAPPED CONCAVE QUADRATIC (ACCQ) REGULARIZER

The proposed framework essentially follows the proximal gradient descent method that has been widely used in convex optimization. At each iteration, we first obtain an aux-

iliary solution $\hat{\mathbf{x}}_t$ by

$$\hat{\mathbf{x}}_t = \mathbf{x}_t - \nabla L(\mathbf{x}_t)$$

where $L(\mathbf{x}) = \frac{1}{2n} \|\mathbf{y} - A\mathbf{x}\|_2^2$. (6)

The updated solution \mathbf{x}_{t+1} is then given by

$$\mathbf{x}_{t+1} = \arg \min_{\mathbf{x}} \frac{1}{2} \|\mathbf{x} - \hat{\mathbf{x}}_t\|_2^2 + \Omega_t(\mathbf{x}) \quad (7)$$

where the regularizer Ω_t has a subscript t and therefore varies from trial to trial.

To ensure Eq. (7) leading to an unbiased sparse estimation, we make some assumptions on the adaptive regularizer $\Omega_t(\mathbf{x})$. The type of $\Omega_t(\mathbf{x})$ is not important at all. We only care about its shrinking strategy in step Eq. (7).

Assumption 1. Define variables τ_t and constant α . The adaptive non-convex regularizer $\Omega_t(\mathbf{x})$ in Eq. (7) shrinks $\hat{\mathbf{x}}_t$ in the following way:

- For $|\hat{\mathbf{x}}_t|_i < \tau_t$, $[\mathbf{x}_{t+1}]_i = 0$.
- For $|\hat{\mathbf{x}}_t|_i > \tau_t + \alpha$, $[\mathbf{x}_{t+1}]_i = [\hat{\mathbf{x}}_t]_i$.
- For $\tau_t \leq |\hat{\mathbf{x}}_t|_i \leq \tau_t + \alpha$, $0 < [\mathbf{x}_{t+1}]_i < [\hat{\mathbf{x}}_t]_i$.

The τ_t is a threshold parameter that adaptively shrinks over iterations. We will describe the updating rule of τ_t later in Eq. (9). α is called *proximal projection gap*. In Assumption 1, if the intermedia solution $|\hat{\mathbf{x}}_t|_i$ is outside $[\tau_t, \tau_t + \alpha]$, the proximal projection of Ω_t is equivalent to hard-thresholding. Otherwise $|\hat{\mathbf{x}}_t|_i$ is projected onto $(0, |\hat{\mathbf{x}}_t|_i)$, whose value depends on the specific regularizer being used. The hard-thresholding is the key to unbiased estimation, which is only possible when using non-convex regularizer. The proximal projection gap α reflects the non-convexity of $\Omega_t(\mathbf{x})$ in the proximal projection. For convex regularizer, α is infinity by definition because they are soft-thresholding methods that never do hard-thresholding. For a particular non-convex regularizer, we naturally prefer small α to avoid involving bias as much as possible.

The shrinking strategy of non-convex regularizer is very similar to greedy algorithms. The following concavity assumption distinguish non-convex methods from greedy methods, which at the same time build a bridge of the two realms.

Assumption 2. $\Omega_t(\mathbf{x})$ is concave in \mathbf{x} :

$$\Omega_t(\mathbf{x}_1) - \Omega_t(\mathbf{x}_2) \leq \langle \partial \Omega_t(\mathbf{x}_2), \mathbf{x}_1 - \mathbf{x}_2 \rangle, \|\partial \Omega_t(\mathbf{x})\| \leq \tau_t,$$

where $\partial \Omega_t(\mathbf{x})$ is the subgradient.

Most popular static non-convex regularizer and their adaptive variants fit Assumption 1 and Assumption 2, with different τ_t and α . We list a few of them in Table 1. We notice that in Table 1, most regularizers' α is not zero. Although our theory could deal with non-zero α , we naturally hope

there is a regularizer that doesn't need to suffer this gap α , which results in a better estimation. Inspired by this observation, we introduce *Adaptive Capped Concave Quadratic* regularizer (ACCQ), defined in the last row of Table 1. Clearly, this regularizer is the only hard-thresholding regularizer whose proximal projection gap is zero. Its proximal projection is given by :

$$[\mathbf{x}_{t+1}]_i = \begin{cases} [\hat{\mathbf{x}}_t]_i & |\hat{\mathbf{x}}_t|_i \geq \tau_t \\ 0 & \text{otherwise} \end{cases} \quad (8)$$

This specific adaptive hard-thresholding strategy allows us to correct the LASSO bias and consequentially achieve the oracle property when the signals in the target vectors are strong.

In the rest of this paper, we only focus on ACCQ and its recovery properties. For regularizers with $\alpha > 0$, all of the following theorems hold true except an extra α in the upper bound. Therefore they are always suboptimal compared with ACCQ.

Threshold parameter τ_t is determined by the following equation

$$\tau_t = Rq^{t-1} + \theta. \quad (9)$$

- Threshold parameter $\theta > 0$ determines the lower bound for τ_t . It is introduced to ensure that the regularization is strong enough to overcome the noise.
- Shrinking parameter $q \in (0, 1)$ controls the speed of shrinkage. The idea of using a shrinking regularizer is motivated by a simple observation: as we go through the iteration t , we expect the solution \mathbf{x}_t will approach the target vector \mathbf{x}_* with a smaller error. As a result, only a smaller regularization is needed to overcome the noise caused by the recovery error. We note that similar shrinking strategy has been used in sparse recovery with the ℓ_1 regularizer (Xiao and Zhang, 2012).

Algorithm 1 gives the details for the proposed algorithm.

Remark 1 In practice, the settings of q and θ is robust, as suggested by our theorems and experiments. We suggest to set $0.9 \leq q < 1$ and $\theta \in [O(\sigma/\sqrt{n}), \lambda_{\min}(\mathbf{x}_*)]$. For example, $q = 0.95$, $\theta = 0.005$ usually satisfies our assumption and works well in practice.

Remark 2 It is interesting to compare Algorithm 1 with greedy hard-thresholding algorithms like GraDeS. GraDeS keeps exactly s entries at each iteration, even if the smallest s -th entry contains large noise. The proposed algorithm gradually collects entries according to their magnitude and current estimation uncertainty. It doesn't keep entries that contain large noise, so at the beginning of each iteration, it will keep less than s entries. Another greedy algorithm is OMP, which greedy select entries then keep them as support set. OMP must ensure that it always collect right entry

Table 1: Adaptive Regularizers And Proximal Projection Gap

Name	$\Omega_t(\mathbf{x}_i)$	Gap α
adaptive ℓ_1 norm	$\tau_t \lambda \mathbf{x}_i $	∞
adaptive capped ℓ_1 norm	$\tau_t \lambda \min(\mathbf{x}_i , \theta) \quad \theta > 0$	$\tau_t(\theta - \lambda)$
adaptive MCP	$\tau_t \lambda \int_0^{ \mathbf{x}_i } \min(1, \frac{[\theta \lambda - x]_+}{(\theta - 1)\lambda}) dx \quad \theta \geq 2$	$\tau_t(\theta - 1)\lambda$
ACCQ	$\Omega_t^{\text{CCQ}}(\mathbf{x}) = \sum_{i=1}^d \begin{cases} -\frac{1}{2}(\mathbf{x} _i - \tau_t)^2 + \frac{1}{2}\tau_t^2 & \mathbf{x} _i < \tau_t \\ \frac{1}{2}\tau_t^2 & \text{otherwise} \end{cases}$	0

at each iteration, otherwise it will fail definitely. The propose algorithm adaptively throw out entries that is collected in the previous iterations. This strategy is clealy much more robst against noise.

3.3 MAIN THEORETICAL RESULTS

The following theorem shows that the recovery error for Algorithm 1 is reduced exponentially, and all the intermediate solutions are $2s$ -sparse.

Theorem 1. Assume \mathbf{x}_* is s -sparse, and $6\delta < 1$. Set parameter q , and θ in Algorithm 1 as

$$q = \max\left(3\delta, 2\sqrt{\frac{\delta}{1-2\delta}}\right), \quad \theta = 2\sigma\sqrt{\frac{\log d}{n}} \quad (10)$$

Let $\mathbf{x}_1, \dots, \mathbf{x}_T$ be the sequence of solutions output from algorithm 1. Let S_t be the support set for \mathbf{x}_t and let S_* be the support set for \mathbf{x}_* . We have

$$|S_t \setminus S_*| \leq s, \quad \|\mathbf{x}_t - \mathbf{x}_*\|_2 \leq Rq^{t-1} + \frac{4\sigma}{1-q}\sqrt{\frac{s \log d}{n}} \quad (11)$$

First, as revealed by Theorem 1, the recovery error will converge geometrically to $O(\sigma\sqrt{s \log d/n})$, which has shown to be minimax optimal in (Raskutti et al., 2009). Second, as indicated in (11), all the intermediate solutions are at most $2s$ -sparse, making it computational appealing as our algorithm only needs to maintain a vector of no more than $2s$ non-zero entries. This is similar to iterative hard thresholding algorithms (e.g. (Garg and Khandekar, 2009)). Finally, the linear convergence takes place when $\delta \leq 1/6$, which worse than some other conditions on δ (e.g. (Garg and Khandekar, 2009)). We believe that this condition is improvable by more carefully tuning the inequalities in our analysis via similar techniques demonstrated in (Garg and Khandekar, 2009).

Next, we will show that the solution found by Algorithm 1 is selection consistent and has the oracle property if $\lambda_{\min}(\mathbf{x}_*)$, the smallest absolute value for the non-zero entries in \mathbf{x}_* , is larger than $O(\sigma\sqrt{\log d/n})$. To this end, we first define the solution of Least Square Oracle (LSE) estimation.

Definition 2 (Least Square Oracle (LSE)). *The Least Square Oracle estimation is the least square estimation of \mathbf{x}_* by assuming that the support set S_* of \mathbf{x}_* is provided. The LSE solution \mathbf{x}_o is given by*

$$\mathbf{x}_o = \mathbf{x}_{S_*} = (A_{S_*}^\top A_{S_*})^{-1} A_{S_*}^\top \mathbf{y}.$$

Definition 3 (Selection Consistent and Oracle Property). *An estimator is selection consistent if the estimated solution $\hat{\mathbf{x}}$ satisfies $\text{supp}(\hat{\mathbf{x}}) = \text{supp}(\mathbf{x}_*)$, and has the oracle property if $\hat{\mathbf{x}} = \mathbf{x}_o$.*

We note that since the solution of oracle LSE \mathbf{x}_o is obtained without using any regularizer, the oracle property (i.e. $\hat{\mathbf{x}} = \mathbf{x}_o$) essentially ensures that the sparse recovery algorithm will not be biased by the regularizer, of course under the assumption that $\lambda_{\min}(\mathbf{x}_*)$ is sufficiently large. We note that the early definition of oracle property (e.g. (Fan and Li, 2001)) requires $\hat{\mathbf{x}}_{S_*} - \mathbf{x}_o$ converge to a Gaussian random vector when the number of measurements n goes to infinity, which is weaker than the finite sample version defined above.

Theorem 2. Assume $6\delta < 1$ and with q and θ set in (10). Define

$$t_0 = \log_2 \left(\frac{\max(R, 1)}{\sigma} \sqrt{\frac{\log d}{n}} \right)$$

Then, we have $S_t = S_*$ for $t > t_0$ (i.e. selection consistency) and

$$\|\mathbf{x}_t - \mathbf{x}_o\|_2 \leq \left(\frac{3\delta}{1-3\delta} \right)^{(t-t_0)/2} \frac{8\sigma}{1-q} \sqrt{\frac{s \log d}{n}}$$

if

$$\lambda_{\min}(\mathbf{x}_*) \geq \frac{4\sigma}{1-\delta} \sqrt{2\frac{\log d}{n}} \quad (12)$$

and

$$s \leq \frac{1}{50\delta} (1-q)^2 (2 - \frac{1}{1-\delta}) \quad (13)$$

As revealed by the above theorem, \mathbf{x}_o , the solution of oracle LSE, can be perfectly recovered by Algorithm 1 with sufficiently large number of iterations, provided (i) the non-zero entries in \mathbf{x}_* are sufficiently large, and (ii) the RIP constant δ is sufficiently small.

Remark 1 Eq. (13) is essentially a particular form of *Generalized Uncertainty Principle* (GUP) (Candès et al., 2006). GUP claims that for any compress sensing methods, the number s of non-zeros elements in \mathbf{x}_* couldn't be larger than half of the number n of frequency sampling, i.e., $s \leq 0.5n$. Otherwise there is no algorithm could recover the sparse signal. In Eq. (13), generally speaking, $\delta = O(1/n)$. So Eq. (13) is claiming that s should be smaller than

$$s \leq cn,$$

where c is a constant. The constant c given by Eq. (13) is slightly loose than $1/2$ which is proven to be optimal in GUP. We believe this could be refined by carefully tuning the inequalities in our analysis.

Remark 2 $\lambda_{\min}(\mathbf{x}_*)$ in Eq. (12) doesn't contain \sqrt{s} thanks to the non-convexity of ACCQ. For convex regularizer, $\lambda_{\min}(\mathbf{x}_*) = O(\sqrt{s}\sigma)$ therefore is significantly sub-optimal compared to Eq. (12).

Remark 3 If the proximal projection gap $\alpha > 0$, Eq. (12) should be modified as :

$$\lambda_{\min}(\mathbf{x}_*) \geq O\left(\sqrt{\frac{\log d}{n}} + \alpha\right).$$

This is inferior than $\alpha = 0$. For $\alpha > 0$, the proof is similar. We will explore $\alpha > 0$ in the journal version of this paper.

3.4 PROOF SKETCH

In this analysis, we provide a sketch of proof for Theorem 1. The proof for Theorem 2 mostly follows the analysis of Theorem 1 by carefully exploiting the property of non-convex regularizer. All the detailed proofs can be found in the supplementary document.

The first step toward the proof for Theorem 1 is to show that the solution \mathbf{x}_{t+1} will be sparse if \mathbf{x}_t is sparse, which is revealed by the following theorem.

Theorem 3. Assume $|S_*| \leq s$, and $|S_t \setminus S_*| \leq s$. Then, if we set

$$\tau_t \geq \frac{3\delta}{\sqrt{s}} \|\mathbf{x}_t - \mathbf{x}_*\|_2 + 2\sigma \sqrt{\frac{\log d}{n}},$$

we have $|S_{t+1} \setminus S_*| \leq s$.

In the second step, we show in the theorem below that the recovery error will be reduced exponentially, up to the stochastic tolerance (i.e. $O(\sigma\sqrt{s \log d/n})$).

Theorem 4. Assume $|S_*| \leq s$, $|S_t \setminus S_*| \leq s$, and $\|\mathbf{x}_t - \mathbf{x}_*\|_2 \leq \Delta_t$. Then, by setting

$$\tau_t = \frac{3\delta}{\sqrt{s}} \Delta_t + 2\sigma \sqrt{\frac{\log d}{n}},$$

we have

$$\|\mathbf{x}_{t+1} - \mathbf{x}_*\|_2 \leq q\Delta_t + 4\sigma \sqrt{\frac{s \log d}{n}}$$

where

$$q = \max\left(3\delta, 2\sqrt{\frac{\delta}{1-2\delta}}\right)$$

With the above two theorems, we will show Theorem 1 by induction. Since $\|\mathbf{x}_1 - \mathbf{x}_*\|_2 = \|\mathbf{x}_*\|_2 \leq R$, Theorem 1 holds for $t = 1$. Let's assume that it holds for \mathbf{x}_t . Using Theorem 3, we have that \mathbf{x}_{t+1} is a $2s$ sparse vector with $|S_{t+1} \setminus S_*| \leq s$. Using Theorem 4, we have

$$\begin{aligned} \|\mathbf{x}_{t+1} - \mathbf{x}_*\|_2 &\leq q\Delta_t + 4\sigma \sqrt{\frac{s \log d}{n}} \\ &\leq q^t R + \frac{4\sigma}{1-q} \sqrt{\frac{s \log d}{n}} \end{aligned}$$

4 EXPERIMENTS

Since there are thousands of papers discussing compress sensing, it is impossible to compare every method published in this paper. We mainly select methods with theoretical guarantees and provable geometrical convergence rate. We compare Algorithm 1 (ACCQ) with five baseline methods:

- the greedy hard thresholding method (GraDeS) (Garg and Khandekar, 2009),
- Multiple Stage Capped ℓ_1 -norm method (MSCL1) (Zhang, 2012),
- non-convex proximal gradient descent with MCP (P-MCP) (Loh and Wainwright, 2013),
- the GIST method (Gong et al., 2013b), and
- Homotopy LASSO (LASSO) (Xiao and Zhang, 2012).

GraDeS is a greedy hard thresholding method with a geometrical convergence rate. We set $\gamma = 3$ in GraDeS as recommended in (Garg and Khandekar, 2009). Homotopy LASSO is a LASSO solver with geometrical convergence rate. We tune the regularizer parameter λ in Homotopy LASSO in set $\{1, 0.1, 10^{-2}, 10^{-3}, 10^{-4}\}$, and report the best performance. MSCL1, GIST and P-MCP are based on non-convex regularizers. The threshold parameter θ in MSCL1 is set to be $\theta = \lambda_{\min}(\mathbf{x}_*)/2 = 0.05$. Any $\theta < \lambda_{\min}(\mathbf{x}_*)$ should work as well (Zhang, 2012). Here we choose $\theta = \lambda_{\min}(\mathbf{x}_*)/2$ because it is at the same time large enough to suppress the noise. For the proposed algorithm, we similarly set $\theta = \lambda_{\min}(\mathbf{x}_*)/2 = 0.05$. We tune parameter q in the set $\{0.8, 0.9, 0.95, 0.99, 0.995\}$.

Two metrics are used to evaluate the recovery performance of different algorithms. To evaluate the recovery error, we follow compress sensing settings (Candès and Tao, 2005;

Table 2: Dataset Statistics

	d	$\ \mathbf{x}_*\ _0$	$\ \mathbf{x}_*\ _\infty$	$\ \mathbf{x}_*\ _2$	$\lambda_{\min}(\mathbf{x}_*)$

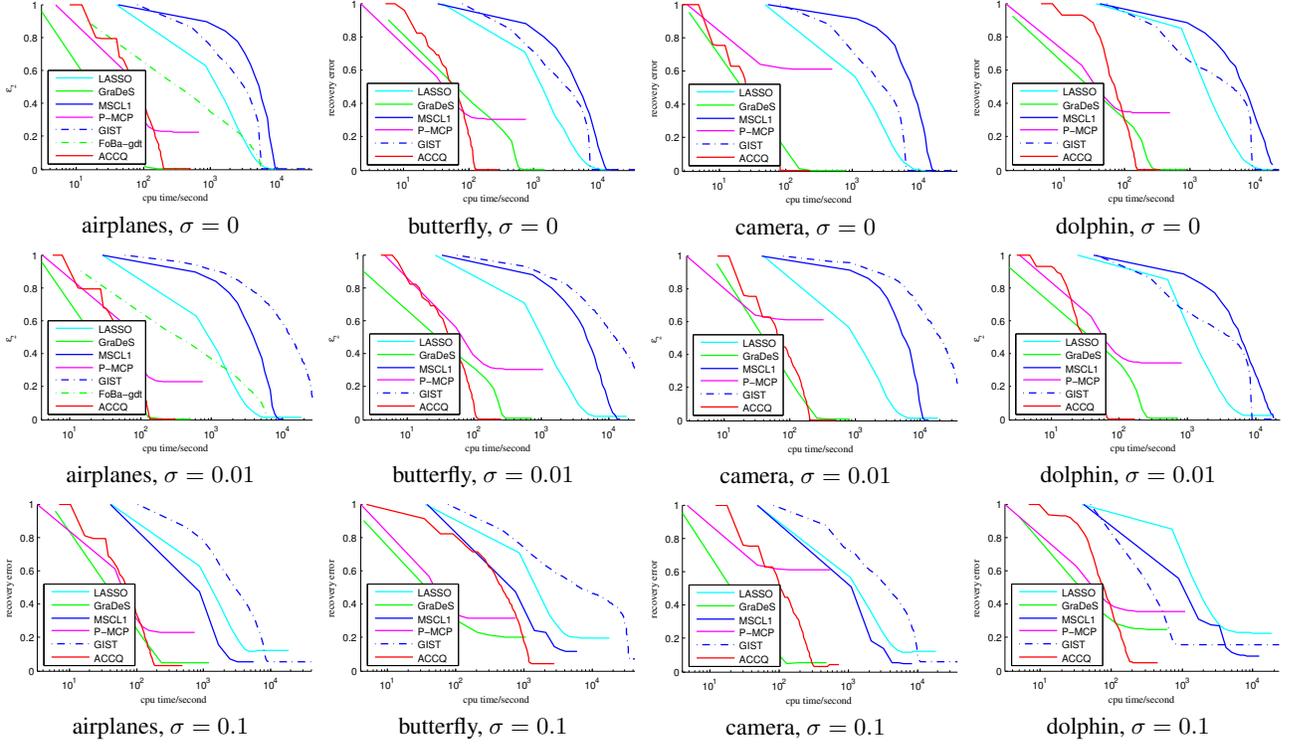

Figure 2: The Recovery Error For Real Images From The Caltech 101 Data Set

Zou and Hastie, 2005; Loh and Wainwright, 2012) and measure the ℓ_2 norm of the difference between the target vector and the recovered one. In order to take into the computational efficiency, we plot the recovery error vs. the running time for each algorithm. To evaluate the property of selection consistency, we also measure the accuracy in recovering the support set of the original sparse vector that defined as follows:

$$\epsilon_{\text{supp}} = (|S_t \setminus S_*| + |S_* \setminus S_t|) / d.$$

Therefore $\epsilon_{\text{supp}} = 0$ if and only if $S_t = S_*$.

All codes are implemented in Matlab, running on Intel(R) Core(TM)2 Duo CPU, P8700@2.53 GHz, Windows 7 64bit, 4GB memory. We terminate each algorithm if it runs more than five hours.

4.1 EXPERIMENTS WITH SYNTHETIC DATA

First we verify the effectiveness of the proposed algorithm on synthetic data. We generate A and \mathbf{z}_* independently from standard normal distributions. To generate the sparse vector \mathbf{x}_* , we first draw a random Gaussian vector \mathbf{x}'_* . We then normalize \mathbf{x}'_* to be one and only keep the largest s entries in \mathbf{x}'_* . We create two synthetic data sets: toy1 ($d = 1000$, $s = 50$, $\sigma = \{0, 0.1\}$, $n = 500$), and toy2 ($d = 5000$, $s = 50$, $\sigma = \{0, 0.5\}$, $n = 1000$). Clearly toy2 is more difficult than toy1 because of the high dimensionality and large noise. The performance averaged over 10 trials

is reported in this study. Since GraDeS needs to set all the entries in the intermediate solution to be zero except for the first k largest entries at each iteration, we tune k in set $\{40, 60, 80, 100\}$, and report the best performance.

Figure 1 shows the recovery results for the synthetic data sets, where the horizontal axis is CPU time (second) in the logarithmic scale. We observe that the proposed method ACCQ, although has the slow start at the beginning, is able to find a solution with small recovery error significantly faster than the other baseline methods. The slow start of the proposed algorithm is mostly due to the fact that the initial threshold τ_1 is set too high, leading to $\mathbf{x}_t = \mathbf{0}$ for the first a few of iterations. The LASSO bias is revealed by the noisy cases, where LASSO has the worst recovery error compared to the other methods. We also observe that the GraDeS method, an iterative hard thresholding algorithm, works well for the two toy datasets, in terms of both computational time and recovery error. We however found that for the real images, the GraDeS method behaves unstably when measurements are contaminated with random noise, as shown in the experimental result in the next subsection.

4.2 EXPERIMENTS WITH REAL IMAGES

Dataset We select a subset of images in Caltech101 as the sparse signals. Five images randomly chosen from four categories—“airplanes”, “butterfly”, “camera” and “dolphin”—are used in this study. For the convenience

of presentation, we denote each of the five images selected from one category by “001.jpg” to “005.jpg”. The total number of images we extract is 20. To generate a truly s -sparse signal, all images are first normalized to be zero-mean and unit variance. We then apply Fourier transform to the normalized image and filter out Fourier components with coefficient smaller than 0.01. The final sparse vector \mathbf{x}_* is constructed based on the survived Fourier components. Table 2 summarizes the statistics of our dataset.

For each s -sparse signal \mathbf{x}_* , we independently generate random Gaussian design matrix A with $n = 5000$. The entries in noise vector \mathbf{z} are independently drawn from a Gaussian distribution with variance σ varied in set $\{0, 0.01, 0.1\}$. When $\sigma > 0.1$, no algorithm could do a good job due to heavy information corruption. For parameter k in GraDeS, i.e. the number of non-zero entries to be kept at each iteration, we tune it in set $\{500, 1000, 2000\}$ and report the best performance.

Figure 2 presents the convergence rate of ℓ_2 -norm recovery error of the six methods. To save space we only show the result for “001.jpg” in each category here, and the results for the remaining images can be found in the supplementary document. Similar to the result of the synthetic data sets, The bias of LASSO is again revealed by its large recovery error for the noisy cases compared to several algorithms in comparison. The proposed algorithm ACCQ, although with a slow start, is able to find the solution with a small error significantly faster than the baseline algorithms on almost all cases except for airplanes with $\sigma = 0$ and camera with $\sigma = 0.1$, where the GraDeS method is the most efficient but with a slightly worse error. We notice that the performance of the GraDeS method appears to be not very consistent across images: it performs well for airplane and camera images, but does poorly for the images of butterfly and dolphin. Similarly, P-MCP and GIST, two sparse recovery algorithms with non-convex regularizers, although works well for the synthetic datasets, performs poorly for a number of cases. More investigation is needed to further understand the behavior of these algorithms.

In Table 2, we report the support set recovery error for each dataset under different noise level. Similar to ℓ_2 norm recovery error, ACCQ achieves perfect support set recovery on almost all datasets under $\sigma = \{0, 0.01\}$ except for *butterfly*. When noise $\sigma = 0.1$ is large, although ACCQ is unable to recover the exact support set, its error in recovering the support set is the smallest among the methods in comparison.

5 CONCLUSION

We propose an adaptive non-convex method to efficiently recover the sparse signal under compress sensing settings. The proposed method achieves a geometrical convergence rate for ℓ_2 -norm recovery error up to the statistical tol-

erance. By using a non-convex regularizer, the proposed method is able to remove the LASSO bias and achieve the selection consistency and oracle property. Experiments with both synthetic data sets and real images verify both the efficiency and effectiveness of the proposed method compared to the state-of-the-art methods for sparse recovery. In the future, we would like to improve our analysis to remove the extra condition in (13) for selection consistency and oracle property. We also plan to extend the proposed algorithm to other sparse recovery problems such as group sparsity and low rank matrix recovery.

Abstract

This paper aims to address a class of nuclear norm regularized least square (NNLS) problems. By exploiting the underlying low-rank matrix manifold structure, the problem with nuclear norm regularization is cast to a Riemannian optimization problem over matrix manifolds. Compared with existing NNLS algorithms involving singular value decomposition (SVD) of large-scale matrices, our method achieves significant reduction in computational complexity. Moreover, the uniqueness of matrix factorization can be guaranteed by our Grassmannian manifold method. In our solution, we first introduce the bilateral factorization into the original NNLS problem and convert it into a Grassmannian optimization problem by using a linearized technique. Then the conjugate gradient procedure on the Grassmannian manifold is developed for our method with a guarantee of local convergence. Finally, our method can be extended to address the graph regularized problem. Experimental results verified both the efficiency and effectiveness of our method.

1 Introduction

In recent years, matrix approximation problems with nuclear norm regularization have occurred in many machine learning and compressed sensing applications such as matrix completion, matrix classification, multi-task learning and dimensionality reduction [6]. In this paper, we consider the following optimization problem over matrices:

$$\min_{X \in \mathbb{R}^{m \times n}} f(X) := g(X) + \mu \|X\|_*, \quad (1)$$

where $g(X)$ is any differentiable convex function (usually called the loss function, e.g. $g(X) = \|\mathcal{A}(X) - b\|_2^2$, where

$\mathcal{A}(\cdot)$ is a linear operator), $\mu > 0$ is a regularization parameter, and $\|X\|_*$ denotes the nuclear (or trace) norm of the matrix X with rank r , that is, the l_1 -norm of the matrix spectrum as $\|X\|_* = \sum_{i=1}^r \sigma_i$, where $\{\sigma_i\}$ are the singular values of X .

Most algorithms for solving the nuclear norm minimization (NNM) problem (1) do not require the rank to be specified and iteratively optimize the nuclear norm penalized problem. Naturally, the singular value decomposition (SVD) tends to play a critical computational role in the design of various nuclear norm solvers, e.g., the singular value thresholding (SVT) [5], soft-impute [14], accelerated proximal gradient approach [9], and so on. Those algorithms involving SVD and applying a soft-thresholding operator on the singular values at each iteration suffer from high computational cost of multiple SVDs [14, 15]. In particular, if the iterations need to pass through a region where the spectrum is dense, those algorithms can become potentially become prohibitively expensive [3]. Noticing that only those singular values exceeding a threshold and their corresponding singular vectors contribute to the soft-thresholding operator, a commonly used strategy is to compute the partial SVD instead of the full one, such as APGL [17] and IALM [12] both use PROPACK [11]. However, it can compute only a given number of largest singular values, and the soft-thresholding operator requires the principal singular values that are greater than a given threshold.

If the rank is known, a class of existing matrix factorization algorithms [10, 4, 22, 15, 18] cast the low-rank matrix estimation problem (1) as the following non-convex model,

$$\min_{X \in \mathbb{R}^{m \times n}} g(X), \quad \text{s.t., } \text{rank}(X) = k. \quad (2)$$

Matrix factorization is arguably the most widely applied method for the low-rank matrix completion problem, due to its high accuracy, scalability and flexibility to incorporating side-information [19]. LMaFit [22] fixes the rank by explicitly formulating the matrix as the product of its low-rank factors and using an optimization technique based on successive over-relaxation to solve (2). In [15] and [18], two improved versions were proposed to optimize it on the

*Corresponding author

Grassmannian manifolds, and improve its convergence by using conjugate gradients rather than the standard gradient descent. Moreover, [10] proved that exact recovery can be obtained with high probability by solving a non-convex optimization problem. In the model (2), the correct rank needs to be known a priori. Unfortunately, the determination of the reduced rank is also an open problem, especially for the noisy matrix estimation.

To address these key problems mentioned above, we propose an effective approximation method for solving nuclear norm regularized least squares problems, which can reduce the SVD computational cost. We achieve it by converting the original NNM problem into a Grassmannian optimization problem. In our framework, we use the nuclear norm term to promote the robustness of the fixed-rank manifold optimization problem with respect to the given rank, in other words, to avoid the over-fitting problems of matrix factorization. Moreover, we present an efficient conjugate gradient descent algorithm on the Grassmannian manifolds with a guarantee of local convergence. Finally, our method is also extended to address the graph regularized problem. In summary, our method inherits the superiority of two classes of frameworks, i.e., the NNM methods and Riemannian manifold optimization methods based on matrix factorizations.

2 Background

When choosing $g(X) := \frac{1}{2} \|\mathcal{P}_\Omega(X) - \mathcal{P}_\Omega(Z)\|_F^2$ for some linear projection operators $\mathcal{P}_\Omega(\cdot)$, i.e., $\mathcal{P}_\Omega(X_{ij}) = X_{ij}$ if $(i, j) \in \Omega$, and $\mathcal{P}_\Omega(X_{ij}) = 0$ otherwise, the above formulation (1) is the low-rank matrix completion (MC) problem. The MC problem is to find out a matrix of the lowest rank whose entries in the observed set Ω correspond to the entries of Z :

$$\min_{X \in \mathbb{R}^{m \times n}} \frac{1}{2} \|\mathcal{P}_\Omega(X) - \mathcal{P}_\Omega(Z)\|_F^2 + \mu \|X\|_*, \quad (3)$$

or the noiseless version,

$$\min_{X \in \mathbb{R}^{m \times n}} \|X\|_*, \quad \text{s.t.}, X_\Omega = Z_\Omega. \quad (4)$$

Recently, many low-complexity algorithms have emerged, such as APGL [17], IALM [12], and FPCA [13]. Involving SVDs in their each iteration, thus those algorithms based on the soft-thresholding operator suffer from high computational cost. This limits the usage of the matrix completion techniques in real-world applications.

Alternatively, low-rank matrix completion based on fixed-rank matrix factorization has received a significant amount of attention [15]. Suppose that the low-rank matrix $X \in \mathbb{R}^{m \times n}$ with rank r is decomposed as $X = UM$, where $U \in \mathbb{R}^{m \times r}$ and $M \in \mathbb{R}^{r \times n}$. LMAFit [22] applies a successive over-relaxation iteration scheme to alternatively solve the

following least-squares problem,

$$\min_{U \in \mathbb{R}^{m \times r}} \min_{M \in \mathbb{R}^{r \times n}} \sum_{(i,j) \in \Omega} \|(UM)_{ij} - Z_{ij}\|^2. \quad (5)$$

However, the factorization of the matrix X into the product UM is not unique. Indeed, for any r -by- r invertible matrix O , we have $UM = (UO)(O^{-1}M)$. Hence, some researchers convert the matrix factorization problem into some corresponding Riemannian manifold optimization problems, such as OptSpace [10], RTRMC [4], RiemannCG [18], and ScGrass [15]. However, in those algorithms we need to know the exact rank which is usually difficult to obtain. Furthermore, they often suffer badly from overfitting due to their least-squares loss functions, especially on noisy matrices.

2.1 Grassmannian Manifold

We will briefly recall the related notions of matrix manifolds (readers may refer to [2] for details).

Definition 1. Grassmannian manifold: *The set of r -dimensional vector subspaces of \mathbb{R}^m is defined as $\mathcal{G}_{m,r}$. Each point $\mathcal{U} \in \mathcal{G}_{m,r}$ can be presented by a generator matrix $U \in \mathcal{N}_{m,r}$, where $\mathcal{N}_{m,r}$ is the set of $m \times r$ matrices with orthonormal columns, i.e., $\mathcal{N}_{m,r} = \{U \in \mathbb{R}^{m \times r} : U^T U = I_r\}$.*

Definition 2. Tangent space: *Consider an arbitrary point on the Grassmannian manifold, $\mathcal{U} \in \mathcal{G}_{m,r}$. To perform differential calculus, the tangent space at \mathcal{U} (the generator matrix of \mathcal{U}) is denoted as $T_{\mathcal{U}}\mathcal{G}_{m,r}$. And the tangent space is represented as $T_{\mathcal{U}}\mathcal{G}_{m,r} = \{\eta \in \mathbb{R}^{m \times r} : U^T \eta = 0\}$.*

As the generalization of the standard optimization methods, some Riemannian manifold optimization methods can be used for solving the following low-rank matrix learning problem with the fixed rank r ,

$$\min_{U \in \mathcal{G}_{m,r}} f(U), \quad (6)$$

where $f(\cdot)$ is a smooth function on Grassmannian manifolds.

2.2 Skeleton of CG Algorithms on Grassmannian Manifolds

In general, the typical nonlinear conjugate gradient (CG) algorithm on Grassmannian manifolds with a line-search rule for the unconstrained optimization problem (6) is outlined in **Algorithm 1**, which we elaborate as follows.

- Ambient gradient: To obtain the Euclidean gradient $\nabla f(U_k)$ in the ambient space.
- Riemannian gradient: It, denoted by $\text{grad}f(U_k)$, is a specific tangent vector η_k which corresponds to the

Algorithm 1 Geometric CG

Input: The fixed rank r and $\text{tol} > 0$.

Output: $X = UM$.

- 1: **while** not converged **do**
 - 2: Compute the ambient gradient: $\nabla f(U_k)$.
 - 3: Compute the Grassmannian gradient:
 $\text{grad}f(U_k)$.
 - 4: Check convergence: $\|\text{grad}f(U_k)\| \leq \text{tol}$.
 - 5: Compute β_k by the PR+ updating rule,
 and compute a conjugate direction ξ_k :
 $\xi_k = -\text{grad}f(U_k) + \beta_k T_{U_{k-1} \rightarrow U_k} \mathcal{G}_{m,r}(\xi_{k-1})$.
 - 6: Find an appropriate step size t_k and compute
 $U: U_{k+1} = \mathfrak{R}_{U_k}(t_k \xi_k)$.
 - 7: **end while**
-

direction of steepest ascent of $f(U_k)$, but is restricted to only directions in the tangent space $T_{U_k} \mathcal{G}_{m,r}$.

- The conjugate direction: It, denoted by $\xi_k \in T_{U_k} \mathcal{G}_{m,r}$, is conjugate to the gradient, and requires taking a linear combination of the Riemannian gradient with the previous search direction ξ_{k-1} . Since ξ_{k-1} does not lie in $T_{U_k} \mathcal{G}_{m,r}$, it needs to be transported to $T_{U_k} \mathcal{G}_{m,r}$. This is done by a mapping $T_{U_{k-1} \rightarrow U_k} \mathcal{G}_{m,r} : T_{U_{k-1}} \mathcal{G}_{m,r} \rightarrow T_{U_k} \mathcal{G}_{m,r}$, the so-called *vector transport*. In total, the conjugate direction $\xi_k = -\text{grad}f(U_k) + \beta_k T_{U_{k-1} \rightarrow U_k} \mathcal{G}_{m,r}(\xi_{k-1})$ can be computed by a variant of the classical Polak-Ribière (PR+) updating rule in the non-linear CG.
- Retraction: Because a tangent vector only gives a direction but not the line search itself on the manifold, a smooth mapping $\mathfrak{R}_{U_k} : T_{U_k} \mathcal{G}_{m,r} \rightarrow \mathcal{G}_{m,r}$, named as *retraction*, is needed to map tangent vectors to the manifold. To retract the search direction ξ_k with a line-search step size t_k back to the manifold is denoted as: $U_{k+1} = \mathfrak{R}_{U_k}(t_k \xi_k)$.

3 Grassmannian Optimization

3.1 Linearization Technique

As in [17], the problem (1) can be approximated iteratively by minimizing the following linearized function,

$$\begin{aligned} \mathcal{L}(X) = & \mu \|X\|_* + g(X_k) + \langle \nabla g(X_k), X - X_k \rangle \\ & + \frac{1}{2\tau} \|X - X_k\|_F^2, \end{aligned} \quad (7)$$

where $\tau > 0$ is a proximal parameter. Without loss of generality, suppose d is an upper bound for $\text{rank}(X) = r$, i.e., $r \leq d$. $X \in \mathbb{R}^{m \times n}$ is decomposed as $X = UM$, where $U \in \mathcal{N}_{m,d}$ and $M \in \mathbb{R}^{d \times n}$. Furthermore, the quotient geometry (i.e., Grassmannian manifold) is used in our paper to guarantee the uniqueness of matrix factorization.

Hence, $U \in \mathcal{N}_{m,d}$ can be viewed as the generator matrix of $\mathcal{U} \in \mathcal{G}_{m,d}$ and is an orthonormal basis of \mathcal{U} . With $U^T U = I$, we have $\|X\|_* = \|M\|_*$. Thus, the problem (7) is rewritten in the following form

$$\begin{aligned} \mathcal{L}(U, M) = & \mu \|M\|_* + \langle \nabla g(U_k M_k), UM - U_k M_k \rangle \\ & + g(U_k M_k) + \frac{1}{2\tau} \|UM - U_k M_k\|_F^2. \end{aligned} \quad (8)$$

For solving the problem (8), then we formulate the following subproblem at the k -th iteration,

$$\begin{aligned} \min_{\mathcal{U} \in \mathcal{G}_{m,d}} \min_{M \in \mathbb{R}^{d \times n}} \tilde{f}_{U_k M_k}(U, M) := \\ \mu\tau \|M\|_* + \frac{1}{2} \|UM - U_k M_k + \tau \nabla g(U_k M_k)\|_F^2. \end{aligned} \quad (9)$$

In the following, the problem (9) is equally converted into a Grassmannian manifold optimization problem with respect to U .

3.2 Objective Function on Grassmannian Manifolds

Similar to [4], we now derive the objective function on Grassmannian manifolds. Given the variable U , computing the matrix M that minimizes $\tilde{f}_{U_k M_k}$ is a nuclear norm regularized least-squares problem. The mapping between U and this (unique) optimal M , denoted by M_U , is given by

$$\begin{aligned} U \mapsto M_U = \\ \arg \min_{M \in \mathbb{R}^{d \times n}} \mu\tau \|M\|_* + \frac{1}{2} \|UM - P_k\|_F^2, \end{aligned} \quad (10)$$

where $P_k = U_k M_k - \tau \nabla g(U_k M_k)$. Following [5], we can obtain a unique closed-form solution to the problem (10) via the SVT operator,

$$M_U = \text{SVT}_{\mu\tau}(U^T P_k), \quad (11)$$

where $\text{SVT}_{\mu\tau}(A) := \bar{U} \text{diag}(\max\{\sigma - \mu\tau, 0\}) \bar{V}$ and $\bar{U} \text{diag}(\sigma) \bar{V}$ is the SVD of A . Substituting (11) into the function $\tilde{f}_{U_k M_k}$, then the cost function $f_{U_k M_k} : \mathcal{G}_{m,r} \rightarrow \mathbb{R}$ on Grassmannian manifolds is given by

$$\min_{\mathcal{U} \in \mathcal{G}_{m,d}} f_{U_k M_k}(U) := \mu\tau \|M_U\|_* + \frac{1}{2} \|UM_U - P_k\|_F^2. \quad (12)$$

3.3 Riemannian Gradient

For solving our problem (12), we first derive the formulas for the Euclidean gradient of the cost function $f_{U_k M_k}$ in (12) at U . Using the chain rule, we have

$$\begin{aligned} \nabla f_{U_k M_k}(U) &= \frac{d}{dU} f_{U_k M_k}(U) \\ &= \frac{\partial}{\partial U} \tilde{f}_{U_k M_k}(U, M_U) + \frac{\partial}{\partial M_U} \tilde{f}_{U_k M_k}(U, M_U) \frac{d}{dU} M_U, \end{aligned} \quad (13)$$

where $\tilde{f}_{U_k M_k}(U, M_U)$, $f_{U_k M_k}(U)$ and the map M_U have been defined in (9), (12) and (11), respectively. The first term of (13), $\frac{\partial}{\partial U} \tilde{f}_{U_k M_k}(U, M_U)$, can be computed easily. To compute the second term in (13), i.e., $\frac{\partial}{\partial M_U} \tilde{f}_{U_k M_k}(U, M_U) \frac{d}{dU} M_U$, we will present the following derivation using the singular value and singular subspace perturbation theories.

3.3.1 Computation of Ambient Gradient

To compute the ambient gradient, we first introduce the following two definitions and give their property, respectively.

Definition 3. Subdifferential: Let $\partial_M \tilde{f}_{U_k M_k}(U, M)$ denote the subdifferential of the non-smooth function $\tilde{f}_{U_k M_k}(U, M)$ at M , then

$$\partial_M \tilde{f}_{U_k M_k}(U, M) = \mu\tau \partial \|M\|_* + (M - U^T P_k), \quad (14)$$

where $\partial \|\cdot\|_*$ denotes the subdifferential of the non-smooth convex function $\|\cdot\|_*$, and is a closed convex set. Specifically, let $M = \hat{U} \hat{\Lambda} \hat{V}$ be the SVD of $M \in \mathbb{R}^{d \times n}$, then $\partial \|M\|_*$ is given by [5], i.e.,

$$\begin{aligned} \partial \|M\|_* = \\ \{\hat{U} \hat{V} + W : \hat{U}^T W = 0, W \hat{V}^T = 0, \|W\|_2 \leq 1\}, \end{aligned} \quad (15)$$

where $\|\cdot\|_2$ is a spectrum norm.

By Definition 3, we can obtain the following property.

Lemma 1. Let M_U be the solution of problem (10), $M_U = \tilde{U} \tilde{\Lambda} \tilde{V}$ be the SVD of M_U , and $\Gamma = \{W : \tilde{U}^T W = 0, W \tilde{V} = 0, \|W\|_2 \leq 1\}$, then $\exists \tilde{W} \in \Gamma$ satisfies

$$\partial_{M_U} \tilde{f}_{U_k M_k} = \{\mu\tau(W - \tilde{W}), W \in \Gamma\}. \quad (16)$$

Proof. Since M_U is a optimal solution, then the first-order optimality condition of the problem (10) is given by,

$$0 \in \mu\tau \partial \|M_U\|_* + (M_U - U^T P_k). \quad (17)$$

By (15), then $\exists \tilde{W} \in \Gamma$ satisfies

$$\mu\tau \tilde{U} \tilde{V} + \mu\tau \tilde{W} + (M_U - U^T P_k) = 0. \quad (18)$$

Furthermore, substituting (18) into the subdifferential in (14), we have

$$\begin{aligned} \partial_M \tilde{f}_{U_k M_k} &= \mu\tau \partial \|M_U\|_* + (M_U - U^T P_k) \\ &= \{\mu\tau \tilde{U} \tilde{V}^T + \mu\tau W + M - U^T P_k, W \in \Gamma\} \\ &= \{\mu\tau(W - \tilde{W}), W \in \Gamma\}. \end{aligned} \quad (19)$$

This completes the proof. \square

Definition 4. Directional Derivative: Let $M_U = \text{SVT}_{\mu\tau}(U^T P_k)$, the directional derivative of the mapping M_U at U along the direction H is defined as

$$M_{U,H} = \lim_{\gamma \rightarrow 0} \frac{\text{SVT}_{\mu\tau}((U + \gamma H)^T P_k) - \text{SVT}_{\mu\tau}(U^T P_k)}{\gamma}. \quad (20)$$

Furthermore, we give the following result by the singular value and singular subspaces perturbation theorems.

Lemma 2. With the same notations as Lemma 1, then for any matrix $W \in \Gamma$, we have

$$\langle M_{U,H}, W \rangle = 0. \quad (21)$$

Proof. To prove the lemma, the classical perturbation theory for singular value and singular subspaces problems is introduced. We use the classical result of [20] that the eigenvalues of a matrix which is an analytic function of a single variable can always be numbered so that they are each analytic functions of the variable. Using the relationship between eigenvalues and singular values, it follows that if the singular values of the matrix $B = A + \gamma R$, where A and R are $m \times n$ matrices, denoted by $\sigma_i(\gamma)$, $i = 1, 2, \dots, n$, then

$$\sigma_i(\gamma) = \sigma_i + \gamma u_i^T R v_i + O_i(\gamma), i = 1, 2, \dots, n, \quad (22)$$

where $O_i(\gamma)$ is an infinitesimal of higher order than γ , u_i and v_i are singular vectors of A corresponding to σ_i . Let $A = \tilde{U} \tilde{\Sigma} \tilde{V} + \tilde{U}' \tilde{\Sigma}' \tilde{V}'$ and $B = \hat{U} \hat{\Sigma} \hat{V} + \hat{U}' \hat{\Sigma}' \hat{V}'$ be the SVDs of A and B respectively, where $\tilde{\Sigma} = \text{diag}(\sigma_1, \dots, \sigma_s)$ and $\hat{\Sigma} = \text{diag}(\sigma_1(\gamma), \dots, \sigma_s(\gamma))$ are s largest singular values of A and B , respectively. \tilde{U} and \hat{U} denote the spaces of \tilde{U} and \hat{U} , and \tilde{V} and \hat{V} denote the spaces of \tilde{V} and \hat{V} , respectively. Then the classic theorem on the perturbation of singular subspaces is due to [21],

$$\begin{aligned} &\sqrt{\|\sin \Theta(\tilde{U}, \hat{U})\|_F^2 + \|\sin \Theta(\tilde{V}, \hat{V})\|_F^2} \\ &\leq \frac{\sqrt{\|E_1\|_F^2 + \|E_2\|_F^2}}{\delta}, \end{aligned} \quad (23)$$

where $E_1 = B \tilde{V} - \tilde{U} \tilde{\Sigma} \equiv \gamma R \tilde{V}$, $E_2 = B^T \hat{U} - \tilde{V} \tilde{\Sigma} \equiv \gamma R^T \hat{U}$, and $\|\sin \Theta(\tilde{U}, \hat{U})\|_F^2$ is a measure that is related to the canonical angles between the subspace \tilde{U} and \hat{U} . Moreover, the gap δ is the distance between two sets of singular values in $\tilde{\Sigma} = \text{diag}(\sigma_1, \dots, \sigma_s)$ and $\tilde{\Sigma}' = \text{diag}(\sigma_{s+1}, \dots, \sigma_n)$ (Please see the details in [21]).

Let $A := U^T P_k$, $R := H^T P_k$, $B := A + \gamma R = U^T P_k + \gamma H^T P_k$, $\sigma_1 \geq \dots \geq \sigma_s \geq \mu\tau$ and $\sigma_{s+1} < \mu\tau$. By using the result in (22) and the definition of the SVT operator with $\gamma \rightarrow 0$, we have

$$\begin{aligned} &\text{SVT}_{\mu\tau}((U + \gamma H)^T P_k) - \text{SVT}_{\mu\tau}(U^T P_k) \\ &= \hat{U}(\hat{\Sigma} - \mu\tau)\hat{V} - \tilde{U}(\tilde{\Sigma} - \mu\tau)\tilde{V} \\ &= T_1 + T_2 + O(\gamma), \end{aligned} \quad (24)$$

where $T_1 = \hat{U}(\tilde{\Sigma} - \mu\tau)\hat{V} - \tilde{U}(\tilde{\Sigma} - \mu\tau)\tilde{V}$, $T_2 = \gamma \hat{U} \Delta \hat{V}$, the i -th element of the diagonal matrix Δ is $\Delta_i = \tilde{u}_i^T H^T P_k \tilde{v}_i$, $O(\gamma) \in \mathbb{R}^{d \times n}$ and its all entries are infinitesimals of higher order than γ .

By the singular subspace perturbation theory of in (23), the subspace $\hat{U} \rightarrow \tilde{U}$, while $\gamma \rightarrow 0$, i.e., $\exists D_1$, such that $\hat{U} \rightarrow$

$\tilde{U}D_1$. Similarly, $\exists D_2$, such that $\hat{V} \rightarrow \tilde{V}D_2$. Thus, it is not difficult to verify $\hat{U} = \tilde{U}D_1 + \delta_1(\gamma)$ and $\hat{V}^T = \tilde{V}^T D_2 + \delta_2(\gamma)^T$, where $\delta_1(\gamma) \in \mathbb{R}^{m \times d}$ and $\delta_2(\gamma) \in \mathbb{R}^{d \times n}$, and all of their entries are infinitesimals of the same order as γ . Then we have

$$\begin{aligned} \langle W, \hat{U}(\tilde{\Sigma} - \mu\tau)\hat{V} \rangle &= \langle \hat{U}^T W \hat{V}^T, (\tilde{\Sigma} - \mu\tau) \rangle \\ &= \langle D_1^T \tilde{U}^T W \hat{V}^T, (\tilde{\Sigma} - \mu\tau) \rangle \\ &\quad + \langle \delta_1(\gamma)^T W \hat{V}^T D_2, (\tilde{\Sigma} - \mu\tau) \rangle \\ &\quad + \langle \delta_1(\gamma)^T W \delta_2(\gamma), (\tilde{\Sigma} - \mu\tau) \rangle, \end{aligned} \quad (25)$$

where W is defined in (15), $\tilde{U}^T W = 0$, $W \tilde{V}^T = 0$, and by (25), then

$$\begin{aligned} \langle W, T_1 \rangle &= \langle W, \hat{U}(\tilde{\Sigma} - \mu\tau)\hat{V} \rangle + \langle W, \tilde{U}(\tilde{\Sigma} - \mu\tau)\tilde{V} \rangle \\ &= \langle \delta_1(\gamma)^T W \delta_2(\gamma), (\tilde{\Sigma} - \mu\tau) \rangle. \end{aligned}$$

Similarly, we have

$$\begin{aligned} \langle W, T_2 \rangle &= \langle W, \gamma \hat{U} \Delta \hat{V} \rangle \\ &= \langle D_1^T \tilde{U}^T W \hat{V}^T, \gamma \Delta \rangle + \langle \delta_1^T W \tilde{V}^T D_2, \gamma \Delta \rangle \\ &\quad + \langle \delta_1^T(\gamma) W \delta_2(\gamma), \gamma \Delta \rangle \\ &= \langle \delta_1^T(\gamma) W \delta_2(\gamma), \gamma \Delta \rangle. \end{aligned}$$

Thus, we have

$$\langle W, M_{U,H} \rangle = \lim_{\gamma \rightarrow 0} \frac{\langle W, T_1 + T_2 + O(\gamma) \rangle}{\gamma} = 0.$$

Thus, this completes the proof. \square

Next we will compute the ambient gradient. Let $\forall \zeta \in \frac{\partial}{\partial M_U} \tilde{f}_{U_k M_k}(U, M_U) \frac{d}{dU} M_U$, by the chain rule of composite function, and substituting the result in Lemma 1 into the chain rule, then $\exists (W - \tilde{W}) \in \Gamma$ satisfies

$$\begin{aligned} \zeta_{ij} &= \langle W - \tilde{W}, M_{U, \tilde{H}^{ij}} \rangle, \\ i &= 1, 2, \dots, m, \quad j = 1, 2, \dots, d, \end{aligned}$$

where ζ_{ij} denotes the element in the i -th row and the j -th column of ζ , and $M_{U, \tilde{H}^{ij}}$ is given by Definition 2, and the direction $\tilde{H}^{ij} \in \mathbb{R}^{m \times d}$ is defined as

$$(\tilde{H}^{ij})_{m,n} = \begin{cases} 1 & m = i \text{ and } n = j, \\ 0 & \text{otherwise.} \end{cases}$$

And by Lemma 2, then

$$\zeta_{ij} = \langle W - \tilde{W}, M_{U, \tilde{H}^{ij}} \rangle = 0. \quad (26)$$

Thus, we have

$$\frac{\partial}{\partial M_U} \tilde{f}_{U_k M_k}(U, M_U) \frac{d}{dU} M_U = 0. \quad (27)$$

By (27), then the ambient gradient in (13) can be rewritten as follows:

$$\begin{aligned} \nabla f_{U_k M_k}(U) &= \frac{\partial}{\partial U} \tilde{f}_{U_k M_k}(U, M_U) \\ &= (U M_U - P_k) M_U^T. \end{aligned} \quad (28)$$

Note the above result implies that the function $f_{U_k M_k}(\cdot)$ is continuously differentiable.

3.3.2 Computation of Riemannian Gradient

Following [18], and $(I - UU^T)U = 0$, then the Grassmannian gradient of $f_{U_k M_k}$ at U is given by

$$\begin{aligned} \text{grad} f_{U_k M_k}(U) &= (I - UU^T) \nabla f_{U_k M_k}(U) \\ &= -(I - UU^T) P_k M_U^T. \end{aligned} \quad (29)$$

3.4 Conjugate Gradient Iteration

In the part, we describe the nonlinear CG algorithm on the Grassmannian manifold for solving the proposed model. The main additional ingredient we need is vector transport which is used to transport the old search direction to the current point on the manifold, i.e., $T_{U_{k-1} \rightarrow U_k} \mathcal{G}_{m,d} : T_{U_{k-1}} \mathcal{G}_{m,d} \rightarrow T_{U_k} \mathcal{G}_{m,d}$. The transport search direction is then combined with the gradient at the current point, e.g. by the Polak-Ribière formula (see [2]), to derive the new search direction. Vector transport can be defined using the Riemann connection, which in turn is defined based on the Riemann metric [1]. In this paper, we will use the canonical metric to derive vector transport when considering the natural quotient manifold structure of the Grassmannian manifold. Following [15], the previous search direction ξ_{k-1} at U_{k-1} will be transported to U_{k+1} as $T_{U_{k-1} \rightarrow U_k} \mathcal{G}_{m,d} = (I - U_k U_k^T) \xi_{k-1}$. Then the new search direction is

$$\xi_k = -\text{grad} f(U_k) + \beta_k T_{U_{k-1} \rightarrow U_k} \mathcal{G}_{m,r}(\xi_{k-1}), \quad (30)$$

where β_k can be calculated by using the Polak-Ribiere formula in [7].

Furthermore, U is updated by

$$U_{k+1} = R(U_k + t_k \xi_k) = \text{qf}(U_k + t_k \xi_k), \quad (31)$$

where $\text{qf}(A)$ is used as a retraction operator, which is the Q factor in the QR factorization of A , and the step size t_k is obtained by the Armijo linear search rule [2].

To solve the Riemannian optimization subproblem (12) at each iteration, we present a non-linear conjugate gradient decent algorithm on Grassmannian manifolds. Overall, the skeleton of our method is listed in **Algorithm 2**.

3.5 Convergence Analysis

In this part, we analyze the convergence of Algorithm 2 using the non-linear conjugate gradient descent scheme.

Algorithm 2 A Riemannian optimization framework for solving the problem (12)

Input: The rank d , the parameters μ, τ and tol.

Output: $X = UM$.

- 1: **while** not converged **do**
 - 2: Formulate the cost function $f_{U_k M_k}$ by (12).
 - 3: Compute the Grassmannian gradient by (29),

$$\eta_k = \text{grad} f_{U_k M_k}(U_k).$$
 - 4: Check convergence: $\eta_k \leq \text{tol}$.
 - 5: Compute a conjugate direction ξ_k by (30).
 - 6: Find an appropriate step size t_k using Armijo rule, and compute U_{k+1} by (31).
 - 7: Compute M_{k+1} by (11).
 - 8: **end while**
-

Lemma 3. Let $g(X) = \|A(X) - b\|_F^2$, $\{(U_k, M_k)\}$ be an infinite sequence of iterates generated by Algorithm 2 with the Armijo backtracking rule, and $\tau \in (0, 1/\rho(\mathcal{A}^T \mathcal{A}))$, where $\rho(\cdot)$ denotes the spectral radius operator, then we have the following results:

- (I) $\lim_{k \rightarrow \infty} \|\text{grad} f_{U_k M_k}(U_k)\| = 0$.
 (II) $\lim_{k \rightarrow \infty} \|U_{k+1} - U_k\| = 0$, and

$$\lim_{k \rightarrow \infty} \|U_{k+1} M_{k+1} - U_k M_k\| = 0.$$

Proof: The detailed proof can be found in the supplementary material.

Theorem 4. Let $\{(U_k, M_k)\}$ be an infinite sequence of iterates generated by Algorithm 2. Then each accumulation point of $\{(U_k, M_k)\}$ is a critical point of the following optimization problem

$$\min_{\mathcal{U} \in \mathcal{G}_{m,d}} \min_{M \in \mathbb{R}^{d \times n}} \mu \tau \|M\|_* + \frac{1}{2} g(UM). \quad (32)$$

Proof: The detailed proof of the theorem can be found in the supplementary material.

3.6 Complexity Analysis

In this part, we discuss the time complexity of our method. For the matrix completion problem (12), the main running time of our algorithm is consumed by performing SVD for the SVT operator, some multiplications and retraction operator. The time complexity of performing the SVT operator in (11) is $O_1 := O(d^2 n)$. The time complexity of some multiplication and retraction operators is $O_2 := O(dmn + d^2 m)$. The time complexity of performing retraction operator is $O_3 := O(d^2 m)$. Thus, the total time complexity of our method is $O(T(O_1 + O_2 + O_3))$, where T is the number of iterations.

4 Graph Regularization Extensions

In this paper, we mainly consider the problem of recovering a noisy low-rank matrix from a few observed entries as

a matrix completion application of our nuclear norm regularized least squares model. In addition, our method is quite general, and can be easily extended to incorporate the contextual information, including social relations of users, social tags issued by users, movie genres, user demographic information, etc. In order to incorporate the social network information, our social network aided context-aware recommender model is formulated as follows:

$$\min_{U \in \mathcal{N}_{m,d}} \min_{M \in \mathbb{R}^{d \times n}} f(U, M) := \frac{1}{2} \|\mathcal{P}_\Omega(UM) - \mathcal{P}_\Omega(Z)\|_F^2 + \mu \|M\|_* + \frac{\lambda_1}{2} \text{tr}(U^T L_U U) + \frac{\lambda_2}{2} \text{tr}(M L_M M^T), \quad (33)$$

where $\text{tr}(A)$ denotes the trace of the matrix A , L_U and L_M are the graph Laplacian matrices, i.e., $L_U = D_U - W_U$, W_U is the weight matrix for the user set, and D_U is the diagonal matrix whose entries are column sums of W_U , i.e., $(D_U)_{ii} = \sum_j (W_U)_{ij}$, and $\lambda_1 \geq 0$ and $\lambda_2 \geq 0$ are regularization constants. It is not difficult to verify, for any matrix $O \in \mathcal{N}_{d,d}$, we have $f(UO, O^T M) = f(U, M)$. Hence, the Grassmannian manifold is also used in our social network aided context-aware recommender model, and it is reformulated as follows:

$$\min_{\mathcal{U} \in \mathcal{G}_{m,d}} \min_{M \in \mathbb{R}^{d \times n}} \frac{1}{2} \|\mathcal{P}_\Omega(UM) - \mathcal{P}_\Omega(Z)\|_F^2 + \mu \|M\|_* + \frac{\lambda_1}{2} \text{tr}(U^T L_U U) + \frac{\lambda_2}{2} \text{tr}(M L_M M^T), \quad (34)$$

where the column orthonormal matrix U is viewed as the generator matrix of \mathcal{U} . Moreover, Algorithm 2 can be extended to solve our graph regularized matrix completion problem (34).

5 Experimental Results

In this section, we evaluate both the effectiveness and efficiency of our method for solving matrix completion problems on both synthetic and real-world data.

5.1 Synthetic Data

The synthetic matrices $Z \in \mathbb{R}^{m \times n}$ with rank r in this subsection are created randomly by the following procedure: two random matrices $U \in \mathbb{R}^{m \times r}$ and $V \in \mathbb{R}^{n \times r}$ with i.i.d. standard Gaussian entries are first generated, and then $X = UV^T$ is assembled. Two test experiments are conducted on random matrix without or with noise, where the observed subset is corrupted by i.i.d. standard Gaussian random variables as in [17]. In both cases, only 10% observed entries are sampled uniformly at random as the training set, and the remaining is used as the testing set. Summaries of the computational results are presented in Figure 1 on noiseless matrices of size 2000×2000 and

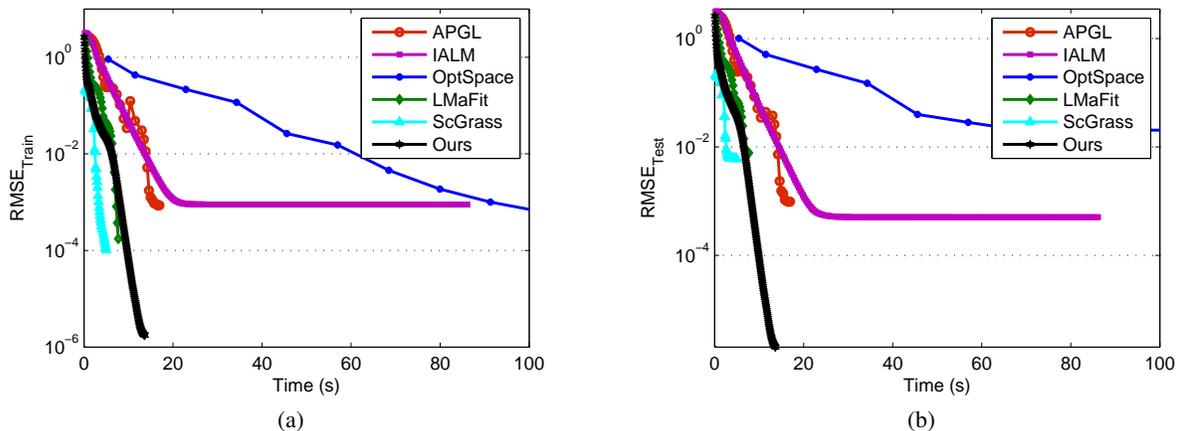

Figure 1: The recovery accuracy on noiseless data vs. running time (seconds): training RMSE (left) and testing RMSE (right).

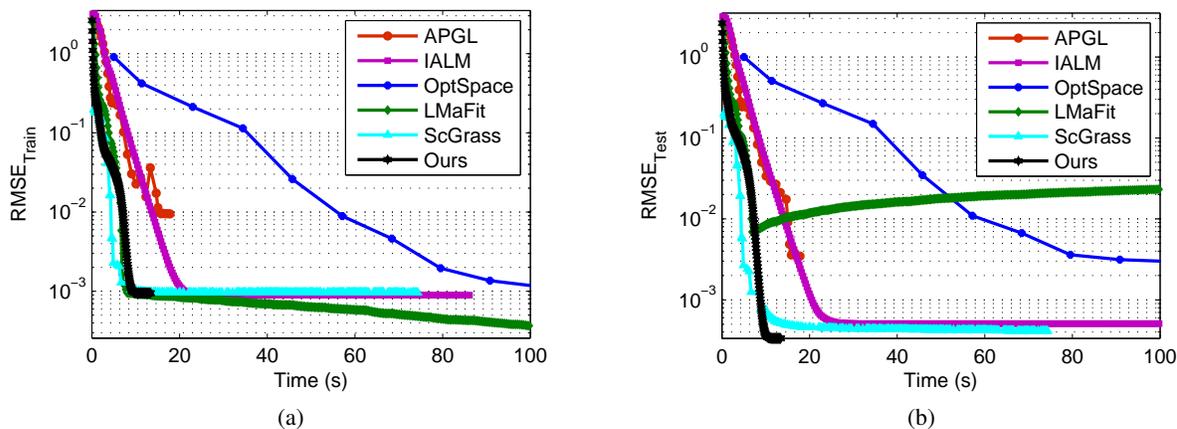

Figure 2: The recovery accuracy on noisy data (where the noise level $nf = 0.001$) vs. running time (seconds): training RMSE (left) and testing RMSE (right).

Figure 2 on noisy matrices of size 2000×2000 , respectively.

We compare our method with APGL¹ [17], IALM² [12], OptSpace³ [10], LMaFit⁴ [22], and ScGrass⁵ [15] on the noiseless or noisy matrices, and illustrate the training and testing recovery accuracies (RMSE) in Figures 1 and 2, respectively, where APGL and IALM use the PROPACK package [11] to compute a partial SVD. All the methods

are implemented in Matlab and use mex files. In terms of running time, the results show that for the noiseless data, our method, LMaFit and ScGrass converge much faster than the other three methods including APGL, IALM, and OptSpace. However, for the noisy data, the testing RMSE of LMaFit becomes worse due to overfitting while the training RMSE gradually decreases.

We also test the robustness of all these methods against the noise, and demonstrate the experimental results (the testing RMSE and running time) in Figure 3. It is clear that when the noise level is higher, our method usually outperforms the other methods in terms of the testing RMSE, that is, our method has the good generation ability. With the increase of the noise level, the running time of the other algorithms dramatically grows except for our method and OptSpace. In contrast, the runtime of our method increases slightly.

5.2 Real-World Data

In order to evaluate our method, experiments were conducted on three widely used recommendation systems data sets⁶: MovieLens100K (ML-100K) with 100K ratings, MovieLens1M (ML-1M) with 1M ratings, and MovieLens10M (ML-10M) with 10M ratings. We randomly split these three data sets to train and test sets such that the ratio of the train set to test set is 9:1, and the experimental results are reported over 20 independent runs. Except for APG, IALM, OptSpace, and LMaFit, we also compare our method with two state-of-the-art optimization methods on manifolds: ScGrass and RTRMC⁷ [4]. For our method, we set the rank $d = 5, 6, 7$, and $\mu = 10^{-2}$. The stopping tolerance for all algorithms is set to $\varepsilon = 10^{-4}$. All other parameters are set to their default values for the algorithms that we compare with. We also use the Root Mean Squared Error (RMSE) as the evaluation measure.

The average RMSE on these three data sets is reported over 20 independent runs and is shown in Table 1. The results show that for some fixed ranks, the matrix factorization methods including OptSpace, ScGrass, RTRMC, LMaFit and our method usually perform better than two nuclear norm minimization methods including APGL and IALM. As expected, our method with $d = 5$ on the MovieLens (1M) data set achieved a RMSE of 0.8711, slightly outperforming the well-known restricted Boltzmann machines’s RMSE of 0.8817 [16]. Moreover, our matrix factorization method with nuclear norm regularization consistently outperforms the other matrix factorization methods including OptSpace, ScGrass, RTRMC and LMaFit, and the two nuclear norm minimization methods including APGL and IALM. This confirms that the proposed matrix factorization model with nuclear norm regularization can avoid the over-fitting problems of matrix factorization.

Furthermore, we also analyze the robustness of our method with regard to its parameters: the given rank and the regularization parameter μ on the MovieLens1M data set, as

⁶<http://www.grouplens.org/node/73>

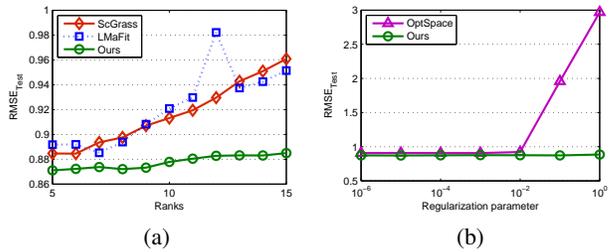

Figure 4: Results of our method with varying parameter values on the MovieLens1M data set.

shown in Figure 4, from which we can see that our method is robust against variations in its parameters. For comparison, we also show the results of two related methods: ScGrass and LMaFit with varying ranks in Figure 4(a). It is clear that, by increasing the number of the given ranks, the RMSE of ScGrass and LMaFit becomes worse. In contrast, the RMSE of our method increases slightly when the number of the given ranks increases. This further confirms that our matrix factorization model with nuclear norm regularization is effective and can avoid overfitting. OptSpace also has a spectral regularization version: $\min_{U,S,V} (1/2) \|\mathcal{P}_\Omega(USV^T - X)\|_F^2 + \mu \|S\|_F^2$. From Figure 4(b), we observe that our method is much more robust than OptSpace in terms of the regularization parameter μ .

Finally, we conduct the running time comparison of all those algorithms on the MovieLens100K and MovieLens1M data sets, as shown in Figure 5. The experiments were performed with Matlab 7.11 on an Intel Core 2 Duo (2.33 GHz) PC running Windows 7 with 2GB main memory. From the results shown in Figure 5, we can observe that our method, ScGrass, RTRMC, and LMaFit are much faster than the other three state-of-the-art algorithms including APGL, IALM and OptSpace. For APGL and IALM, SVD-related calculations essentially dominate their total costs. Therefore, avoiding SVD-related calculations on relative large-scale matrices is a main reason why our method is much faster than the nuclear norm minimization algorithms such as APGL and IALM, validating our original motivation of solving the matrix factorization model with nuclear norm regularization.

5.3 The Impact of Social Context

We also investigate the effects of social context on the MovieLens100K data set, which is suitable to evaluate the impacts of user demographic information and item genre information because it consists of demographic information (e.g. gender, age and occupation) of users and genre of movies. According to [8], a two dimensional feature vector is used to characterize the user’s gender, that is, if the user is male, then the first feature is 1 while the second is 0, and vice versa. The users are partitioned into 7 age group: 1-17,

Table 1: RMSE of different methods on three data sets: MovieLens 100K, MovieLens 1M, and MovieLens 10M.

Methods	MovieLens (100K)			MovieLens (1M)			MovieLens (10M)		
APGL	1.2142			1.1528			0.8637		
IALM	1.2585			1.0153			0.8989		
OptSpace	0.9411			0.9068			1.1357		
Ranks	5	6	7	5	6	7	5	6	7
ScGrass	0.9236	0.9392	0.9411	0.8847	0.8846	0.8936	0.8359	0.8290	0.8247
RTRMC	0.9837	1.0617	1.1642	0.8901	0.8906	0.8977	0.8463	0.8442	0.8386
LMaFit	0.9468	0.9540	0.9568	0.8918	0.8920	0.8853	0.8576	0.8530	0.8423
Ours	0.9216	0.9243	0.9330	0.8711	0.8723	0.8738	0.8330	0.8261	0.8217

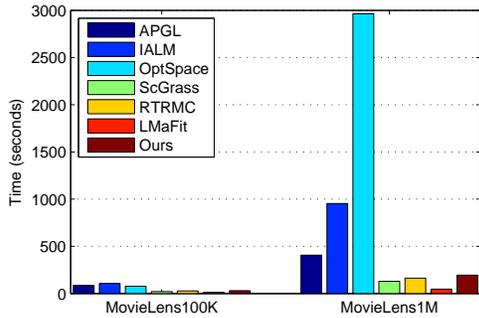

Figure 5: Running time (seconds) for comparison on the MovieLens100K and MovieLens1M data sets.

18-24, 25-34, 35-44, 45-49, 50-55, 56+. Then a seven dimensional feature vector is used to describe the user’s age group. In addition, there are totally 21 occupations: administrator, doctor, educator, engineer, entertainment, executive, healthcare, homemaker, lawyer, librarian, marketing, programmer, retired, salesman, scientist, student, technician, writer, other and none. Thus, a 21 dimensional feature vector is used to describe the user’s occupation. In total, a 30 dimensional feature vector is achieved for user i . On the other hand, there are 19 genres of movies. Likewise, we use a 19 dimensional feature vector for movie j . We evaluate the impact of user demographic and item genre information on this data set with 60% and 90% training sets, and we report in Fig. 6 the RMSE results yielded by our method without graph regularization, with user or item graph regularization and both graph regularizations. When with the effect of the user demographic or the item genre context, the performance of our method improves. For example, compared with our method without graph regularization, on average, our method with user or item graph regularization have 0.35% and 1.04% relative performance improvement in terms of RMSE, respectively. When with the effects of both the user demographic and the item genre context, our method obtains the best performance, suggesting that the user demographic and the item genre context

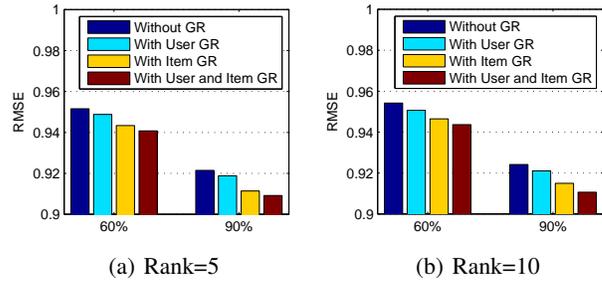

Figure 6: The performance of variants of our method on the the MovieLens100K data set.

contain complementary information to each other for recommendation.

6 Conclusions

In this paper, we proposed a Grassmannian manifold optimization method to tackle the nuclear norm regularized least squares problems with a guarantee of local convergence, such as the noisy matrix completion problem. Our method inherits the superiority of two classes of methods, i.e. soft thresholding approaches and hard thresholding approaches, and has good generation ability. In addition, our method is extended to address the graph regularized problem. We demonstrated with convincing experimental results that our regularized formulation is effective, and our method is robust to noise or against variations in its parameters.

Philadelphia, PA, 19104-6340

Abstract

We propose a new two stage algorithm LING for large scale regression problems. LING has the same risk as the well known Ridge Regression under the fixed design setting and can be computed much faster. Our experiments have shown that LING performs well in terms of both prediction accuracy and computational efficiency compared with other large scale regression algorithms like Gradient Descent, Stochastic Gradient Descent and Principal Component Regression on both simulated and real datasets.

1 INTRODUCTION

Ridge Regression (RR) is one of the most widely applied penalized regression algorithms in machine learning problems. Suppose \mathbf{X} is the $n \times p$ design matrix and \mathbf{Y} is the $n \times 1$ response vector, ridge regression tries to solve the problem

$$\hat{\beta} = \arg \min_{\beta \in \mathcal{R}^p} \|\mathbf{X}\beta - \mathbf{Y}\|^2 + n\lambda\|\beta\|^2 \quad (1)$$

which has an explicit solution

$$\hat{\beta} = (\mathbf{X}^\top \mathbf{X} + n\lambda)^{-1} \mathbf{X}^\top \mathbf{Y} \quad (2)$$

However, for modern problems with huge design matrix \mathbf{X} , computing (2) costs $O(np^2)$ FLOPS. When $p > n \gg 1$ one can consider the dual formulation of (1) which also has an explicit solution as mentioned in (Lu et al., 2013; Saunders et al., 1998) and the cost is $O(n^2p)$ FLOPS. In summary, trying to solve (1) exactly costs $O(np \min\{n, p\})$ FLOPS which can be very slow.

There are faster ways to approximate (2) when computational cost is the concern. One can view RR as an optimization problem and use Gradient Descent (GD) which

takes $O(np)$ FLOPS in every iteration. However, the convergence speed for GD depends on the spectrum of \mathbf{X} and the magnitude of λ . When \mathbf{X} is ill conditioned and λ is small, GD requires a huge number of iterations to converge which makes it very slow. For huge datasets, one can also apply stochastic gradient descent (SGD) (Zhang, 2004; Johnson and Zhang, 2013; Bottou, 2010), a powerful tool for solving large scale optimization problems.

Another alternative for regression on huge datasets is Principal Component Regression (PCR) as mentioned in (Artemiou and Li, 2009; Jolliffe, 2005), which runs regression only on the top k_1 principal components (PCs) of the \mathbf{X} matrix. PCA for huge \mathbf{X} can be computed efficiently by randomized algorithms like (Halko et al., 2011a,b). The cost for computing top k_1 PCs of \mathbf{X} is $O(npk_1)$ FLOPS. The connection between RR and PCR is well studied by (Dhillon et al., 2013). The problem of PCR is that when a large proportion of signal sits on the bottom PCs, it has to regress on a lot of PCs which makes it both slow and inaccurate (see later sections for detailed explanations).

In this paper, we propose a two stage algorithm LING¹ which is a faster way of computing the RR solution (2). A detailed description of the algorithm is given in section 2. In section 3, we prove that LING has the same risk as RR under the fixed design setting. In section 4, we compare the performance of PCR, GD, SGD and LING in terms of prediction accuracy and computational efficiency on both simulated and real data sets.

2 THE ALGORITHM

2.1 DESCRIPTION OF THE ALGORITHM

LING is a two stage algorithm. The intuition of LING is quite straight forward. We start with the observation that regressing \mathbf{Y} on \mathbf{X} (OLS) is essentially projecting \mathbf{Y} onto the span of \mathbf{X} . Let \mathbf{U}_1 denote the top k_2 PCs (left singular vectors) of \mathbf{X} and let \mathbf{U}_2 denote the remaining PCs. The projection of \mathbf{Y} onto the span of \mathbf{X} can be decom-

^{*} yichaolu@wharton.upenn.edu

[†] foster@wharton.upenn.edu

¹LING is the Chinese of ridge

Algorithm 1 LING

Input : Data matrix \mathbf{X}, \mathbf{Y} . \mathbf{U}_1 , an orthonormal matrix consists of top k_2 PCs of \mathbf{X} . d_1, d_2, \dots, d_{k_2} , top k_2 singular values of \mathbf{X} . Regularization parameter λ , an initial vector $\hat{\gamma}_{2,0}$ and number of iterations n_2 for GD .

Output : $\hat{\gamma}_{1,s}, \hat{\gamma}_2$, the regression coefficients.

1. Regress \mathbf{Y} on \mathbf{U}_1 , let $\hat{\gamma}_1 = \mathbf{U}_1^\top \mathbf{Y}$.

2. Compute the residual of previous regression problem.

Let $\mathbf{Y}_r = \mathbf{Y} - \mathbf{U}_1 \hat{\gamma}_1$.

3. Compute the residual of \mathbf{X} regressing on \mathbf{U}_1 . Use $\mathbf{X}_r = \mathbf{X} - \mathbf{U}_1 \mathbf{U}_1^\top \mathbf{X}$ to denote the residual of \mathbf{X} .

4. Use gradient descent with optimal step size with initial value $\hat{\gamma}_{2,0}$ (see algorithm 3) to solve the RR problem $\min_{\hat{\gamma}_2 \in \mathcal{R}^p} \|\mathbf{X}_r \hat{\gamma}_2 - \mathbf{Y}_r\|^2 + n\lambda \|\hat{\gamma}_2\|^2$.

5. Compute a shrinkage version of $\hat{\gamma}_1$ by $(\hat{\gamma}_{1,s})_i = \frac{d_i^2}{d_i^2 + n\lambda} (\hat{\gamma}_1)_i$

6. The final estimator is $\hat{\mathbf{Y}} = \mathbf{U}_1 \hat{\gamma}_{1,s} + \mathbf{X}_r \hat{\gamma}_2$.

posed into two orthogonal parts, the projection onto \mathbf{U}_1 and the projection onto \mathbf{U}_2 . In the first stage, we pick a $k_2 \ll p$ and the projection onto \mathbf{U}_1 can be computed directly by $\hat{\mathbf{Y}}_1 = \mathbf{U}_1 \mathbf{U}_1^\top \mathbf{Y}$ which is exactly the same as running a PCR on top k_2 PCs. For huge \mathbf{X} , computing the top k_2 PCs exactly is very slow, so we use a faster randomized SVD algorithm for computing \mathbf{U}_1 which is proposed by (Halko et al., 2011a) and described below. In the second stage, we first compute $\mathbf{Y}_r = \mathbf{Y} - \hat{\mathbf{Y}}_1$ and $\mathbf{X}_r = \mathbf{X} - \mathbf{U}_1 \mathbf{U}_1^\top \mathbf{X}$ which are the residual of \mathbf{Y} and \mathbf{X} after projecting onto \mathbf{U}_1 . Then we compute the projection of \mathbf{Y} onto the span of \mathbf{U}_2 by solving the optimization problem $\min_{\hat{\gamma}_2 \in \mathcal{R}^p} \|\mathbf{X}_r \hat{\gamma}_2 - \mathbf{Y}_r\|^2$ with GD (Algorithm 3). Finally, since RR shrinks the projection of \mathbf{Y} onto \mathbf{X} (the OLS solution) via regularization, we also shrink the projections in both stages accordingly. Shrinkage in the first stage is performed directly on the estimated regression coefficients and shrinkage in the second stage is performed by adding a regularization term to the optimization problem mentioned above. Detailed description of LING is shown in Algorithm 1.

Remark 1. LING can be regarded as a combination of PCR and GD. The first stage of LING is a very crude estimation of \mathbf{Y} and the second stage adds a correction to the first stage estimator. Since we do not need a very accurate estimator in the first stage it suffices to pick a very small k_2 in contrast with the k_1 PCs needed for PCR. In the second stage, the design matrix \mathbf{X}_r is a much better conditioned matrix than the original \mathbf{X} since the directions with largest singular values are removed. As introduced in section 2.2, Algorithm 3 converges much faster with a better conditioned matrix. Hence GD in the second stage of LING converges faster than directly applying GD for solving (1). The above property guarantees that LING is both fast and accurate compared with PCR and GD. More details about

Algorithm 2 Random SVD

Input : design matrix \mathbf{X} , target dimension k_2 , number of power iterations i .

Output : $\mathbf{U}_1 \in n \times k_2$, the matrix of top k_2 left singular vectors of \mathbf{X} , d_1, d_2, \dots, d_{k_2} , the top k_2 singular values of \mathbf{X} .

1. Generate random matrix $R_1 \in p \times k_2$ with i.i.d standard Gaussian entries.

2. Estimate the span of top k_2 left singular vectors of \mathbf{X} by $A_1 = (\mathbf{X}\mathbf{X}^\top)^i \mathbf{X}R_1$.

3. Use QR decomposition to compute Q_1 which is an orthonormal basis of the column space of A_1 .

4. Compute SVD of the reduced matrix $Q_1^\top \mathbf{X} = \mathbf{U}_0 \mathbf{D}_0 \mathbf{V}_0^\top$.

5. $\mathbf{U}_1 = Q_1 \mathbf{U}_0$ gives the top k_2 singular vectors of \mathbf{X} and the diagonal elements of \mathbf{D}_0 gives the singular values.

Algorithm 3 Gradient Descent with Optimal Step Size (GD)

Goal : Solve the ridge problem $\min_{\hat{\gamma} \in \mathcal{R}^p} \|\mathbf{X}\hat{\gamma} - \mathbf{Y}\|^2 + n\lambda \|\hat{\gamma}\|^2$.

Input : Data matrix \mathbf{X}, \mathbf{Y} , regularization parameter λ , number of iterations n_2 , an initial vector $\hat{\gamma}_0$

Output : $\hat{\gamma}$

for $t = 0$ **to** $n_2 - 1$ **do**

$Q = 2\mathbf{X}^\top \mathbf{X} + 2n\lambda \mathbf{I}$

$w_t = 2\mathbf{X}^\top \mathbf{Y} - Q\hat{\gamma}_t$

$s_t = \frac{w_t^\top w_t}{w_t^\top Q w_t}$. s_t is the step size which makes the target function decrease the most in direction w_t .

$\hat{\gamma}_{t+1} = \hat{\gamma}_t + s_t \cdot w_t$.

end for

on the computational cost will be discussed in section 2.2.

Remark 2. Algorithm 2 is essentially approximating the subspace of top left singular vectors by random projection. It provides a fast approximation of the top singular values and vectors for large \mathbf{X} when computing the exact SVD is very slow. Theoretical guarantees and more detailed explanations can be found in (Halko et al., 2011a). Empirically we find in the experiments, Algorithm 2 may occasionally generate a bad subspace estimator due to randomness which makes PCR perform badly. On the other hand, LING is much more robust since in the second stage it compensates for the signal missing in the first stage. In all the experiments, we set $i = 1$.

The shrinkage step (step 5) in Algorithm 1 is only necessary for theoretical purposes since the goal is to approximate Ridge Regression which shrinks the Least Square estimator over all directions. In practice shrinkage over the top k_2 PCs is not necessary. Usually the number of PCs selected (k_2) is very small. From the bias variance trade off perspective, the variance reduction gained from the shrinkage over top k_2 PCs is at most $O(\frac{k_2}{n})$ under

the fixed design setting (Dhillon et al., 2013) which is a tiny number. Moreover, since the top singular values of $\mathbf{X}^\top \mathbf{X}$ are usually very large compared with $n\lambda$ in most real problems, the shrinkage factor $\frac{d_i^2}{d_i^2 + n\lambda}$ will be pretty close to 1 for top singular values. We use shrinkage in Algorithm 1 because the risk of the shrinkage version of LING is exactly the same as RR as proved in section 3.

Algorithm 2 can be further simplified if we skip the shrinkage step mentioned in previous paragraph. Instead of computing the top k_2 PCs, the only thing we need to know is the subspace spanned by these PCs since the first stage is essentially projecting \mathbf{Y} onto this subspace. In other words, we can replace \mathbf{U}_1 in step 1, 2, 3 of Algorithm 1 with Q_1 obtained in step 3 of Algorithm 2 and directly let $\hat{\mathbf{Y}} = Q_1 \hat{\gamma}_1 + \mathbf{X}_r \hat{\gamma}_2$. In the experiments of section 4 we use this simplified version.

2.2 COMPUTATIONAL COST

We claim that the cost of LING is $O(np(k_2 + n_2))$ where k_2 is the number of PCs used in the first stage and n_2 is the number of iterations of GD in the second stage. According to (Halko et al., 2011a), the dominating step in Algorithm 2 is computing $(\mathbf{X}\mathbf{X}^\top)^k \mathbf{X}R_1$ and $Q_1^\top \mathbf{X}$ which costs $O(npk_2)$ FLOPS. Computing $\hat{\gamma}_1$ and \mathbf{Y}_r cost less than $O(npk_2)$. Computing \mathbf{X}_r costs $O(npk_2)$. So the computational cost before the GD step is $O(npk_2)$. For the GD stage, note that in every iteration Q never needs to be constructed explicitly. While computing w_t and s_t , always multiplying matrix and vector first gives a cost of $O(np)$ for every iteration. So the cost for GD stage is $O(n_2 np)$. Add all pieces together the cost of LING is $O(np(k_2 + n_2))$ FLOPS.

Let n_1 be the number of iterations required for solving (1) directly by GD and k_1 be the number of PCs used for PCR. It's easy to check that the cost for GD is $O(n_1 np)$ FLOPS and the cost for PCR is $O(npk_1)$. As mentioned in remark 1, the advantage of LING over GD and PCR is that k_1 and n_1 might have to be really large to achieve high accuracy but much smaller values of the pair (k_2, n_2) will work for LING.

In the remaining part of the paper we use "signal on certain PCs" to refer to the projection of \mathbf{Y} onto certain principal components of \mathbf{X} . Consider the case when the signal is widely spread among all PCs (i.e. the projection of \mathbf{Y} onto the bottom PCs of \mathbf{X} is not very small) instead of concentrating on the top ones, k_1 needs to be large to make PCR perform well since the signal on bottom PCs are discarded by PCR. But LING does not need to include all the signal in the first stage regression since the signal left over will be estimated in the second GD stage. Therefore LING is able to recover most of the signal even with a small k_2 .

In order to understand the connection between accuracy and number of iterations in Algorithm 3, we state the fol-

lowing theorem in A.Epelman (2007):

Theorem 1. *Let $g(z) = \frac{1}{2}z^\top Mz + q^\top z$ be a quadratic function where M is a PSD matrix. Suppose $g(z)$ achieves minimum at z^* . Apply Algorithm 3 to solve the minimization problem. Let z_t be the z value after t iterations, then the gap between $g(z_t)$ and $g(z^*)$, the minimum of the objective function satisfies*

$$\frac{g(z_{t+1}) - g(z^*)}{g(z_t) - g(z^*)} \leq C = \left(\frac{A - a}{A + a} \right)^2 \quad (3)$$

where A, a are the largest and smallest eigenvalue of the M matrix.

Theorem 1 shows that the sub optimality of the target function decays exponentially as the number of iterations increases and the speed of decay depends on the largest and smallest singular value of the PSD matrix that defines the quadratic objective function. If we directly apply GD to solve (1), Let $f_1(\beta) = \|\mathbf{X}\beta - \mathbf{Y}\|^2 + n\lambda\|\beta\|^2$. Assume f_1 reaches its minimum at $\hat{\beta}$. Let $\hat{\beta}_t$ be the coefficient after t iterations and let d_i denote the i^{th} singular value of \mathbf{X} . Applying theorem 1, we have

$$\frac{f_1(\hat{\beta}_{t+1}) - f_1(\hat{\beta})}{f_1(\hat{\beta}_t) - f_1(\hat{\beta})} \leq C = \left(\frac{d_1^2 - d_p^2}{d_1^2 + d_p^2 + 2n\lambda} \right)^2 \quad (4)$$

Similarly for the second stage of LING, Let $f_2(\gamma_2) = \|\mathbf{X}_r \gamma_2 - \mathbf{Y}_r\|^2 + n\lambda\|\gamma_2\|^2$. Assume f_2 reaches its minimal at $\hat{\gamma}_2$. We have

$$\frac{f_2(\hat{\gamma}_{2,t+1}) - f_2(\hat{\gamma}_2)}{f_2(\hat{\gamma}_{2,t}) - f_2(\hat{\gamma}_2)} \leq C = \left(\frac{d_{k_2+1}^2}{d_{k_2+1}^2 + 2n\lambda} \right)^2 \quad (5)$$

In most real problems, the top few singular values of $\mathbf{X}^\top \mathbf{X}$ are much larger than the other singular values and $n\lambda$. Therefore the constant C obtained in (4) can be very close to 1 which makes GD algorithm converges very slowly. On the other hand, removing the top few PCs will make C in (5) significantly smaller than 1. In other words, GD may take a lot of iterations to converge when solving (1) directly while the second stage of LING takes much less iterations to converge. This can also be seen in the experiments of section 4.

3 THEOREMS

In this section we compute the risk of LING estimator (explained below) under the fixed design setting. For simplicity, assume $\mathbf{U}_1, \mathbf{D}_0$ generated by Algorithm 2 give exactly the top k_2 left singular vectors and singular values of \mathbf{X} and GD in step 4 of Algorithm 1 converges to the optimal solution. Let $\mathbf{X} = \mathbf{U}\mathbf{D}\mathbf{V}^\top$ be the SVD of \mathbf{X} where $\mathbf{U} = (\mathbf{U}_1, \mathbf{U}_2)$ and $\mathbf{V} = (\mathbf{V}_1, \mathbf{V}_2)$. Here $\mathbf{U}_1, \mathbf{V}_1$ are top k_2 singular vectors and $\mathbf{U}_2, \mathbf{V}_2$ are bottom

$p - k_2$ singular vectors. Let $\mathbf{D} = \text{diag}(\mathbf{D}_1, \mathbf{D}_2)$ where $\mathbf{D}_1 \in k_2 \times k_2$ contains top k_2 singular values denoted by $d_1 \geq d_2 \geq \dots \geq d_{k_2}$ and $\mathbf{D}_2 \in p - k_2 \times p - k_2$ contains bottom $p - k_2$ singular values. Let $\mathbf{D}_3 = \text{diag}(\mathbf{0}, \mathbf{D}_2)$ (replace \mathbf{D}_1 in \mathbf{D} by a zero matrix of the same size).

3.1 THE FIXED DESIGN MODEL

Assume \mathbf{X} , \mathbf{Y} comes from the fixed design model $\mathbf{Y} = \mathbf{X}\beta + \epsilon$ where $\epsilon \in n \times 1$ are i.i.d noise with mean 0 and variance σ^2 . Here \mathbf{X} is fixed and the randomness of \mathbf{Y} only comes from ϵ . Note that $\mathbf{X} = \mathbf{U}_1 \mathbf{D}_1 \mathbf{V}_1^\top + \mathbf{X}_r$, the fixed design model can also be written as

$$\mathbf{Y} = (\mathbf{U}_1 \mathbf{D}_1 \mathbf{V}_1^\top + \mathbf{X}_r) \beta + \epsilon = \mathbf{U}_1 \gamma_1 + \mathbf{X}_r \gamma_2 + \epsilon$$

where $\gamma_1 = \mathbf{D}_1 \mathbf{V}_1^\top \beta$ and $\gamma_2 = \beta$. We use the l_2 distance between $\mathbb{E}(\mathbf{Y}|\mathbf{X})$ (the best possible prediction given \mathbf{X} under l_2 loss) and $\hat{\mathbf{Y}} = \mathbf{U}_1 \hat{\gamma}_{1,s} + \mathbf{X}_r \hat{\gamma}_2$ (the prediction by LING) as the loss function, which is called risk in the following discussions. Actually $\mathbb{E}(\mathbf{Y}|\mathbf{X}) = \mathbf{X}\beta$ is linear in \mathbf{X} under fixed design model. The risk of LING can be written as

$$\begin{aligned} & \frac{1}{n} \mathbb{E} \|\mathbb{E}(\mathbf{Y}|\mathbf{X}) - \mathbf{U}_1 \hat{\gamma}_{1,s} - \mathbf{X}_r \hat{\gamma}_2\|^2 \\ &= \frac{1}{n} \mathbb{E} \|\mathbf{U}_1 \gamma_1 + \mathbf{X}_r \gamma_2 - \mathbf{U}_1 \hat{\gamma}_{1,s} - \mathbf{X}_r \hat{\gamma}_2\|^2 \end{aligned}$$

We can further decompose the risk into two terms:

$$\begin{aligned} & \frac{1}{n} \mathbb{E} \|\mathbf{U}_1 \gamma_1 + \mathbf{X}_r \gamma_2 - \mathbf{U}_1 \hat{\gamma}_{1,s} - \mathbf{X}_r \hat{\gamma}_2\|^2 = \\ & \frac{1}{n} \mathbb{E} \|\mathbf{U}_1 \gamma_1 - \mathbf{U}_1 \hat{\gamma}_{1,s}\|^2 + \frac{1}{n} \mathbb{E} \|\mathbf{X}_r \gamma_2 - \mathbf{X}_r \hat{\gamma}_2\|^2 \end{aligned} \quad (6)$$

because $\mathbf{U}_1^\top \mathbf{X}_r = \mathbf{0}$. Note that here the expectation is taken with respect to ϵ .

Let's calculate the two terms in (6) separately. For the first term we have:

Lemma 1.

$$\frac{1}{n} \mathbb{E} \|\mathbf{U}_1 \gamma_1 - \mathbf{U}_1 \hat{\gamma}_{1,s}\|^2 = \frac{1}{n} \sum_{j=1}^{k_2} \frac{d_j^4 \sigma^2 + \gamma_{1,j}^2 n^2 \lambda^2}{(d_j^2 + n\lambda)^2} \quad (7)$$

Here $\gamma_{1,j}$ is the j^{th} element of γ_1 .

Proof. Let $S \in k_2 \times k_2$ be the diagonal matrix with $S_{j,j} = \frac{d_j^2}{d_j^2 + n\lambda}$. So we have $\hat{\gamma}_{1,s} = S \mathbf{U}_1^\top \mathbf{Y} = S \gamma_1 + S \mathbf{U}_1^\top \epsilon$,

$$\mathbb{E}(\hat{\gamma}_{1,s}) = S \gamma_1.$$

$$\begin{aligned} & \frac{1}{n} \mathbb{E} \|\mathbf{U}_1 \gamma_1 - \mathbf{U}_1 \hat{\gamma}_{1,s}\|^2 \\ &= \frac{1}{n} \mathbb{E} \|\mathbf{U}_1 \mathbb{E}(\hat{\gamma}_{1,s}) - \mathbf{U}_1 \hat{\gamma}_{1,s}\|^2 \\ & \quad + \frac{1}{n} \|\mathbf{U}_1 \gamma_1 - \mathbf{U}_1 \mathbb{E}(\hat{\gamma}_{1,s})\|^2 \\ &= \frac{1}{n} \mathbb{E} \|\mathbf{U}_1 S \mathbf{U}_1^\top \epsilon\|^2 + \frac{1}{n} \|\gamma_1 - S \gamma_1\|^2 \\ &= \frac{1}{n} \mathbb{E} \text{Tr}(\mathbf{U}_1 S^2 \mathbf{U}_1^\top \epsilon \epsilon^\top) + \frac{1}{n} \|\gamma_1 - S \gamma_1\|^2 \\ &= \frac{1}{n} \mathbb{E} \text{Tr}(S^2) \sigma^2 + \frac{1}{n} \|\gamma_1 - S \gamma_1\|^2 \\ &= \frac{1}{n} \sum_{j=1}^{k_2} \frac{d_j^4 \sigma^2 + \gamma_{1,j}^2 n^2 \lambda^2}{(d_j^2 + n\lambda)^2} \end{aligned}$$

□

Now consider the second term in (6).

Note that

$$\mathbf{X}_r = \mathbf{U} \mathbf{D}_3 \mathbf{V}^\top$$

The residual \mathbf{Y}_r after the first stage can be represented by

$$\mathbf{Y}_r = \mathbf{Y} - \mathbf{U}_1 \hat{\gamma}_1 = (\mathbf{I} - \mathbf{U}_1 \mathbf{U}_1^\top) \mathbf{Y} = \mathbf{X}_r \gamma_2 + (\mathbf{I} - \mathbf{U}_1 \mathbf{U}_1^\top) \epsilon$$

and the optimal coefficient obtained in the second GD stage is

$$\hat{\gamma}_2 = (\mathbf{X}_r^\top \mathbf{X}_r + n\lambda \mathbf{I})^{-1} \mathbf{X}_r^\top \mathbf{Y}_r$$

For simplicity, let $\epsilon_2 = (\mathbf{I} - \mathbf{U}_1 \mathbf{U}_1^\top) \epsilon$.

Lemma 2.

$$\mathbb{E} \|\mathbf{X}_r \gamma_2 - \mathbf{X}_r \hat{\gamma}_2\|^2 = \sum_{i=k_2+1}^p \frac{1}{(d_i^2 + n\lambda)^2} (d_i^4 \sigma^2 + n\lambda^2 d_i^2 \alpha_i^2) \quad (8)$$

where α_i is the i^{th} element of $\alpha = \mathbf{V}^\top \gamma_2$

Proof. First define

$$\begin{aligned} \mathbf{X}_\lambda &= \mathbf{X}_r^\top \mathbf{X}_r + n\lambda \mathbf{I} \\ \mathbf{D}_\lambda &= \mathbf{D}_3^2 + n\lambda \mathbf{I} \end{aligned}$$

$$\begin{aligned} \mathbb{E} \|\mathbf{X}_r \gamma_2 - \mathbf{X}_r \hat{\gamma}_2\|^2 &= \|\mathbf{X}_r \gamma_2 - \mathbf{X}_r \mathbb{E}(\hat{\gamma}_2)\|^2 \quad (9) \\ & \quad + \mathbb{E} \|\mathbf{X}_r \mathbb{E}(\hat{\gamma}_2) - \mathbf{X}_r \hat{\gamma}_2\|^2 \quad (10) \end{aligned}$$

Consider (9) and (10) separately.

$$\begin{aligned} (9) &= \|\mathbf{X}_r \mathbf{X}_\lambda^{-1} \mathbf{X}_r^\top \mathbf{X}_r \gamma_2 - \mathbf{X}_r \gamma_2\|^2 \\ &= \|\mathbf{U} \mathbf{D}_3 \mathbf{D}_\lambda^{-1} \mathbf{D}_3^2 \mathbf{V}^\top \gamma_2 - \mathbf{U} \mathbf{D}_3 \mathbf{V}^\top \gamma_2\|^2 \\ &= \|\mathbf{D}_3 \mathbf{D}_\lambda^{-1} \mathbf{D}_3^2 \alpha - \mathbf{D}_3 \alpha\|^2 \\ &= \sum_{i=k_2+1}^p \alpha_i^2 d_i^2 \left(\frac{n\lambda}{d_i^2 + n\lambda} \right)^2 \end{aligned}$$

$$\begin{aligned}
(10) &= \mathbb{E}_{\epsilon_2} \|\mathbf{X}_r \mathbf{X}_\lambda^{-1} \mathbf{X}_r^\top \epsilon_2\|^2 \\
&= \mathbb{E}_{\epsilon_2} \text{Tr}(\mathbf{X}_r \mathbf{X}_\lambda^{-1} \mathbf{X}_r^\top \mathbf{X}_r \mathbf{X}_\lambda^{-1} \mathbf{X}_r^\top \epsilon_2 \epsilon_2^\top) \\
&= \mathbb{E}_{\epsilon_2} \text{Tr}(\mathbf{D}_3 \mathbf{D}_\lambda^{-1} \mathbf{D}_3^2 \mathbf{D}_\lambda^{-1} \mathbf{D}_3 \mathbf{U}^\top \epsilon_2 \epsilon_2^\top \mathbf{U}) \\
&= \text{Tr}(\mathbf{D}_3 \mathbf{D}_\lambda^{-1} \mathbf{D}_3^2 \mathbf{D}_\lambda^{-1} \mathbf{D}_3 \mathbb{E}_{\epsilon_2} [\mathbf{U}^\top \epsilon_2 \epsilon_2^\top \mathbf{U}])
\end{aligned}$$

Note that

$$\mathbb{E}_{\epsilon_2} [\mathbf{U}^\top \epsilon_2 \epsilon_2^\top \mathbf{U}] = \text{diag}(0, I_{p-k_2}) \sigma^2$$

($\text{diag}(0, I_{p-k_2})$) replace the top $k_2 \times k_2$ block of the identity matrix with 0),

$$(10) = \sum_{i=k_2+1}^p \frac{d_i^4}{(d_i^2 + n\lambda)^2} \sigma^2 \quad (11)$$

Add the two terms together finishes the proof. \square

Plug (7) (8) into (6) we have

Theorem 2. *The risk of LING algorithm under fixed design setting is*

$$\frac{1}{n} \sum_{j=1}^{k_2} \frac{d_j^4 \sigma^2 + \gamma_{1,j}^2 n^2 \lambda^2}{(d_j^2 + n\lambda)^2} + \frac{1}{n} \sum_{i=k_2+1}^p \frac{d_i^4 \sigma^2 + n^2 \lambda^2 d_i^2 \alpha_i^2}{(d_i^2 + n\lambda)^2} \quad (12)$$

Remark 3. *This risk is the same as the risk of ridge regression provided by Lemma 1 in (Dhillon et al., 2013). Actually, LING gets exactly the same prediction as RR on the training dataset. This is very intuitive since on the training set LING is essentially decomposing the RR solution into the first stage shrinkage PCR predictor on top k_2 PCs and the second stage GD predictor over the residual spaces as explained in section 2.*

4 EXPERIMENTS

In this section we compare the accuracy and computational cost (evaluated in terms of FLOPS) of 3 different algorithms for solving Ridge Regression: Gradient Descent with Optimal step size (GD), Stochastic Variance Reduction Gradient (SVRG) (Johnson and Zhang, 2013) and LING. Here SVRG is an improved version of stochastic gradient descent which achieves exponential convergence with constant step size. We also consider Principal Component Regression (PCR) (Artemiou and Li, 2009; Jolliffe, 2005) which is another common way for running large scale regression. Experiments are performed on 3 simulated models and 2 real datasets. In general, LING performs well on all 3 simulated datasets while GD, SVRG and PCR fails in some cases. For two real datasets, all algorithms give reasonable performance while SVRG and LING are the best. Moreover, both stages of LING require only a moderate amount of matrix multiplications each cost $O(np)$, much faster to run on matlab compared with SVRG which contains a lot of loops.

Table 1: parameter setup for simulated data

	MODEL 1	MODEL 2	MODEL 3
k_1	21,22,23,26 30,50,100	20,30,50 100,150,400	20,30,50,100 150,400
n_1	10,20,30 50,80,100 150,200	2,4,6,8,10 15,20,30	6,10,15,20 30,50,80 120,180,250
k_2	20	20	20
n_2	1,2,3,5 8,13,20	2,4,6,8,10 15,20,30	2,4,6,8,10 15,30
n_{SVRG}	30,50,80 120,150	5,10,20 30,50	5,10,15,25 40,60,90

4.1 SIMULATED DATA

Three different datasets are constructed based on the fixed design model $\mathbf{Y} = \mathbf{X}\beta + \epsilon$ where \mathbf{X} is of size 2000×1500 . In the three experiments \mathbf{X} and β are generated randomly in different ways (more details in following sections) and i.i.d Gaussian noise is added to $\mathbf{X}\beta$ to get \mathbf{Y} . Then GD, SVRG, PCR and LING are performed on the dataset. For GD, we try different number of iterations n_1 . For SVRG, we vary the number of passes through data denoted by n_{SVRG} . The number of iterations SVRG takes equals the number of passes through data times sample size and each iteration takes $O(p)$ FLOPS. The step size of SVRG is chosen by cross validation but this cost is not considered when evaluating the total computational cost. Note that one advantage of GD and LING is that due to the simple quadratic form of the target function, their step size can be computed directly from the data without cross validation which introduces extra cost. For PCR we pick different number of PCs (k_1). For LING we pick top k_2 PCs in the first stage and try different number of iterations n_2 in the second stage. The computational cost and the risk of the four algorithms are computed. The above procedure is repeated over 20 random generation of \mathbf{X} , β and \mathbf{Y} . The risk and computational cost of the traditional RR solution (2) for every dataset is also computed as a benchmark.

The parameter set up for the three datasets are listed in table 1.

4.1.1 MODEL 1

In this model the design matrix \mathbf{X} has a steep spectrum. The top 30 singular values of \mathbf{X} decay exponentially as 1.3^i where $i = 40, 39, 38, \dots, 11$. The spectrum of \mathbf{X} is shown in figure 4. To generate \mathbf{X} , we fix the diagonal matrix \mathbf{D}_e with the designed spectrum and construct \mathbf{X} by $\mathbf{X} = \mathbf{U}_e \mathbf{D}_e \mathbf{V}_e^\top$ where $\mathbf{U}_e, \mathbf{V}_e$ are two random orthonormal matrices. The elements of β are sampled uniformly from interval $[-2.5, 2.5]$. Under this set up, most of the energy of the \mathbf{X} matrix lies in top PCs since the top singular values are much larger than the remaining ones so PCR works well. But as indicated by (4), the convergence of GD

is very slow.

The computational cost and average risk of the four algorithms and also the RR solution (2) over 20 repeats are shown in figure 1. As shown in figure 1 both PCR and LING work well by achieving risk close to RR at less computational cost. SVRG is worse than PCR and LING but much better than GD.

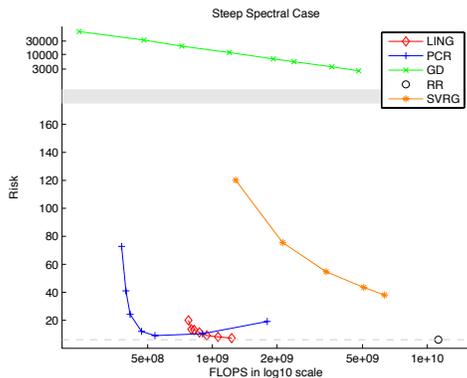

Figure 1: Model 1, Risk VS. Computational Cost plot. PCR and LING approaches the RR risk very fast. SVRG also approaches RR risk but cost more than the previous two. GD is very slow and inaccurate.

4.1.2 MODEL 2

In this model the design matrix \mathbf{X} has a flat spectrum. The singular values of \mathbf{X} are sampled uniformly from $[\frac{\sqrt{2000}}{2}, \sqrt{2000}]$. The spectrum of \mathbf{X} is shown in figure 5. To generate \mathbf{X} , we fix the diagonal matrix \mathbf{D}_e with the designed spectrum and construct \mathbf{X} by $\mathbf{X} = \mathbf{U}_e \mathbf{D}_e \mathbf{V}_e^T$ where $\mathbf{U}_e, \mathbf{V}_e$ are two random orthonormal matrices. The elements of β are sampled uniformly from interval $[-2.5, 2.5]$. Under this set up, the signal are widely spread among all PCs since the spectrum of \mathbf{X} is relatively flat. PCR breaks down because it fails to catch the signal on bottom PCs. As indicated by (4), GD converges relatively fast due to the flat spectrum of \mathbf{X} .

The computational cost and average risk of the four algorithms and also the RR solution (2) over 20 repeats are shown in figure 2. As shown by the figure GD works best since it approaches the risk of RR at the the lowest computational cost. LING and SVRG also works by achieving reasonably low risk with less computational cost. PCR works poorly as explained before.

4.1.3 MODEL 3

This model presented a special case where both PCR and GD will break down. The singular values of $\mathbf{X} \in 2000 \times 1500$ are constructed by first uniformly sample from $[\frac{\sqrt{2000}}{2}, \sqrt{2000}]$. The top 15 sampled values are then multiplied by 10. The top 100 singular values of \mathbf{X} are shown in

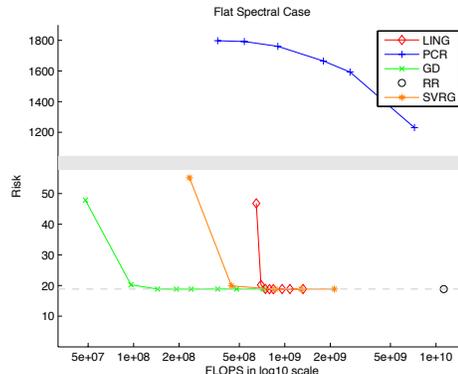

Figure 2: Model 2, Risk VS. Computational Cost plot. GD approaches the RR risk very fast. SVRG and LING are slower than GD but still achieves risk close to RR at less cost. PCR is slow and has huge risk.

figure 6. To generate \mathbf{X} , we fix the diagonal matrix \mathbf{D}_e with the designed spectrum and construct \mathbf{X} by $\mathbf{X} = \mathbf{U}_e \mathbf{D}_e$ where \mathbf{U}_e is a random orthonormal matrix. The first 15 and last 1000 elements of the coefficient vector $\beta \in 1500 \times 1$ are sampled uniformly from interval $[-2.5, 2.5]$ and other elements of β remains 0. In this set up, \mathbf{X} has orthogonal columns which are the PCs, and the signal lies only on the top 15 and bottom 1000 PCs. PCR won't work since a large proportion of signal lies on the bottom PCs. On the other hand, GD won't work as well since the top few singular values are too large compared with other singular values, which makes GD converges very slowly.

The computational cost and risk of the four algorithms and also the RR solution (2) over 20 repeats are shown in figure 3. As shown by the figure LING works best in this set up. SVRG is slightly worse than LING but still approaching RR with less cost. In this case, GD converges slowly and PCR is completely off target as explained before.

4.2 REAL DATA

In this section we compare PCR, GD, SVRG and LING with the RR solution (2) on two real datasets.

4.2.1 GISETTE DATASET

The first is the gisette data set (Guyon et al., 2004) from the UCI repository which is a bi-class classification task. Every row of the design matrix $\mathbf{X} \in 6000 \times 5000$ consists of pixel features of a single digit "4" or "9" and \mathbf{Y} gives the class label. Among the 6000 samples, we use 5000 for training and 1000 for testing. The classification error rate for RR solution (2) is 0.019. Since the goal is to compare different algorithms for regression, we don't care about achieving the state of the art accuracy for this dataset as long as regression works reasonably well. When running

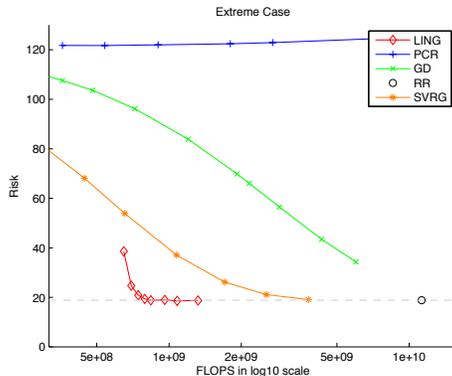

Figure 3: Model 3, Risk VS. Computational Cost plot. LING approaches RR risk the fastest. SVRG is slightly slower than LING. GD also approaches RR risk but cost more than LING. PCR has a huge risk no matter how many PCs are selected.

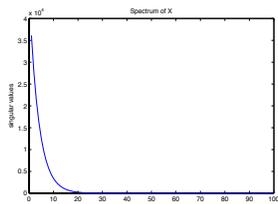

Figure 4: Top 100 singular values of \mathbf{X} in Model 1

PCR, we pick top $k_1 = 10, 20, 40, 80, 150, 300, 400$ PCs and in GD we iterate $n_1 = 2, 5, 10, 15, 20, 30, 50, 100, 150$ times. For SVRG we try $n_{SVRG} = 1, 2, 3, 5, 10, 20, 40, 80$ passes through the data. For LING we pick $k_2 = 5, 15$ PCs in the first stage and try $n_2 = 1, 2, 4, 8, 10, 15, 20, 30, 50$ iterations in the second stage. The computational cost and average classification error of the four algorithms and also the RR solution (2) on test set over 6 different train test splits are shown in figure 7. The top 150 singular values of \mathbf{X} are shown in figure 9. As shown in the figure, SVRG gets close to the RR error very fast. The two curves of LING with $k_2 = 5, 15$ are slower than SVRG since some initial FLOPS are spent on computing top PCs but after that they approach RR error very fast. GD also converges to RR but cost more than the previous two algorithms. PCR performs worst in terms of error and computational cost.

4.2.2 BUZZ IN SOCIAL MEDIA

The second dataset is the UCI buzz in social media dataset which is a regression task. The goal is to predict popularity (evaluated by the mean number of active discussion) of a certain topic on Twitter over a period. The original feature matrix contains some statistics about this topic over that period like number of discussions created and new authors interacting at the topic. The original feature dimen-

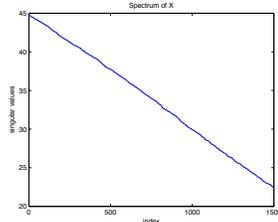

Figure 5: Singular values of \mathbf{X} in Model 2

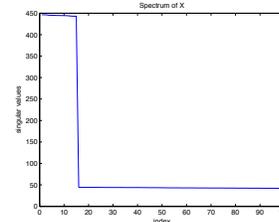

Figure 6: Top 100 singular values of \mathbf{X} in Model 3

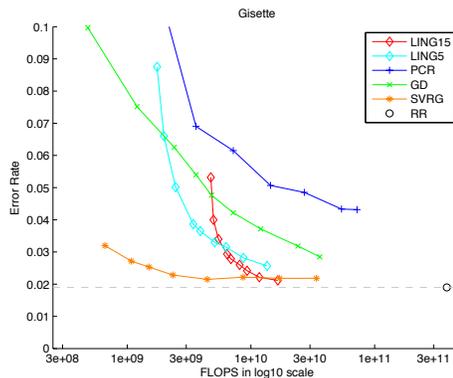

Figure 7: Gisette, Error Rate VS. Computational Cost plot. SVRG achieves small error rate fastest. Two LING lines with different n_2 spent some FLOPS on computing top PCs first, but then converges very fast to a lower error rate. GD and PCR also provide reasonably small error rate and are faster than RR, but suboptimal compared with SVRG and LING.

sion is 77. We add quadratic interactions to make it 3080. To save time, we only used a subset of 8000 samples. The samples are split into 6000 train and 2000 test. We use MSE on the test data set as the error measure. For PCR we pick $k_1 = 10, 20, 30, 50, 100, 150$ PCs and in GD we iterate $n_1 = 1, 2, 4, 6, 8, 10, 15, 20, 30, 40, 60, 100$ times. For SVRG we try $n_{SVRG} = 1, 2, 3, 5, 10, 15, 20, 40, 80$ passes through the dataset and for LING we pick $k_2 = 5, 15$ in the first stage and $n_2 = 0, 1, 2, 4, 6, 8, 10, 15, 20, 25$ iterations in the second stage. The computational cost and average MSE on test set over 5 different train test splits are shown in figure 8. The top 150 singular values of \mathbf{X} are shown in figure 10. As shown in the figure, SVRG approaches MSE of RR very fast. LING spent some initial FLOPS for computing top PCs but after that converges fast. GD and PCR also achieves reasonable performance but suboptimal compared with SVRG and LING. The MSE of PCR first decays when we add more PCs into regression but finally goes up due to overfit.

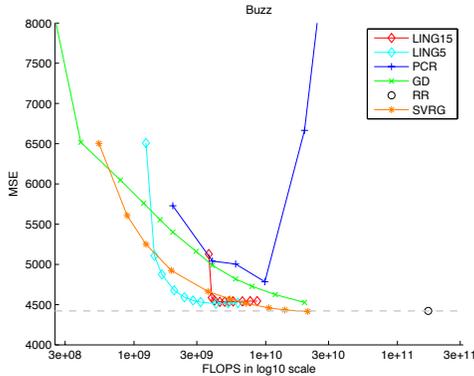

Figure 8: Buzz, MSE VS. Computational Cost plot. SVRG and two LING lines with different n_2 achieves small MSE fast. GD is slower than LING and SVRG. PCR reaches its smallest MSE at $k_1 = 50$ then overfits.

5 SUMMARY

In this paper we present a two stage algorithm LING for computing large scale Ridge Regression which is both fast and robust in contrast to the well known approaches GD and PCR. We show that under the fixed design setting LING actually has the same risk as Ridge Regression assuming convergence. In the experiments, LING achieves good performances on all datasets when compare with three other large scale regression algorithms.

We conjecture that same strategy can be also used to accelerate the convergence of stochastic gradient descent when solving Ridge Regression since the first stage in LING essentially removes the high variance directions of \mathbf{X} , which will lead to variance reduction for the random gradient direction generated by SGD.

Abstract

We develop an adaptive monotone shrinkage estimator for regression models with the following characteristics: i) dense coefficients with small but important effects; ii) *a priori* ordering that indicates the probable predictive importance of the features. We capture both properties with an empirical Bayes estimator that shrinks coefficients monotonically with respect to their anticipated importance. This estimator can be rapidly computed using a version of Pool-Adjacent-Violators algorithm. We show that the proposed monotone shrinkage approach is competitive with the class of all Bayesian estimators that share the prior information. We further observe that the estimator also minimizes Stein’s unbiased risk estimate. Along with our key result that the estimator mimics the oracle Bayes rule under an order assumption, we also prove that the estimator is robust. Even without the order assumption, our estimator mimics the best performance of a large family of estimators that includes the least squares estimator, constant- λ ridge estimator, James-Stein estimator, etc. All the theoretical results are non-asymptotic. Simulation results and data analysis from a model for text processing are provided to support the theory.

1 INTRODUCTION

Feature selection and coefficient estimation are familiar topics in both statistics and machine learning communities. Many results in this area concern models that are ‘nearly black,’ possessing a handful of large effects against a wide field of noise. Consider the widely used linear model

$$Y = X\beta + \epsilon \quad \text{where} \quad \epsilon \sim N(0, \sigma^2 I_n), \quad (1)$$

X is full-rank, $n \times p$ matrix of explanatory features with $p \leq n$, and β is a p dimensional vector of unknown coeffi-

cients. In the ‘nearly black’ case, all but a few of the coordinates of β are zero. A long sequence of results leverage this sparsity (Foster and George [1994]; Tibshirani [1996]; Abramovich et al. [2006]; Candes and Tao [2007]; Fan and Lv [2008]; Bickel et al. [2009]). Sparsity assumptions are well suited to many applications, especially within the field of signal and image processing (Donoho [1995], Wright et al. [2009]).

Despite the prevalence of research on sparse models, some applications do not conform to this paradigm. For example, Foster et al. [2013] used methods such as latent semantic analysis, essentially principal components analysis (PCA), to convert text into features for regression analysis. The estimated coefficients of these principal components show two specific characteristics that draw our attention: dense coefficient estimates with a monotonically decaying effect size. Rather than concentrate in a few estimates, the predictive power of the model spreads across many features. Sparsity-based methods such as hard or soft thresholding that set small effects to zero produce fitted models with greatly diminished predictive ability. Too much predictive signal has been lost by eliminating small, but nonetheless informative, coefficients. Dense coefficients appear in other applications as well. Hall et al. [2009] and Dicker [2011, 2012] also propose models for dense signals and Dicker [2011, 2012] discusses several shrinkage estimators in high dimensions.

The second characteristic of this application is the monotone decrease in typical effect size. The signal tends to concentrate in the leading principal components, then gradually decay. We may not know the signal strength, but we do have an ordering. In this sense, the unsupervised PCA of the text data provides useful information that can be exploited within the regression. In particular, the eigenvalues from the PCA provide an external ordering of the features that is suggestive of the effect size. Such exogenous information appears in other domains. In time series analysis, data collected more recently are expected to be more informative for the prediction of future trends. In principal components regression, we tend to expect the first principal

component to be more important than the second. Therefore, models without incorporating this prior knowledge might be suboptimal.

In this paper, we capture both characteristics with an empirical Bayes estimator that shrinks coefficients monotonically with respect to their anticipated importance. The procedure is tuning free and can be efficiently implemented using Pool-Adjacent-Violators algorithm. We further show that the estimator can be derived from frequentists' perspective as well by minimizing Stein's unbiased risk estimate. Finally, we establish non-asymptotic results to guarantee that the proposed estimator is nearly Bayes optimal under the order assumption and even when the order assumption (or say, prior knowledge) is wrong, it still mimics the best performance of a large family of estimators that includes the least squares estimator, ridge estimator, James-Stein estimator, etc.

The rest of this paper is organized as follows. In section 2, we describe the monotone shrinkage model in detail and introduce the maximum marginal likelihood estimator(MMLE) and Pool-Adjacent-Violators algorithm. In section 3, we show that the proposed estimator also minimizes Stein's unbiased risk estimate and establish its non-asymptotic oracle properties both with and without order assumption. In section 4, we suggest an estimator of the error variance σ^2 . In section 5, we present simulation results and an analysis of text to support our theory. Concluding remarks are given in section 6. Details of the technique are provided in the Appendix.

2 ADAPTIVE MONOTONE SHRINKAGE

2.1 Model Formulation

We use a Bayesian framework to encode the prior knowledge about the importance of explanatory features in our model. We express this prior knowledge in a distribution of the coefficients β . Intuitively, if the features within the regression are standardized such that $X^T X = I_p$, then the coefficient $|\beta_i|$ gives the importance of the i th feature: a unit change in X_i is associated with a change of $|\beta_i|$ in the response. A natural prior that captures the sense that the elements of β have decaying size specifies a monotone decreasing sequence of variances for the coefficients. For convenience, we assume that the size of signal in β_i is decreasing with the index i :

$$\begin{aligned} \beta_i &\sim N(0, \sigma_i^2) \\ \sigma_1^2 &\geq \sigma_2^2 \geq \dots \geq \sigma_p^2 \geq 0 \end{aligned} \quad (2)$$

Since we know the order, we can always rearrange β_i so that the unknown σ_i^2 are monotone as above. Throughout, we consider only orthonormal designs for which $X^T X =$

I_p . Then the Bayes rule β^* in (1) and (2) is:

$$\beta_i^* = \frac{\sigma_i^2}{\sigma_i^2 + \sigma^2} \tilde{\beta}_i,$$

where $\tilde{\beta} = (\tilde{\beta}_1, \dots, \tilde{\beta}_p) = X^T Y$ is the least squares estimator. The Bayes rule shrinks $\tilde{\beta}_i$ monotonically, shrinking more and more harshly as the index and σ_i^2 increase. For our application, we know only the order of the features, not the signal strength σ_i^2 , so the Bayes rule is not a real estimator because it depends on the unknown parameter σ_i^2 . To mimic the performance of the Bayes rule, we estimate the σ_i^2 s from data under the order constraint and use the resulting plug-in estimator. For convenience, we write the model as $\beta \sim N(0, \Sigma)$ where $\Sigma = \text{diag}(\sigma_1^2, \dots, \sigma_p^2)$.

2.2 Maximum Marginal Likelihood Estimator

To estimate the ordered prior variances on the diagonal of Σ , we observe that the marginal distribution of Y is $N(0, X \Sigma X^T + \sigma^2 I_n)$. If we further assume the error variance σ^2 from (1) is known (or we can plug in a consistent estimator), a simple calculation shows that the least square estimator $\hat{\beta} = X^T Y$ is a sufficient statistic for Σ . So, in the following discussions, we base our inference on $\hat{\beta}$, whose marginal distribution is $N(0, \sigma^2 I_p + \Sigma)$. A natural estimator of Σ is the maximum marginal likelihood estimator (MMLE). The log marginal likelihood function is

$$l(\Sigma) = -\frac{1}{2} \sum_{i=1}^p \left(\log(2\pi) + \log(\sigma^2 + \sigma_i^2) + \frac{\hat{\beta}_i^2}{\sigma^2 + \sigma_i^2} \right)$$

Consequently, the MMLE is the solution to the following optimization problem:

$$\begin{aligned} \arg \min_{\sigma_i} \sum_{i=1}^p \left(\log(\sigma^2 + \sigma_i^2) + \frac{\hat{\beta}_i^2}{\sigma^2 + \sigma_i^2} \right) \\ \text{subject to } \sigma_1^2 \geq \sigma_2^2 \geq \dots \geq \sigma_p^2 \geq 0 \end{aligned} \quad (3)$$

2.3 Pool-Adjacent-Violators Algorithm

The optimization problem (3) resembles the well-known isotonic regression problem

$$\hat{\beta}^{iso} = \arg \min_{\beta} \sum_{i=1}^n (y_i - \beta_i)^2 \text{ subject to } \beta_1 \geq \dots \geq \beta_n \quad (4)$$

whose unique solution can be efficiently obtained by running the Pool-Adjacent-Violators (PAV) algorithm. Roughly speaking, this algorithm solves (4) as follows. Set $i = 1$. Move to the right (increase the index i) until finding a pair (y_i, y_{i+1}) that violates the monotonicity constraint, that is $y_i < y_{i+1}$. Pool y_i and the adjacent y_{i+1} and replace both by their average. Next check whether $y_{i-1} < \frac{y_i + y_{i+1}}{2}$. If so, replace (y_{i-1}, y_i, y_{i+1}) with their average. Continue

to the left until monotonicity is satisfied and then proceed to the right until the whole sequence is monotone. Hence, PAV algorithm outputs an decreasing blockwise constant sequence. As far as we know, the PAV algorithm dates back to Ayer et al. [1955], where it is used to compute the MLE of independent binomial distributions. Brunk [1955, 1958] considered rather general scenarios and established some consistency properties. According to Grotzinger and Witzgall [1984], if carefully implemented, the PAV algorithm has computational complexity $O(n)$.

Although the optimization problem (3) is not convex, it can be solved efficiently by the PAV algorithm. Before establishing this result, we introduce some notations.

$$f_i(x) = \log(x + \sigma^2) + \frac{\tilde{\beta}_i^2}{x + \sigma^2}$$

$$\hat{\sigma}_i^2 = \arg \min_x f_i(x) = \tilde{\beta}_i^2 - \sigma^2$$

Proposition 2.1. *The following two-step algorithm produces the MMLE denoted by $(\hat{\sigma}_1^2, \dots, \hat{\sigma}_p^2)$*
Step 1. $(\tilde{\sigma}_1^2, \dots, \tilde{\sigma}_p^2) = PAV(\tilde{\sigma}_1^2, \dots, \tilde{\sigma}_p^2)$
Step 2. $\hat{\sigma}_i^2 = \tilde{\sigma}_i^2 I_{(\tilde{\sigma}_i^2 \geq 0)}$.

For those σ_i^2 estimated to be 0, it means the corresponding features are not included in the model. To prove the proposition, we first introduce a lemma:

Lemma 2.1. *Consider optimization problem*

$$\min \sum_{i=1}^p f_i(\theta_i)$$

subject to: $\theta_1 \geq \theta_2 \geq \dots \geq \theta_p$

where the element-by-element solution $\tilde{\theta}_i = \arg \min_{\theta} f_i(\theta)$ is finite. If the following two conditions are satisfied, then the optimization problem has the unique solution $(\hat{\theta}_1, \dots, \hat{\theta}_p) = PAV(\tilde{\theta}_1, \dots, \tilde{\theta}_p)$.

Condition 1. (Pooling Property)

Let $\bar{\theta}_{ij} = \frac{\sum_{k=i}^j \tilde{\theta}_k}{j-i+1}$. Then $\forall i \leq j$, $\arg \min_{\theta} \sum_{k=i}^j f_k(\theta) = \bar{\theta}_{ij}$ and $\sum_{k=i}^j f_k(\theta)$ is strictly decreasing when $\theta \leq \bar{\theta}_{ij}$ and strictly increasing when $\theta \geq \bar{\theta}_{ij}$.

Condition 2. (Violating Property)

If $\tilde{\theta}_i \leq \tilde{\theta}_{i+1}$, then $\hat{\theta}_i^k = \hat{\theta}_{i+1}^k, \forall i+1 \leq k \leq p$, where $(\hat{\theta}_1^k, \dots, \hat{\theta}_k^k)$ is the solution to the following optimization problem (P^k) :

$$\min \sum_{i=1}^k f_i(\theta_i)$$

subject to: $\theta_1 \geq \theta_2 \geq \dots \geq \theta_k$

Although the conditions in the lemma seem weird, actually they are nearly necessary. Helpfully, the conditions can be

easily checked. Numerous distributions have log likelihood functions that satisfy the conditions. These include the binomial distribution, Poisson distribution, normal distribution with fixed variance and variable mean, normal distribution with fixed mean and variable variance, and so on.

Proof of Proposition 2.1

The situation we are faced up with is normal distribution with fixed mean and variable variance, which satisfies the conditions in Lemma 1. According to the lemma, $(\tilde{\sigma}_1^2, \dots, \tilde{\sigma}_p^2) = PAV(\tilde{\sigma}_1^2, \dots, \tilde{\sigma}_p^2)$ solves:

$$\min \sum_{i=1}^p (\log(\sigma^2 + \sigma_i^2) + \frac{\tilde{\beta}_i^2}{\sigma^2 + \sigma_i^2})$$

subject to: $\sigma_1^2 \geq \sigma_2^2 \geq \dots \geq \sigma_p^2$

which is only slightly different from our original optimization problem. To finish the proof, we just need to introduce some auxiliary functions. Let $f_{-k} = \log(\sigma^2 + \sigma_{-k}^2) + \frac{\sigma^2}{\sigma^2 + \sigma_{-k}^2}, 1 \leq k \leq n$, so $\tilde{\sigma}_{-k}^2 = \arg \min f_{-k}(\sigma_{-k}^2) = 0$. Consider the following optimization problem (Q^n) :

$$\min \sum_{i=1}^p (\log(\sigma^2 + \sigma_i^2) + \frac{\tilde{\beta}_i^2}{\sigma^2 + \sigma_i^2})$$

$$+ \sum_{i=1}^n (\log(\sigma^2 + \sigma_{-i}^2) + \frac{\sigma^2}{\sigma^2 + \sigma_{-i}^2})$$

subject to $\sigma_1^2 \geq \dots \geq \sigma_p^2 \geq \sigma_{-1}^2 \geq \dots \geq \sigma_{-n}^2$

Lemma 1 shows $PAV(\tilde{\sigma}_1^2, \dots, \tilde{\sigma}_p^2, 0, \dots, 0)$ solves (Q^n) . Denote it $(\hat{\sigma}_{n1}^2, \dots, \hat{\sigma}_{np}^2, \hat{\sigma}_{-n1}^2, \dots, \hat{\sigma}_{-n1}^2)$. Notice that $(\hat{\sigma}_1^2, \dots, \hat{\sigma}_p^2, 0, \dots, 0)$ is a feasible solution, which should be suboptimal, that is to say,

$$\sum_{i=1}^p (\log(\sigma^2 + \hat{\sigma}_{ni}^2) + \frac{\tilde{\beta}_i^2}{\sigma^2 + \hat{\sigma}_{ni}^2}) + \sum_{i=1}^n f_{-k}(\hat{\sigma}_{-ni}^2)$$

$$\leq \sum_{i=1}^p (\log(\sigma^2 + \hat{\sigma}_i^2) + \frac{\tilde{\beta}_i^2}{\sigma^2 + \hat{\sigma}_i^2}) + \sum_{i=1}^n f_{-k}(0)$$

Recall that $\tilde{\sigma}_{-k}^2 = \arg \min f_{-k}(\sigma_{-k}^2) = 0$, which implies

$$\sum_{i=1}^p (\log(\sigma^2 + \hat{\sigma}_{ni}^2) + \frac{\tilde{\beta}_i^2}{\sigma^2 + \hat{\sigma}_{ni}^2})$$

$$\leq \sum_{i=1}^p (\log(\sigma^2 + \hat{\sigma}_i^2) + \frac{\tilde{\beta}_i^2}{\sigma^2 + \hat{\sigma}_i^2})$$

Let n goes to infinity, $PAV(\tilde{\sigma}_1^2, \dots, \tilde{\sigma}_p^2, 0, \dots, 0)$ converges to $(\hat{\sigma}_1^2 I_{(\hat{\sigma}_1^2 \geq 0)}, \dots, \hat{\sigma}_p^2 I_{(\hat{\sigma}_p^2 \geq 0)}, 0, \dots, 0)$ and the inequality above implies $(\hat{\sigma}_1^2 I_{(\hat{\sigma}_1^2 \geq 0)}, \dots, \hat{\sigma}_p^2 I_{(\hat{\sigma}_p^2 \geq 0)})$ is the solution to the original optimization problem. \square

2.4 Data-Driven Blockwise James-Stein Estimator: Global and Local Adaptivity

Proposition 1 and the nature of Pool-Adjacent-Violators algorithm show that the MMLE $(\hat{\sigma}_1^2, \dots, \hat{\sigma}_p^2)$ is decreasing and blockwise constant. We now change notation in this part and let $\hat{\sigma}_i^2$ denote the common variance estimate of the i th block. Define $\beta_i = (\beta_{i1}, \dots, \beta_{in_i})$ to be the coefficients within the i th block and correspondingly define $\tilde{\beta}_i, \tilde{\beta}_i$. With these notations, we can write explicitly $\hat{\sigma}_i^2 = \left(\frac{\sum_{j=1}^{n_i} (\tilde{\beta}_{ij}^2 - \sigma^2)}{n_i} \right)_+$ and

$$\begin{aligned} \hat{\beta}_i &= \frac{\hat{\sigma}_i^2}{\hat{\sigma}_i^2 + \sigma^2} \tilde{\beta}_i \\ &= \left(1 - \frac{n_i \sigma^2}{\sum_{j=1}^{n_i} \tilde{\beta}_{ij}^2} \right)_+ \tilde{\beta}_i, \end{aligned}$$

which is exactly the positive part of the James-Stein type estimator. Hence the proposed estimator can be interpreted as a monotone blockwise James-Stein estimator. Blockwise James-Stein estimator is well-studied in the wavelet setting (Cai [1999], Cai and Zhou [2009]). In Cai [1999], the block size is fixed before observing the data and is the same for all blocks. Cai and Zhou [2009] proposed an adaptive procedure to make the block size data-driven but the block size remains the same for all blocks. As for our procedure, the number of blocks and the size of each block are completely data-driven. The difference is due to different assumptions. The former is based on smoothness of Besov bodies while the later is based on monotonicity.

The advantage of our data-driven, monotone blockwise James-Stein estimator is the ability to achieve both global and local adaptivity. Blockwise shrinkage utilizes information about neighboring coefficients. However, if the block size is too large, local inhomogeneity might be overlooked. So, the best way to achieve a good balance is to let the data speak for itself.

3 ORACLE RISK PROPERTIES

3.1 Equivalence between MMLE and SURE Estimator

In this section, we show that our empirical Bayes estimator can also be derived within a frequentist framework by minimizing Stein's unbiased risk estimate (SURE). Under squared error loss: $l(\hat{\beta}, \beta) = \frac{1}{p} \sum_{i=1}^p (\hat{\beta}_i - \beta_i)^2$. If one uses the shrinkage estimator $\hat{\beta}^\lambda$ defined by $\hat{\beta}_i^\lambda = \frac{\lambda_i}{\lambda_i + \sigma^2} \tilde{\beta}_i$ to estimate β_i , the risk for a given β is:

$$R_p(\hat{\beta}^\lambda, \beta) = E[l(\hat{\beta}^\lambda, \beta)] = \frac{1}{p} \sum_{i=1}^p \frac{\sigma^2}{(\sigma^2 + \lambda_i)^2} (\sigma^2 \beta_i^2 + \lambda_i^2)$$

and an unbiased estimate for the risk is

$$SURE(\lambda) = \frac{1}{p} \sum_{i=1}^p \left[\left(\frac{\sigma^2}{\sigma^2 + \lambda_i} \right)^2 \tilde{\beta}_i^2 + \frac{\sigma^2 (\lambda_i - \sigma^2)}{\sigma^2 + \lambda_i} \right]$$

Generally, $SURE(\lambda)$ is unbiased estimate of the risk only if λ is a fixed constant and cannot depend on data. We say $\hat{\beta}^{\hat{\lambda}}$ is a **monotone shrinkage estimator** if $\hat{\beta}_i^{\hat{\lambda}} = \frac{\hat{\lambda}_i}{\hat{\lambda}_i + \sigma^2} \tilde{\beta}_i$ and $\hat{\lambda}_1 \geq \dots \geq \hat{\lambda}_p \geq 0$, where $\hat{\lambda}_i$ can be data dependent. A monotone shrinkage estimator is completely determined by the **monotone shrinkage parameter** $\hat{\lambda} = (\hat{\lambda}_1, \dots, \hat{\lambda}_p)$. If only considering the family of monotone shrinkage estimators, the relationship suggests that the data-dependent $\hat{\lambda}$ which minimizes $SURE(\lambda)$ should be a good choice. Define:

$$\hat{\lambda}_{SURE} = \arg \min_{\lambda_1 \geq \dots \geq \lambda_p \geq 0} \sum_{i=1}^n \left[\left(\frac{\sigma^2}{\sigma^2 + \lambda_i} \right)^2 \tilde{\beta}_i^2 + \frac{\sigma^2 (\lambda_i - \sigma^2)}{\sigma^2 + \lambda_i} \right]$$

which is of the same form as optimization problem (3). Let $g_i(\lambda_i) = \left(\frac{\sigma^2}{\sigma^2 + \lambda_i} \right)^2 \tilde{\beta}_i^2 + \frac{\sigma^2 (\lambda_i - \sigma^2)}{\sigma^2 + \lambda_i}$. Then it is easy to see that $\hat{\lambda}_i = \arg \min_{\lambda_i} g_i(\lambda_i) = \tilde{\beta}_i^2 - \sigma^2$. Checking that $g_i(\lambda_i)$ satisfy the two conditions in Lemma 2.1, the same argument used to show Proposition 2.1 implies:

Proposition 3.1. *MMLE equals SURE estimator $\hat{\beta}^{\hat{\lambda}_{SURE}}$.*

In the rest of the paper, we will use $\hat{\beta}_{SURE} = \hat{\beta}^{\hat{\lambda}_{SURE}}$ to denote the proposed estimator.

Remark 3.1. *Monotone shrinkage estimator was also investigated in Xie et al. [2012] when dealing with heteroscedastic normal sequence model. Different empirical Bayes estimators were studied in this paper and SURE estimator was shown to dominate MMLE and method of moments. While in our context, the three estimators turned out to be the same.*

3.2 Oracle Property with Order Assumption

Proposition 3.1 provides us with a powerful tool to investigate the risk properties of the proposed estimate. First of all, we introduce the oracle estimator, namely the Bayes rule $\beta^* = (\beta_1^*, \dots, \beta_p^*)$ defined by

$$\beta_i^* = \frac{\sigma_i^2}{\sigma_i^2 + \sigma^2} \tilde{\beta}_i$$

Of course, β^* is not an practical estimator because it depends on the unknown parameter $\lambda^* = (\sigma_1^2, \dots, \sigma_p^2)$. It is easy to see the oracle risk is:

$$R(\beta^*) = \frac{1}{p} \sum_{i=1}^p \frac{\sigma^2 \sigma_i^2}{\sigma^2 + \sigma_i^2}$$

Then we introduce another lemma, which is the building block of the oracle properties. It says that $E[SURE(\hat{\lambda})]$

is uniformly good approximation of the true risk $E[l(\hat{\beta}_{\hat{\lambda}})]$, where the expectation is with respect to both data and parameter β .

Lemma 3.1.

$$\sup_{\sigma_1^2, \dots, \sigma_p^2} \sup_{\hat{\lambda}_1 \geq \dots \geq \hat{\lambda}_p} |E\{E[l(\hat{\beta}_{\hat{\lambda}}) - SURE(\hat{\lambda}) | \beta]\}| \leq 4\sqrt{\frac{2}{p}}\sigma^2$$

where $\hat{\lambda} = (\hat{\lambda}_1, \dots, \hat{\lambda}_p)$ is arbitrary monotone shrinkage parameter and can be data dependent.

Theorem 3.1.

$$\sup_{\sigma_1^2 \geq \dots \geq \sigma_p^2 \geq 0} (R(\hat{\beta}_{SURE}) - R(\beta^*)) \leq 4\sqrt{\frac{2}{p}}\sigma^2$$

Proof: Because λ^* is fixed constant, we have

$$\begin{aligned} & R(\hat{\beta}_{SURE}, \beta) - R(\beta^*, \beta) \\ &= E[l(\hat{\beta}_{SURE}, \beta) | \beta] - E[SURE(\lambda^*) | \beta] \\ &= E[l(\hat{\beta}_{SURE}, \beta) - SURE(\hat{\lambda}_{SURE}) + \\ &\quad SURE(\hat{\lambda}_{SURE}) - SURE(\lambda^*) | \beta] \\ &\leq E[l(\hat{\beta}_{SURE}, \beta) - SURE(\hat{\lambda}_{SURE}) | \beta] \end{aligned}$$

The inequality is due to the definition of $\hat{\lambda}_{SURE}$. So the Bayes risk satisfies:

$$\begin{aligned} & R(\hat{\beta}_{SURE}) - R(\beta^*) \\ &\leq E\{E[l(\hat{\beta}_{SURE}, \beta) - SURE(\hat{\lambda}_{SURE}) | \beta]\} \\ &\leq \sup_{\sigma_1^2, \dots, \sigma_p^2} \sup_{\hat{\lambda}_1 \geq \dots \geq \hat{\lambda}_p \geq 0} |E\{E[l(\hat{\beta}_{\hat{\lambda}}, \beta) - SURE(\hat{\lambda}) | \beta]\}| \end{aligned}$$

Applying lemma 3.1 finishes the proof. \square

Remark 3.2. Theorem 3.1 shows that SURE estimator mimics the oracle Bayes rule and therefore outperforms all other estimators. What needs to be highlighted is that this is a non-asymptotic result with rate of convergence $O(p^{-\frac{1}{2}})$ independent of the true σ_i^2 s. No matter how the σ_i^2 s vary, as long as the order is known, the proposed adaptive procedure can uniformly capture the truth.

Corollary 3.1. $\sup_{\sigma_1^2 \geq \dots \geq \sigma_p^2 \geq 0} \frac{R(\hat{\beta}_{SURE})}{\sigma^2 + R(\beta^*)} = 1 + 4\sqrt{\frac{2}{p}}$

3.3 Oracle Property without Order Assumption

In this section, we show that even without knowing the order of the σ_i^2 s, the proposed estimator retains an oracle property among monotone shrinkage estimators.

Theorem 3.2.

$$\sup_{\sigma_1^2, \dots, \sigma_p^2} (R(\hat{\beta}_{SURE}) - \inf_{\hat{\gamma}_1 \geq \dots \geq \hat{\gamma}_p \geq 0} R(\hat{\beta}_{\hat{\gamma}})) \leq 8\sqrt{\frac{2}{p}}\sigma^2$$

Proof: For any given $(\sigma_1^2, \dots, \sigma_p^2)$, we can always find $\hat{\eta} = (\hat{\eta}_1, \dots, \hat{\eta}_p)$ that satisfies $\hat{\eta}_1 \geq \dots \geq \hat{\eta}_p \geq 0$ and $R(\hat{\beta}_{\hat{\eta}}) < \inf_{\hat{\gamma}_1 \geq \dots \geq \hat{\gamma}_p \geq 0} R(\hat{\beta}_{\hat{\gamma}}) + \epsilon$. Then,

$$R(\hat{\beta}_{SURE}) - \inf_{\hat{\gamma}_1 \geq \dots \geq \hat{\gamma}_p \geq 0} R(\hat{\beta}_{\hat{\gamma}}) \leq R(\hat{\beta}_{SURE}) - R(\hat{\beta}_{\hat{\eta}}) + \epsilon$$

Notice that,

$$\begin{aligned} & l(\beta, \hat{\beta}_{SURE}) - l(\beta, \hat{\beta}_{\hat{\eta}}) = (l(\beta, \hat{\beta}_{SURE}) - SURE(\hat{\lambda}_{SURE})) \\ &+ (SURE(\hat{\lambda}_{SURE}) - SURE(\hat{\eta})) + (SURE(\hat{\eta}) - l(\beta, \hat{\beta}_{\hat{\eta}})) \\ &\leq (l(\beta, \hat{\beta}_{SURE}) - SURE(\hat{\lambda}_{SURE})) + (SURE(\hat{\eta}) - l(\beta, \hat{\beta}_{\hat{\eta}})) \end{aligned}$$

Take expectations, we have

$$\begin{aligned} & R(\hat{\beta}_{SURE}) - R(\hat{\beta}_{\hat{\eta}}) \leq E\{E[l(\beta, \hat{\beta}_{SURE}) - \\ &\quad SURE(\hat{\lambda}_{SURE}) + SURE(\hat{\eta}) - l(\beta, \hat{\beta}_{\hat{\eta}}) | \beta]\} \\ &\leq 2 \sup_{\sigma_1^2, \dots, \sigma_p^2} \sup_{\hat{\lambda}_1 \geq \dots \geq \hat{\lambda}_p \geq 0} |E\{E[l(\beta_{\hat{\lambda}}, \beta) - SURE(\hat{\lambda}) | \beta]\}| \end{aligned}$$

Lemma 3.1 implies,

$$R(\hat{\beta}_{SURE}) - \inf_{\hat{\gamma}_1 \geq \dots \geq \hat{\gamma}_p \geq 0} R(\hat{\beta}_{\hat{\gamma}}) \leq 8\sqrt{\frac{2}{p}}\sigma^2 + \epsilon$$

Since the upper bound does not depend on σ_i^2 , let $\epsilon \rightarrow 0$, and the theorem follows. \square

If we replace the data dependent shrinkage parameters in Theorem 2 with fixed ones, we can improve the error bound by a factor of 2, which is

Corollary 3.2.

$$\sup_{\sigma_1^2, \dots, \sigma_p^2} (R(\hat{\beta}_{SURE}) - \inf_{\hat{\gamma}_1 \geq \dots \geq \hat{\gamma}_p \geq 0} R(\hat{\beta}_{\hat{\gamma}})) \leq 4\sqrt{\frac{2}{p}}\sigma^2$$

Theorem 2 shows that even when the order assumption is invalid, the proposed estimator is nearly the best in the family of monotone shrinkage estimators. In particular, uniform shrinkage estimators such as least square estimator, ridge estimator and James-Stein estimator and step-wise regression methods such as monotone AIC, BIC, RIC (just search for p nested submodels: with i th submodel as $\{1, \dots, i\}$) are included. This is also a non-asymptotic result with rate of convergence $O(p^{-\frac{1}{2}})$ independent of the σ_i^2 s. Therefore, the proposed estimator is robust and good enough for practical use. Actually, Theorem 3.2 states about the worst case. If the order is partially right, the proposed procedure benefits where the order is right and retains good properties where the order is wrong.

Remark 3.3. The robustness is due to the ‘soft constraint’. Instead of restricting the norm of regression coefficients to be monotone, we incorporate the constraint in the prior distribution, which makes the model flexible and robust.

4 ESTIMATION OF σ^2

We have assumed σ^2 is known to establish the theoretical properties of our estimator. Here we suggest a reasonable estimate in practice that is based on maximum marginal likelihood. Unlike section 2.2, within this section the unknown parameter becomes $\theta = (\sigma_1^2, \dots, \sigma_p^2, \sigma^2)$. Recall that the marginal distribution of Y is $N(0, X\Sigma X^T + \sigma^2 I_n)$. So, the log marginal likelihood function:

$$l(\theta|y) \propto -\log(|X\Sigma X^T + \sigma^2 I_n|) - y^T (X\Sigma X^T + \sigma^2 I_n)^{-1} y$$

where $|\cdot|$ means determinant. Let $X = (x_1, \dots, x_p)$, we can add another $n - p$ vectors x_{p+1}, \dots, x_n to make $\tilde{X} = (X, x_{p+1}, \dots, x_n)$ an orthonormal matrix. Let $\tilde{\Sigma} = \text{diag}(\Sigma + \sigma^2 I_p, \sigma^2 I_{n-p})$. Then $X\Sigma X^T + \sigma^2 I_n = \tilde{X}\tilde{\Sigma}\tilde{X}^T$ and thus $(X\Sigma X^T + \sigma^2 I_n)^{-1} = \tilde{X}\tilde{\Sigma}^{-1}\tilde{X}^T$. Plug this expression back into the marginal likelihood function,

$$l(\theta|y) \propto -\log(|\tilde{X}\tilde{\Sigma}\tilde{X}^T|) - y^T \tilde{X}\tilde{\Sigma}^{-1}\tilde{X}^T y$$

We abuse notation in this section and let $\tilde{\beta} = \tilde{X}^T y$. If we introduce variable $(\tau_1^2, \dots, \tau_n^2) = \text{diag}(\tilde{\Sigma}) = (\sigma_1^2 + \sigma^2, \dots, \sigma_p^2 + \sigma^2, \sigma^2, \dots, \sigma^2)$, then

$$l(\Sigma) \propto -\sum_{i=1}^n (\log \tau_i^2 + \frac{\tilde{\beta}_i^2}{\tau_i^2})$$

So, the MMLE is the solution to the following optimization problem.

$$\min \sum_{i=1}^p (\log \tau_i^2 + \frac{\tilde{\beta}_i^2}{\tau_i^2})$$

$$\text{subject to: } \tau_1^2 \geq \dots \geq \tau_p^2 \geq \tau_{p+1}^2 = \dots = \tau_n^2 \geq 0$$

Following a similar but slightly different argument in Proposition 2.1, we get:

Proposition 4.1. *The solution is uniquely given by*

$$(\hat{\tau}_1^2, \dots, \hat{\tau}_p^2, \hat{\tau}_{p+1}^2, \dots, \hat{\tau}_n^2) = \text{PAV}(\tilde{\beta}_1^2, \dots, \tilde{\beta}_p^2, \frac{\sum_{i=p+1}^n \tilde{\beta}_i^2}{n-p}, \dots, \frac{\sum_{i=p+1}^n \tilde{\beta}_i^2}{n-p})$$

The MMLE of original parameters can be recovered by $(\hat{\tau}_1^2, \dots, \hat{\tau}_p^2, \hat{\tau}_{p+1}^2, \dots, \hat{\tau}_n^2) = (\hat{\sigma}_1^2 + \hat{\sigma}^2, \dots, \hat{\sigma}_p^2 + \hat{\sigma}^2, \hat{\sigma}^2, \dots, \hat{\sigma}^2)$.

5 NUMERICAL EXPERIMENTS

5.1 Simulation Results

In this section, we compare the proposed monotone shrinkage approach with several other popular methods for feature selection and estimation. For simplicity, we only consider the normal sequence model and assume the error variance σ^2 is known.

- PAV, the proposed adaptive monotone shrinkage procedure computed by Pool-Adjacent-Violators algorithm.
- Lasso, with λ selected by minimizing Stein's unbiased risk estimate. Under orthogonal design, it is also known as Sureshrink (Donoho and Johnstone [1995]).
- Ridge estimator with λ selected by Cross-Validation.
- Positive part of James-Stein estimator
- Classical stepwise regression, we use AIC for penalty criterion.
- Monotone AIC: AIC that just searches for p nested submodels, i.e., with k_{th} submodel = $\{1, \dots, k\}$

We consider the following scenarios ($p = 100, \sigma^2 = 1$):

1. Signals with Decaying Size: $(\sigma_1^2, \dots, \sigma_p^2)$ are generated from decreasing order statistics of $2\chi^2$.
2. Signals with Same Size: $\sigma_i^2 = 2, \forall 1 \leq i \leq p$
3. Sparse Signals: first 90% of the σ_i^2 are 0 and remaining 10% of σ_i^2 are generated from decreasing order statistics of $4\chi^2$.
4. Signals with Increasing Size: $(\sigma_1^2, \dots, \sigma_p^2)$ are generated from increasing order statistics of $2\chi^2$. This scenario does not satisfy our order assumption (actually, the worst case), which is used to show the robustness of our procedure.

With $(\sigma_1^2, \dots, \sigma_p^2)$ fixed, we adopt the following simulation strategy.

1. Generate $\beta = (\beta_1, \dots, \beta_p)$ by $\beta_i \sim N(0, \sigma_i^2)$
2. Condition on β , generate the observation $X = (x_1, \dots, x_p)$ by $x_i \sim N(\beta_i, \sigma^2)$
3. Use the methods discussed above to estimate the signal β and compute the mean square error.
4. Repeat 1-3 for 400 times. The average of the mean square errors is an estimate of the Bayes risk.

Mean square error condition on different β are given below using box plot and the middle line of each box represents Bayes risk of each procedure. The red line in the figure stands for the oracle risk, i.e., the Bayes risk of the oracle Bayes rule.

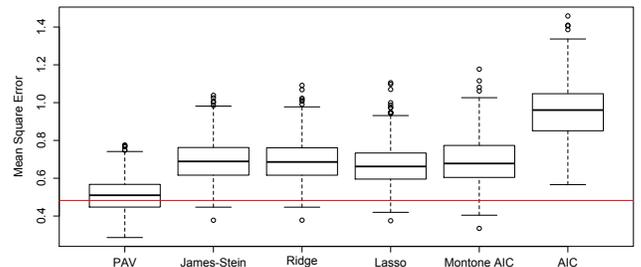

Figure 1: Signals with decaying size, i.e. $\{\sigma_i^2\}$ is decreasing. The adaptive monotone shrinkage procedure pools signals of similar sizes together and shrinks blockwisely and monotonically. Red line stands for oracle Bayes risk.

For signals with decaying size, oracle estimator shrink monotonically with respect to the size of the signals. Uniform shrinkage estimators such as ridge and James-Stein estimator are suboptimal. The proposed adaptive monotone procedure makes use of the prior information and mimics the oracle Bayes rule by pooling signals of similar size together so that it shrinks blockwisely and monotonically. AIC overfits the data while monotone AIC makes use of the order structure and therefore performs better.

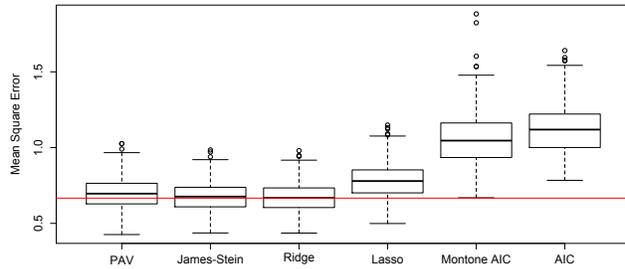

Figure 2: Signals with same size, i.e. σ_i^2 s are the same. This is the case where ridge and James-Stein estimator capture the truth with full power while our procedure will regard the σ_i^2 as different(decreasing) and will generally divide the σ_i^2 s into more than one blocks, which leads to slight power loss. Red line stands for oracle Bayes risk.

For signals with same size, the oracle estimator shrink uniformly. Ridge and James-Stein estimator mimic the oracle Bayes rule with full power. The proposed adaptive procedure does not necessarily guarantee uniform shrinkage but the power loss is negligible.

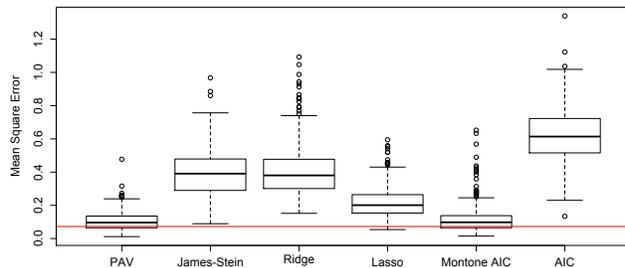

Figure 3: Sparse Signals, i.e. the size of the signals remain decreasing while 90% of them are 0. The proposed monotone shrinkage procedure can effectively kill the noise and shrink the signals properly. Red line stands for oracle Bayes risk.

For sparse signals, the oracle estimator kill the noise and shrink the signals monotonically. Monotone AIC can efficiently distinguish signal and noise while does not shrink the signals. The proposed adaptive procedure not only kills the noise but also shrinks the real signals properly according to their sizes. For those methods that cannot make use of the order structure, Lasso does better in this sparse case.

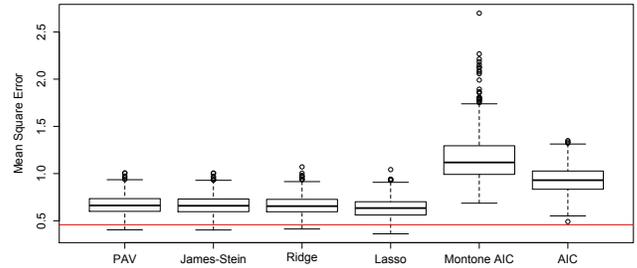

Figure 4: Signals with increasing size, i.e. $\{\sigma_i^2\}$ is increasing, which is opposite to our assumption that the size of signals is decaying. The adaptive monotone shrinkage procedure is robust and performs as good as other estimators. Red line stands for oracle Bayes risk.

For signals with increasing size, the proposed estimator uses completely reverse order. As theorem 2 expects, wrong prior knowledge won't ruin our estimator. It still mimics the best performance of the monotone shrinkage family. However, monotone AIC, which is not as robust as our procedure, suffers a lot from wrong prior knowledge.

5.2 Analysis of Text Processing Data

In this section, we apply the proposed adaptive monotone shrinkage approach to text data of real estate described in Foster et al. [2013]. The features included in the regression model are the leading 1500 principal components of the bag-of-words of text. The response is the log transformation of the real estate price. We use the eigenvalues from PCA to order the effect size of the features (see Figure 5 for the absolute t-statistics of the leading 500 principal components). Although the data dose not ideally satisfy the assumptions of our model, the proposed adaptive procedure is robust enough to leverage this rough prior knowledge.

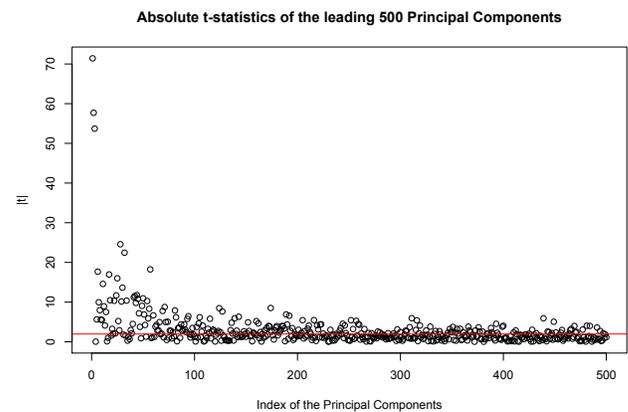

Figure 5: Absolute t-statistics of the leading 500 Principal Components. Those above the red line are significant.

The sample size is 7384 and we use 10 fold cross validation to estimate the prediction error of each procedure.

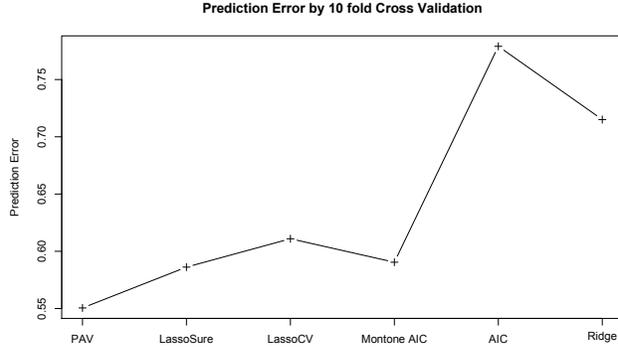

Figure 6: Prediction error comparison of different methods. LassoSURE: Lasso with tuning parameter selected by minimizing Stein's unbiased risk estimate. LassoCV: Lasso computed by LARS (Efron et al. [2004]) and parameter tuned by cross validation.

The result shows

- PAV outperforms Ridge regression. From Figure 5, we can see that the signals are of different sizes. Uniform shrinkage method shrink the important features too much while shrink weak signals less harshly than it should be. PAV can adaptively pool the signals of similar size together and shrink blockwisely and monotonically.
- PAV outperforms LassoSure and LassoCV. Lasso can capture the sparse pattern of the data but as sacrifice, it might shrink important features a bit more than they should be.
- PAV outperforms Monotone AIC. Both procedures make use of prior information but PAV is more robust. There are several informative principal components corresponding to small eigenvalues so that Monotone AIC will exclude them from the model.

6 CONCLUSIONS

In this paper, we proposed an adaptive monotone shrinkage approach for regression with features of ordered effect size. We showed that the procedure can be rapidly computed via Pool-Adjacent-Violators algorithm and holds oracle risk properties. Non-asymptotic results are established. Furthermore, although the procedure is based on knowing the right prior knowledge about the features, we proved that, when the prior knowledge is wrong or in the absence of prior knowledge, the estimator still mimics the best performance of the family of monotone shrinkage estimators. Hence, it is robust enough to use in practice.

Compared with penalized least square methods which require heavy computational effort to find the best regularization parameter, the proposed adaptive procedure is tuning free. As noticed in the analysis of text data, the monotone shrinkage approach naturally works with PCA since the

principal components are essentially ordered and orthogonal. Recent developments in randomized algorithms (Halko et al. [2011]) enable us to quickly compute the PCA of a huge matrix so that the proposed procedure can be easily applied to large-scale datasets.

7 APPENDIX

7.1 Proof of Lemma 2.1

It is sufficient to prove the following two claims:

- i) $(\hat{\theta}_1^k, \dots, \hat{\theta}_k^k) = \text{PAV}(\tilde{\theta}_1, \dots, \tilde{\theta}_k)$, $1 \leq k \leq p$ ii) $\forall 1 \leq i, j \leq k$, $\hat{\theta}_i^k = \hat{\theta}_j^k \Rightarrow \hat{\theta}_i^m = \hat{\theta}_j^m$, $\forall k \leq m \leq p$

We prove the claim by induction:

1. It is trivial for $k = 1$ since $\hat{\theta}_1^1 = \tilde{\theta}_1$
2. Assuming the claim holds for k . If $\tilde{\theta}_{k+1} < \hat{\theta}_k^k$, we can see that

$$\begin{aligned} & \sum_{i=1}^k f_i(\hat{\theta}_i^k) + f_{k+1}(\tilde{\theta}_{k+1}) \\ &= \min_{\theta_1 \geq \dots \geq \theta_k} \sum_{i=1}^k f_i(\theta_i) + \min_{\theta_{k+1}} f_{k+1}(\theta_{k+1}) \\ &\leq \min_{\theta_1 \geq \dots \geq \theta_{k+1}} \sum_{i=1}^{k+1} f_i(\theta_i) \end{aligned}$$

which implies,

$$\begin{aligned} (\hat{\theta}_1^{k+1}, \dots, \hat{\theta}_{k+1}^{k+1}) &= (\hat{\theta}_1^k, \dots, \hat{\theta}_k^k, \tilde{\theta}_{k+1}) \\ &= \text{PAV}(\tilde{\theta}_1, \dots, \tilde{\theta}_k) \end{aligned}$$

So we prove claim i). Notice that $\hat{\theta}_{k+1}^{k+1} \neq \hat{\theta}_j^{k+1}$, $\forall j \leq k$, claim ii) is true by induction.

If $\tilde{\theta}_{k+1} \geq \hat{\theta}_k^k$, denote j the smallest integer such that $\hat{\theta}_j^k = \hat{\theta}_{j+1}^k = \dots = \hat{\theta}_k^k$. Because the boundary condition is not active between θ_{j-1} and θ_j , we can conclude that $(\hat{\theta}_j^k, \hat{\theta}_{j+1}^k, \dots, \hat{\theta}_k^k) = \arg \min_{\theta_j \geq \dots \geq \theta_k} \sum_{i=j}^k f_i(\theta_i)$. Then

condition 1 implies that $\hat{\theta}_j^k = \dots = \hat{\theta}_k^k = \frac{\sum_{i=j}^k \tilde{\theta}_i}{k-j+1} \leq \tilde{\theta}_{k+1}$.

We claim: $\hat{\theta}_j^m = \hat{\theta}_{j+1}^m = \dots = \hat{\theta}_{k+1}^m$, $\forall k \leq m \leq p$. By induction we have already known that $\hat{\theta}_j^m = \hat{\theta}_{j+1}^m = \dots = \hat{\theta}_k^m$. If $\hat{\theta}_k^m \leq \tilde{\theta}_{k+1}$, then by condition 1, $f_{k+1}(\theta_{k+1})$ is strictly decreasing on $(0, \hat{\theta}_k^m)$, which forces $\hat{\theta}_{k+1}^m = \hat{\theta}_k^m$.

If $\hat{\theta}_k^m \geq \tilde{\theta}_{k+1}$, then $\hat{\theta}_{k+1}^m \geq \tilde{\theta}_{k+1}$. $\tilde{\theta}_{k+1} \geq \frac{\sum_{i=j}^k \tilde{\theta}_i}{k-j+1}$ and condition 1 force $\hat{\theta}_k^m = \hat{\theta}_{k+1}^m$. Thus we proved

$\hat{\theta}_j^m = \hat{\theta}_{j+1}^m = \dots = \hat{\theta}_{k+1}^m$, $\forall m > k$. Specifically,

$\hat{\theta}_j^{k+1} = \hat{\theta}_{j+1}^{k+1} = \dots = \hat{\theta}_{k+1}^{k+1}$. If $\frac{\sum_{i=j}^{k+1} \tilde{\theta}_i}{k-j} \leq \hat{\theta}_{j-1}^k$, again by condition 1, $\hat{\theta}_j^{k+1} = \dots = \hat{\theta}_{k+1}^{k+1} = \frac{\sum_{i=j}^{k+1} \tilde{\theta}_i}{k-j}$ and consequently $\hat{\theta}_i^{k+1} = \hat{\theta}_i^k$, $1 \leq i \leq j-1$. We are done because the

solution is exactly PAV($\tilde{\theta}_1, \dots, \tilde{\theta}_{k+1}$), which proves claim i) and $\hat{\theta}_j^m = \hat{\theta}_{j+1}^m = \dots = \hat{\theta}_{k+1}^m, \forall m > k$ implies claim ii). If $\frac{\sum_{i=j}^{k+1} \tilde{\theta}_i}{k-j} > \hat{\theta}_{j-1}^k$, assume i to be the smallest integer such that $\hat{\theta}_i^k = \hat{\theta}_{i+1}^k = \dots = \hat{\theta}_{j-1}^k$. By similar argument, we can prove that $\hat{\theta}_i^m = \hat{\theta}_{i+1}^m = \dots = \hat{\theta}_{k+1}^m, \forall m > k$. If $\frac{\sum_{t=i}^{k+1} \tilde{\theta}_t}{k-i} < \hat{\theta}_{i-1}^k$, we are done. If not, continue the same argument. \square

7.2 Proof of Lemma 3.1

Plug in the expression of SURE(λ), we have

$$\begin{aligned} & E[l(\beta_{\hat{\lambda}}, \beta) - SURE(\hat{\lambda})|\beta] \\ &= E\left[\frac{1}{p} \sum_{i=1}^p \frac{2\hat{\lambda}_i}{\sigma^2 + \hat{\lambda}_i} (\tilde{\beta}_i^2 - \tilde{\beta}_i \beta_i - \sigma^2) - (\tilde{\beta}_i^2 - \sigma^2 - \beta_i^2)|\beta\right] \\ &= E\left[\frac{1}{p} \sum_{i=1}^p \frac{2\hat{\lambda}_i}{\sigma^2 + \hat{\lambda}_i} (\tilde{\beta}_i^2 - \tilde{\beta}_i \beta_i - \sigma^2)|\beta\right] \end{aligned}$$

Take expectation with respect to β , we get

$$\begin{aligned} & E\{E[l(\beta_{\hat{\lambda}}, \beta) - SURE(\hat{\lambda})|\beta]\} = \\ & E\left\{E\left[\frac{1}{p} \sum_{i=1}^p \frac{2\hat{\lambda}_i}{\sigma^2 + \hat{\lambda}_i} (\tilde{\beta}_i^2 - \tilde{\beta}_i \beta_i - \sigma^2)|\beta\right]\right\} \end{aligned}$$

Notice that $\beta_i|\tilde{\beta}_i \sim N(\frac{\sigma_i^2}{\sigma^2 + \sigma_i^2} \tilde{\beta}_i, \frac{\sigma^2 \sigma_i^2}{\sigma^2 + \sigma_i^2})$ and the marginal distribution of $\tilde{\beta}_i$ is $N(0, \sigma^2 + \sigma_i^2)$, we change the order of expectation and get:

$$\begin{aligned} & E\{E[l(\beta_{\hat{\lambda}}, \beta) - SURE(\hat{\lambda})|\beta]\} = \\ & 2E\left[\frac{1}{p} \sum_{i=1}^p \frac{\hat{\lambda}_i}{\sigma^2 + \hat{\lambda}_i} \left(\frac{\sigma^2}{\sigma^2 + \sigma_i^2} \tilde{\beta}_i^2 - \sigma^2\right)\right] \end{aligned}$$

where the expectation is with respect to $\tilde{\beta}_i \sim N(0, \sigma^2 + \sigma_i^2)$.

$$\begin{aligned} & |E\{E[l(\beta_{\hat{\lambda}}, \beta) - SURE(\hat{\lambda})|\beta]\}| \leq \\ & 2\sigma^2 E\left|\frac{1}{p} \sum_{i=1}^p \frac{\hat{\lambda}_i}{\sigma^2 + \hat{\lambda}_i} \left(\frac{\tilde{\beta}_i^2}{\sigma^2 + \sigma_i^2} - 1\right)\right| \\ & \leq 2\sigma^2 E\left\{\sup_{1 \geq c_1 \geq \dots \geq c_p \geq 0} \frac{1}{p} \left|\sum_{i=1}^p c_i \left(\frac{\tilde{\beta}_i^2}{\sigma^2 + \sigma_i^2} - 1\right)\right|\right\} \\ & = 2\sigma^2 E\left\{\sup_{1 \geq c_1 \geq \dots \geq c_p \geq 0} \frac{1}{p} \left|\sum_{i=1}^p c_i (Z_i - 1)\right|\right\} \end{aligned}$$

where $Z_i \sim i.i.d \chi^2$. Observe that

$$\begin{aligned} & \sup_{1 \geq c_1 \geq \dots \geq c_p \geq 0} \left|\frac{1}{p} \sum_{i=1}^p c_i (Z_i - 1)\right| \\ &= \max_{1 \leq j \leq p} \left|\frac{1}{p} \sum_{i=1}^j (Z_i - 1)\right| \end{aligned}$$

which is also used in Lemma 7.2 of Li [1985] and Theorem 3.1 in Xie et al. [2012], we have:

$$\begin{aligned} & |E\{E[l(\beta_{\hat{\lambda}}, \beta) - SURE(\hat{\lambda})|\beta]\}| \\ & \leq 2\sigma^2 E\left\{\max_{1 \leq j \leq p} \left|\frac{1}{p} \sum_{i=1}^j (Z_i - 1)\right|\right\} \end{aligned}$$

Let $M_j = \sum_{i=1}^j (Z_i - 1)$, then M_j is a martingale. So the L^2 maximal inequality implies:

$$E\left(\max_{1 \leq j \leq p} M_j^2\right) \leq 4E(M_p^2) = 8p$$

$$\begin{aligned} & |E\{E[l(\beta_{\hat{\lambda}}, \beta) - SURE(\hat{\lambda})|\beta]\}| \\ & \leq 2\sigma^2 E\left\{\max_{1 \leq j \leq p} \left|\frac{1}{p} \sum_{i=1}^j (Z_i - 1)\right|\right\} \\ & \leq \frac{2\sigma^2}{p} (E(\max_{1 \leq j \leq p} M_j^2))^{\frac{1}{2}} \end{aligned}$$

Combine the two inequalities, we have

$$|E\{E[l(\beta_{\hat{\lambda}}, \beta) - SURE(\hat{\lambda})|\beta]\}| \leq 4\sqrt{\frac{2}{p}} \sigma^2$$

Since the error bound does not depend on $\hat{\lambda}$ and σ_i^2 , the lemma follows. \square

Abstract

Markov chain Monte Carlo (MCMC) is a popular and successful general-purpose tool for Bayesian inference. However, MCMC cannot be practically applied to large data sets because of the prohibitive cost of evaluating every likelihood term at every iteration. Here we present *Firefly Monte Carlo* (FlyMC) an auxiliary variable MCMC algorithm that only queries the likelihoods of a potentially small subset of the data at each iteration yet simulates from the exact posterior distribution, in contrast to recent proposals that are approximate even in the asymptotic limit. FlyMC is compatible with a wide variety of modern MCMC algorithms, and only requires a lower bound on the per-datum likelihood factors. In experiments, we find that FlyMC generates samples from the posterior more than an order of magnitude faster than regular MCMC, opening up MCMC methods to larger datasets than were previously considered feasible.

1 INTRODUCTION

The Bayesian approach to probabilistic modeling is appealing for a several reasons: the generative framework allows one to separate out modeling assumptions from inference procedures, outputs include estimates of uncertainty that can be used for decision making and prediction, and it provides clear ways to perform model selection and complexity control. Unfortunately, the fully-Bayesian approach to modeling is often very computationally challenging. It is unusual for non-trivial models of real data to have closed-form posterior distributions. Instead, one uses approximate inference via Monte Carlo, variational approximations, Laplace approximations, or other tools.

One of the persistent challenges to Bayesian computation is that coherent procedures for inference appear to require

examination of all of the data in order to evaluate a new hypothesis regarding parameters or latent variables. For example, when performing Metropolis–Hastings (MH), it is necessary to evaluate the target posterior density for each proposed parameter update, and this posterior will usually contain a factor for each datum. Similarly, typical variational Bayesian procedures need to build local approximations for each of the data in order to update the approximation to any global parameters. In both cases, it may be necessary to perform these data-intensive computations many times as part of an iterative procedure.

Recent methods have been proposed to partially overcome these difficulties. Stochastic and online variational approximation procedures (Hoffman et al., 2010, 2013) can use subsets of the data to make approximations to global parameters. As these procedures are optimizations, it is possible to build on convergence results from the stochastic optimization literature and achieve guarantees on the resulting approximation. For Markov chain Monte Carlo, the situation is somewhat murkier. Recent work has shown that approximate transition operators based on subsets of data can be used for predictive prefetching to help parallelize MCMC (Angelino et al., 2014). Other work uses approximate transition operators directly, for Metropolis-Hastings (MH) and related algorithms (Welling and Teh, 2011). Kottikara et al. (2014) and Bardenet et al. (2014) have shown that such approximate MH moves can lead to stationary distributions which are approximate but that have bounded error, albeit under strong conditions of rapid mixing.

In this paper, we present a Markov chain Monte Carlo algorithm, *Firefly Monte Carlo* (FlyMC), that is in line with these latter efforts to exploit subsets of data to construct transition operators. What distinguishes the approach we present here, however, is that this new MCMC procedure is *exact* in the sense that it leaves the true full-data posterior distribution invariant. FlyMC is a latent variable model which introduces a collection of Bernoulli variables – one for each datum – with conditional distributions chosen so that they effectively turn on and off data points in the posterior, hence “firefly”. The introduction of these latent vari-

ables does not alter the marginal distribution of the parameters of interest. Our only requirement is that it be possible to provide a “collapsible” lower bound for each likelihood term. FlyMC can lead to dramatic performance improvements in MCMC, as measured in wallclock time.

The paper is structured as follows. In Section 2, we introduce Firefly Monte Carlo and show why it is valid. Section 3 discusses practical issues related to implementation of FlyMC. Section 4 evaluates the new method on several different problems, and Section 5 discusses its limitations and possible future directions.

2 FIREFLY MONTE CARLO

The Firefly Monte Carlo algorithm tackles the problem of sampling from the posterior distribution of a probabilistic model. We will denote the parameters of interest as θ and assume that they have prior $p(\theta)$. We assume that N data have been observed $\{x_n\}_{n=1}^N$ and that these data are conditionally independent given θ under a likelihood $p(x_n | \theta)$. Our target distribution is therefore

$$p(\theta | \{x_n\}_{n=1}^N) \propto p(\theta, \{x_n\}_{n=1}^N) = p(\theta) \prod_{n=1}^N p(x_n | \theta). \quad (1)$$

For notational convenience, we will write the n th likelihood term as a function of θ as

$$L_n(\theta) = p(x_n | \theta).$$

An MCMC sampler makes transitions from a given θ to a new θ' such that posterior distribution remains invariant. Conventional algorithms, such as Metropolis–Hastings, require evaluation of the unnormalized posterior in full at every iteration. When the data set is large, evaluating all N likelihoods is a computational bottleneck. This is the problem that we seek to solve with FlyMC.

For each data point, n , we introduce a binary auxiliary variable, $z_n \in \{0, 1\}$, and a function $B_n(\theta)$ which is a strictly positive lower bound on the n th likelihood: $0 < B_n(\theta) \leq L_n(\theta)$. Each z_n has the following Bernoulli distribution conditioned on the parameters:

$$p(z_n | x_n, \theta) = \left[\frac{L_n(\theta) - B_n(\theta)}{L_n(\theta)} \right]^{z_n} \left[\frac{B_n(\theta)}{L_n(\theta)} \right]^{1-z_n}.$$

We now augment the posterior distribution with these N variables:

$$\begin{aligned} p(\theta, \{z_n\}_{n=1}^N | \{x_n\}_{n=1}^N) &\propto p(\theta, \{x_n, z_n\}_{n=1}^N) \\ &= p(\theta) \prod_{n=1}^N p(x_n | \theta) p(z_n | x_n, \theta). \end{aligned}$$

As in other auxiliary variable methods such as slice sampling, Swendsen-Wang, or Hamiltonian Monte Carlo, augmenting the joint distribution in this way does not damage

the original marginal distribution of interest:

$$\begin{aligned} &\sum_{z_1} \cdots \sum_{z_N} p(\theta) \prod_{n=1}^N p(x_n | \theta) p(z_n | x_n, \theta) \\ &= p(\theta) \prod_{n=1}^N p(x_n | \theta) \sum_{z_n} p(z_n | x_n, \theta) \\ &= p(\theta) \prod_{n=1}^N p(x_n | \theta) \end{aligned}$$

However, this joint distribution has a remarkable property: to evaluate the probability density over θ , given a particular configuration of $\{z_n\}_{n=1}^N$, it is only necessary to evaluate those likelihood terms for which $z_n = 1$. Consider factor n from the product above:

$$\begin{aligned} &p(x_n | \theta) p(z_n | x_n, \theta) \\ &= L_n(\theta) \left[\frac{L_n(\theta) - B_n(\theta)}{L_n(\theta)} \right]^{z_n} \left[\frac{B_n(\theta)}{L_n(\theta)} \right]^{1-z_n} \\ &= \begin{cases} L_n(\theta) - B_n(\theta) & \text{if } z_n = 1 \\ B_n(\theta) & \text{if } z_n = 0 \end{cases}. \end{aligned}$$

The “true” likelihood term $L_n(\theta)$ only appears in those factors for which $z_n = 1$ and we can think of these data as forming a “minibatch” subsample of the full set. If most $z_n = 0$, then transition updates for the parameters will be much cheaper, as these are applied to $p(\theta | \{x_n, z_n\}_{n=1}^N)$.

Of course, we do have to evaluate all N bounds $B_n(\theta)$ at each iteration. At first glance, we seem to have just shifted the computational burden from evaluating the $L_n(\theta)$ to evaluating the $B_n(\theta)$. However, if we choose $B_n(\theta)$ to have a convenient form, a scaled Gaussian or other exponential family distribution, for example, then the full product $\prod_{n=1}^N B_n(\theta)$ can be computed for each new θ in $O(1)$ time using the sufficient statistics of the distribution, which only need to be computed once. To make this clearer, we can rearrange the joint distribution in terms of a “pseudo-prior,” $\tilde{p}(\theta)$ and “pseudo-likelihood,” $\tilde{L}_n(\theta)$ as follows:

$$p(\theta, \{z_n\}_{n=1}^N | \{x_n\}_{n=1}^N) \propto \tilde{p}(\theta) \prod_{n:z_n=1} \tilde{L}_n(\theta) \quad (2)$$

where the product only runs over those n for which $z_n = 1$, and we have defined

$$\tilde{p}(\theta) = p(\theta) \prod_{n=1}^N B_n(\theta) \quad \tilde{L}_n(\theta) = \frac{L_n(\theta) - B_n(\theta)}{B_n(\theta)}.$$

We can generate a Markov chain for the joint distribution in Equation (2) by alternating between updates of θ conditional on $\{z_n\}_{n=1}^N$, which can be done with any conventional MCMC algorithm, and updates of $\{z_n\}_{n=1}^N$ conditional on θ for which we discuss efficient methods in Section 3.2. We emphasize that the marginal distribution over

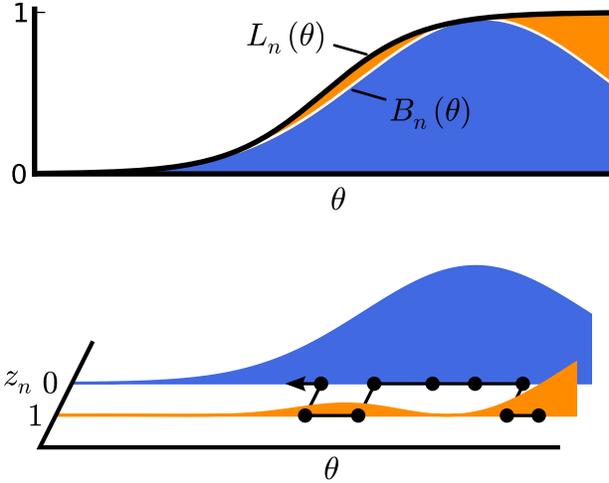

Figure 1: Illustration of the auxiliary variable representation of a single likelihood for a one-dimensional logistic regression model. The top panel shows how the likelihood function, $L_n(\theta)$, corresponding to a single datum n , can be partitioned into two parts: a lower bound, $B_n(\theta)$, shaded blue, and the remainder, shaded orange. The bottom panel shows that we can introduce a Bernoulli random variable z_n and construct a Markov chain in this new, higher dimensional space, such that marginalizing out (i.e. ignoring) the z_n recovers the original likelihood. If $B_n(\theta) \gg L_n(\theta) - B_n(\theta)$, the Markov chain will tend to occupy $z_n = 0$ and we can avoid evaluating $L_n(\theta)$ at each iteration.

θ is still the correct posterior distribution given in Equation (1).

At a given iteration, the $z_n = 0$ data points are “dark”: we simulate the Markov chain without computing their likelihoods. Upon a Markov transition in the space of $\{z_n\}_{n=1}^N$, a smattering of these dark data points become “bright” with their $z_n = 1$, and we include their likelihoods in subsequent iterations. The evolution of the chain evokes an image of fireflies, as the individual data blink on and off due to updates of the z_n .

The details of choosing a lower bound and efficiently sampling the $\{z_n\}$ are treated in the proceeding sections, but the high-level picture is now complete. Figure 1 illustrates the augmented space, and a simple version of the algorithm is shown in Algorithm 1. Figure 2 shows several steps of Firefly Monte Carlo on a toy logistic regression model.

3 IMPLEMENTATION CONSIDERATIONS

In this section we discuss two important practical matters for implementing an effective FlyMC algorithm: how to

choose and compute lower bounds, and how to sample the brightness variables z_n . For this discussion we will assume that we are dealing with a data set consisting of N data points, and a parameter set, θ , of dimension $D \ll N$. We will also assume that it takes at least $O(ND)$ time to evaluate the likelihoods at some θ for the whole data set and that evaluating this set of likelihoods at each iteration is the computational bottleneck for MCMC. We will mostly assume that space is not an issue: we can hold the full data set in memory and we can afford additional data structures occupying a few bytes for each of the N data.

The goal of an effective implementation of FlyMC is to construct a Markov chain with similar convergence and mixing properties to that of regular MCMC, while only evaluating a subset of the data points on average at each iteration. If the average number of “bright” data points is M , we would like this to achieve a computational speedup of nearly N/M over regular MCMC.

3.1 Choosing a lower bound

The lower bounds, $B_n(\theta)$ of each data point’s likelihood $L_n(\theta)$ should satisfy two properties. They should be relatively tight, and it should be possible to efficiently summarize a product of lower bounds $\prod_n B_n(\theta)$ in a way that (after setup) can be evaluated in time independent of N .

The tightness of the bounds is important because it determines the number of bright data points at each iteration, which determines the time it takes to evaluate the joint posterior. For a burned-in chain, the average number of bright data points, M , will be:

$$M = \sum_{n=1}^N \langle z_n \rangle = \sum_{n=1}^N \int p(\theta | \{x_n\}_{n=1}^N) \frac{L_n(\theta) - B_n(\theta)}{L_n(\theta)} d\theta.$$

Therefore it is important that the bounds are tight at values of θ where the posterior puts the bulk of its mass.

The second important property is that the product of the lower bounds must be easy to compute and represent. This property emerges naturally if we use scaled exponential-family lower bounds so that their product can be summarized via a set of sufficient statistics. We should also mention that the individual bounds $B_n(\theta)$ should be easy to compute themselves, since these are computed alongside $L_n(\theta)$ for all the bright points at each iteration. In all the examples considered in this paper, the rate-limiting step in computing either $L_n(\theta)$ or $B_n(\theta)$ is the evaluation of the dot product of a feature vector with a vector of weights. Once we have computed $L_n(\theta)$ the extra cost of computing $B_n(\theta)$ is negligible.

At this stage it is useful to consider a concrete example. The logistic regression likelihood is

$$L_n(\theta) = \text{logit}^{-1}(t_n \theta^\top x_n) = \frac{1}{1 + \exp\{-t_n \theta^\top x_n\}},$$

21:   return  $P$ 
22: end function

```

where $x_n \in \mathbb{R}^D$ is the set of features for the n th data point and $t_n \in \{-1, 1\}$ is its class. The logistic function has a family of scaled Gaussian lower bounds, described in Jaakkola and Jordan (1997), parameterized by ξ , the location at which the bound is tight:

$$\log(B_n(\theta)) = a(t_n \theta^\top x_n)^2 + b(t_n \theta^\top x_n) + c$$

where:

$$a = \frac{-1}{4\xi} \left(\frac{e^\xi - 1}{e^\xi + 1} \right) \quad b = \frac{1}{2}$$

$$c = -a * \xi^2 + \frac{\xi}{2} - \log(e^\xi + 1)$$

This is the bound shown in Fig. 1. The product of these bounds can be computed for a given θ in $O(D^2)$ time, provided we have precomputed the moments of the data, at a one-time setup cost of $O(ND^2)$:

$$\frac{1}{N} \log \prod_{n=1}^N B_n(\theta) = a \theta^\top \hat{S} \theta + b \theta^\top \hat{\mu} + c$$

where

$$\hat{S} = \frac{1}{N} \sum_{n=1}^N x_n x_n^\top \quad \hat{\mu} = \frac{1}{N} \sum_{n=1}^N t_n x_n.$$

This bound can be quite tight. For example, if we choose $\xi = 1.5$ the probability of a data point being bright

is less than 0.02 in the region where $0.1 < L_n(\theta) < 0.9$. With a bit of up-front work, we can do even better than this by choosing bounds that are tight in the right places. For example, we can perform a quick optimization to find an approximate maximum *a posteriori* (MAP) value of θ and construct the bounds to be tight there. We explore this idea further in Section 4.

3.2 Sampling and handling the auxiliary brightness variables

The resampling of the z_n variables, as shown in lines 3 to 6 of Algorithm 1, takes a step by explicitly sampling z_n from its conditional distribution for a random fixed-size subset of the data. We call this approach *explicit resampling* and it has a clear drawback: if the fixed fraction is α (shown as RESAMPLEFRACTION in Algorithm 1), then the chain cannot have a mixing time faster than $1/\alpha$, as each data point is only visited a fraction of the time.

Nevertheless, explicit resampling works well in practice since the bottleneck for mixing is usually the exploration of the space of θ , not space of z_n . Explicit resampling has the benefit of being a simple, low-overhead algorithm that is easy to vectorize for speed. The variant shown in Algorithm 1 is the simplest: data points are chosen at random, with replacement. We could also sample without replacement but this is slightly harder to do efficiently. Another variant would be to deterministically choose a subset from which to Gibbs sample at each iteration. This is more in

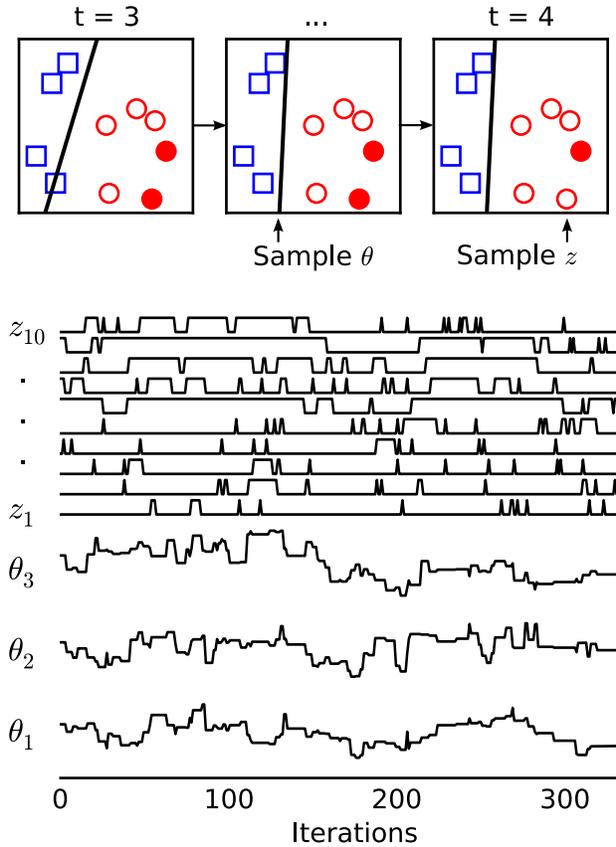

Figure 2: Illustration of the FlyMC algorithm operating on a logistic regression model of a toy synthetic data set, a two-class classification problem in two dimensions (and one bias dimension). The top panel shows a single iteration of FlyMC, from $t = 3$ to $t = 4$, which consists of two steps: first we sample θ , represented by the line of equal class probability. Next we sample the z_n . In this case, we see one ‘bright’ (solid) data point become dark. The bottom panel shows the trajectories of all components of θ and z .

line with the traditional approach of stochastic gradient descent optimization. Such an approach may be appropriate for data sets which are too large to fit into memory, since we would no longer need random access to all data points. The resulting Markov chain would be non-reversible, but still satisfy stationarity conditions.

Explicitly sampling a subset of the z_n seems wasteful if $M \ll N$, since most updates to z_n will leave it unchanged. We can do better by drawing each update for z_n from a pair of tunable Bernoulli proposal distributions $q(z'_n = 1 | z_n = 0) = q_{d \rightarrow b}$ and $q(z'_n = 0 | z_n = 1) = q_{b \rightarrow d}$, and then performing a Metropolis–Hastings accept/reject step with the true auxiliary probability $p(z_n | x_n, \theta)$. This proposal can be efficiently made for each data point, but it is only necessary

to evaluate $p(z_n | x_n, \theta)$ – and therefore the likelihood function – for the subset of data points which are proposed to change state. That is, if a sample from the proposal distribution sends $z_n = 0$ to $z_n = 0$ then it doesn’t matter whether we accept or reject. If we use samples from a geometric distribution to choose the data points, it is not even necessary to explicitly sample all of the N proposals.

The probabilities $q_{b \rightarrow d}$ and $q_{d \rightarrow b}$ can be tuned as hyper-parameters. If they are larger than $p(z_n = 0 | x_n, \theta)$ and $p(z_n = 1 | x_n, \theta)$ respectively, then we obtain near-perfect Gibbs sampling. But larger values also require more likelihood evaluations per iteration. Since the likelihoods of the bright data points have already been evaluated in the course of the Markov step in θ we can reuse these values and set $q_{b \rightarrow d} = 1$, leaving $q_{d \rightarrow b}$ as the only hyper-parameter, which we can set to something like M/N . The resulting algorithm, which we call *implicit resampling*, is shown as Algorithm 2.

3.3 Data structure for brightness variables

In the algorithms shown so far, we have aimed to construct a valid Markov chain while minimizing the number of likelihood evaluations, on the (reasonable) assumption that likelihood evaluations dominate the computational cost. However, the algorithms presented do have some steps which appear to scale linearly with N , even when M is constant. These are steps such as “loop over the bright data points” which takes time linear in N . With a well-chosen data structure for storing the variables z_n , we can ensure that these operations only scale with M .

The data structure needs to store the values of z_n for all n from 1 to N , and it needs to support the following methods in $O(1)$ time:

- `Brighten(n)`: Set $z_n = 1$
- `ithBright(i)`: Return n , the i th bright data point (in some arbitrary ordering).

We similarly require `Darken` and `ithDark`. The data structure should also keep track of how many bright data points there are.

To achieve this, we use the cache-like data structure shown in Figure 3. We store two arrays of length N . The first is `z.arr`, which contains a single copy of each of the indices n from 1 to N . All of the bright indices appear before the dark indices. A variable `z.B` keeps track of how many bright indices there are, and thus where the bright-dark transition occurs. In order to also achieve $O(1)$ assignment of indices, we also maintain a direct lookup table `z.tab` whose n th entry records the position in array `z.arr` where n is held. `Brighten(n)` works by looking up `int z.tab` the position of n in `z.arr`, swapping it with

Algorithm 2 Implicit z_n sampling

```

1: for  $n \leftarrow 1 \dots N$  do
2:   if  $z_n = 1$  then
3:      $u \sim \text{Uniform}(0, 1)$ 
4:     if  $\frac{q_{d \rightarrow b}}{\tilde{L}_n(\theta)} > u$  then
5:        $z_n \leftarrow 0$ 
6:     end if
7:   else
8:     if  $v < q_{d \rightarrow b}$  where  $v \sim \text{Uniform}(0, 1)$  then
9:        $u \sim \text{Uniform}(0, 1)$ 
10:      if  $\frac{\tilde{L}_n(\theta)}{q_{d \rightarrow b}} < u$  then
11:         $z_n \leftarrow 1$ 
12:      end if
13:    end if
14:  end if
15: end for
  
```

▷ Loop over all the auxiliary variables.
 ▷ If currently bright, propose going dark.
 ▷ Sample the MH threshold.
 ▷ Compute MH ratio with $\tilde{L}_n(\theta)$ cached from θ update.
 ▷ Flip from bright to dark.
 ▷ Already dark, consider proposing to go bright.
 ▷ Flip a biased coin with probability $q_{d \rightarrow b}$.
 ▷ Sample the MH threshold.
 ▷ Compute MH ratio.
 ▷ Flip from dark to bright.

the index at position $z.B$, incrementing $z.B$, and updating $z.tab$ accordingly.

4 EXPERIMENTS

For FlyMC to be a useful algorithm it must be able to produce effectively independent samples from posterior distributions more quickly than regular MCMC. We certainly expect it to iterate more quickly than regular MCMC since it evaluates fewer likelihoods per iteration. But we might also expect it to mix more slowly, since it has extra auxiliary variables. To see whether this trade-off works out in FlyMC’s favor we need to know how much faster it iterates and how much slower it mixes. The answer to the first question will depend on the data set and the model. The answer to the second will depend on these too, and also on the choice of algorithm for updating θ .

We conducted three experiments, each with a different data set, model, and parameter-update algorithm, to give an impression of how well FlyMC can be expected to perform. In each experiment we compared FlyMC, with two choices of bound selection, to regular full-posterior MCMC. We looked at the average number of likelihoods queried at each iteration and the number of effective samples generated per iteration, accounting for autocorrelation. The results are summarized in Figure 4 and Table 1. The broad conclusion is that FlyMC offers a speedup of at least one order of magnitude compared with regular MCMC if the bounds are tuned according to a MAP-estimate of θ . In the following subsections we describe the experiments in detail.

4.1 Logistic regression

We applied FlyMC to the logistic regression task described in Welling and Teh (2011) using the Jaakkola-

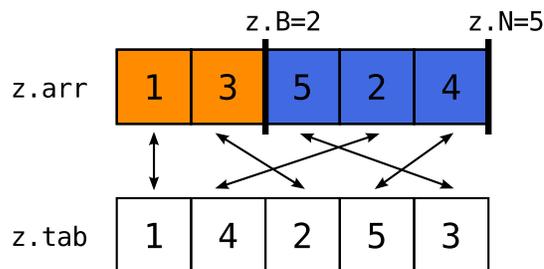

Figure 3: Illustration of a data structure allowing for efficient operations on the sets of bright and dark data points. Data points 1 and 3 are bright, the rest are dark.

Jordan bounds described earlier. The task is to classify MNIST 7s and 9s, using the first 50 principal components (and one bias) as features. We used a Gaussian prior over the weights and chose the scale of that prior by evaluating performance on a held-out test set. To sample over θ , we used symmetric Metropolis-Hasting proposals, with step size chosen to yield an acceptance rate of 0.234 (Roberts et al., 1997), optimized for each algorithm separately. We sampled the z_n using the implicit Metropolis-Hastings sampling algorithm.

We compared three different algorithms: regular MCMC, untuned FlyMC, and MAP-tuned FlyMC. For untuned FlyMC, we chose $\xi = 1.5$ for all data points. To compute the bounds for the MAP-tuned algorithm, we performed stochastic gradient descent optimization to find a set of weights close to the MAP value and gave each data point its own ξ to make the bounds tight at the MAP parameters: $L_n(\theta_{\text{MAP}}) = B_n(\theta_{\text{MAP}})$ for all n . For untuned FlyMC, and MAP-tuned FlyMC we used $q_{d \rightarrow b} = 0.1$ and $q_{d \rightarrow b} = 0.01$ respectively, chosen to be similar to the typi-

		Algorithm	Average Likelihood queries per iteration	Effective Samples per 1000 iterations	Speedup relative to regular MCMC

Table 1: Results from empirical evaluations. Three experiments are shown: logistic regression applied to MNIST digit classification, softmax classification for three categories of CIFAR-10, and robust regression for properties of organic photovoltaic molecules, sampled with random-walk Metropolis–Hastings, Langevin-adjusted Metropolis, and slice sampling, respectively. For each of these, the vanilla MCMC operator was compared with both untuned FlyMC and FlyMC where the bound was determined from a MAP estimate of the posterior parameters. We use likelihood evaluations as an implementation-independent measure of computational cost and report the number of such evaluations per iteration, as well as the resulting sample efficiency (computed via R-CODA (Plummer et al., 2006)), and relative speedup.

cal fraction of bright data points in each case.

The results are shown in Figure 4a and summarized in Table 1. On a per-iteration basis, the FlyMC algorithms mix and burn-in more slowly than regular MCMC by around a factor of two, as illustrated by the autocorrelation plots. Even on a per-likelihood basis, the naïve FlyMC algorithm, with a fixed ξ , performs worse than regular MCMC, by a factor of 0.7, despite needing fewer likelihood evaluations per iteration. The MAP-tuned algorithm was much more impressive: after burn-in, it queried only 207 of the 12,2214 likelihoods per iteration on average, giving a speedup of more than 20, even taking into account the slower per-iteration mixing time. We initialized all chains with draws from the prior. Notice that the MAP-tuned algorithm performs poorly during burn-in, since the bounds are less tight during this time, whereas the reverse is true for the untuned algorithm.

4.2 Softmax classification

Logistic regression can be generalized to multi-class classification problems by softmax classification. The softmax likelihood of a data point belonging to class k of K classes is

$$L_n(\theta) = \frac{\exp(\theta_k^\top x_n)}{\sum_{k'=1}^K \exp(\theta_{k'}^\top x_n)}$$

Where θ is now a $K \times D$ matrix. The Jaakkola-Jordan bound does not apply to this softmax likelihood, but we can use a related bound, due to Böhning (1992), whose log matches the value and gradient of the log of the softmax likelihood at some particular θ , but has a tighter curvature. Murphy (2012) has the result in full in the chapter on variational inference.

We applied softmax classification to a three-class version of CIFAR-10 (airplane, automobile and bird) using 256 binary features discovered by Krizhevsky (2009) using a deep autoencoder. Once again, we used a Gaussian prior on the weights, chosen to maximize out-of-sample performance. This time we used the Metropolis-adjusted Langevin algorithm (MALA, Roberts and Tweedie (1996)) for our parameter updates. We chose the step sizes to yield acceptance rates close to the optimal 0.57 (Roberts and Rosenthal, 1998). Other parameters were tuned as in the logistic regression experiment.

The softmax experiment gave qualitatively similar results to the logistic regression experiment, as seen in Figure 4b and Table 1. Again, the MAP-tuned FlyMC algorithm dramatically outperformed both the lackluster untuned FlyMC and regular MCMC, offering an 11-fold speedup over the latter.

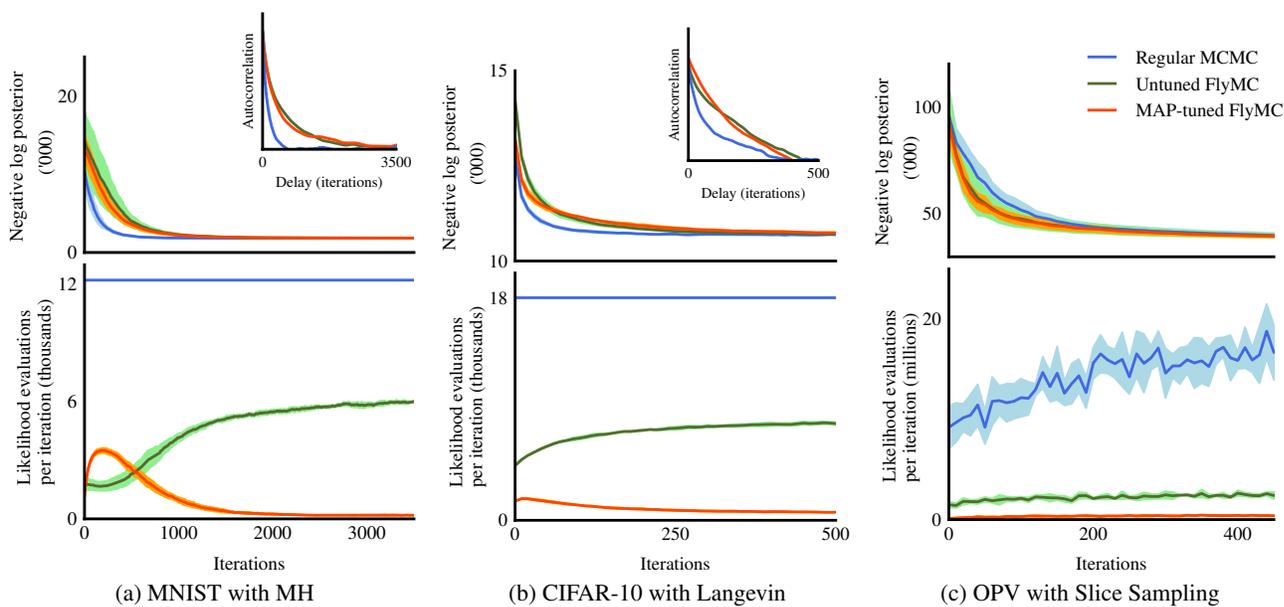

Figure 4: Tuned and untuned Firefly Monte Carlo compared to regular MCMC with three different operators, data sets, and models: (a) the digits 7 and 9 from the MNIST data are classified using logistic regression, with a random-walk Metropolis-Hastings operator; (b) softmax classification on three classes (airplane, automobile, and bird) from the CIFAR-10 image dataset, using Langevin-adjusted Metropolis; (c) robust regression on the HOMO-LUMO gap (as computed by density functional theory calculations) for a large set of organic photovoltaic molecules, using slice sampling. In each subfigure, the top shows the trace of the log posterior density to illustrate convergence, and the bottom shows the average number of likelihoods computed per iteration. One standard deviation is shown around the mean value, as computed from five runs of each. The blue lines are computed using the full-data posterior, and the green and orange lines show the untuned and tuned Firefly MC traces, respectively.

4.3 Robust sparse linear regression

Linear regression with Gaussian likelihoods yields a closed-form expression for the posterior. Non-Gaussian likelihoods, however, like heavy-tailed distributions used in so-called “robust regression” do not. Our final experiment was to perform inference over robust regression weights for a very large dataset of molecular features and computed electronic properties. The data set, described by Hachmann et al. (2011, 2014) consists of 1.8 million molecules, with 57 cheminformatic features each (Oliveres-Amaya et al., 2011; Amador-Bedolla et al., 2013). The task was to predict the HOMO-LUMO energy gap, which is useful for predicting photovoltaic efficiency.

We used a student-t distribution with $\nu = 4$ for the likelihood function and we computed a Gaussian lower bound to this by matching the value and gradient of the t distribution probability density function value at some ξ ($\xi = 0$ for the untuned case, $\xi = \theta_{MAP}^T x$ for the MAP-tuned case). We used a sparsity-inducing Laplace prior on the weights. As before, we chose the scales of the prior and the likelihood to optimize out-of sample performance.

We performed parameter updates using slice sampling (Neal, 2003). Note that slice sampling results in a variable

number of likelihood evaluations per iteration, even for the regular MCMC algorithm. Again, we found that MAP-tuned FlyMC substantially outperformed regular MCMC, as shown in Figure 4c and Table 1.

5 DISCUSSION

In this paper, we have presented Firefly Monte Carlo, an algorithm for performing Markov chain Monte Carlo using subsets (minibatches) of data. Unlike other recent proposals for such MCMC operators, FlyMC is exact in the sense that it has the true full-data posterior as its target distribution. This is achieved by introducing binary latent variables whose states represent whether a given datum is bright (used to compute the posterior) or dark (not used in posterior updates). By carefully choosing the conditional distributions of these latent variables, the true posterior is left intact under marginalization. The primary requirement for this to be efficient is that the likelihoods term must have lower bounds that collapse in an efficient way.

There are several points that warrant additional discussion and future work. First, we recognize that useful lower bounds can be difficult to obtain for many problems. It would be helpful to produce such bounds automatically for

a wider class of problems. As variational inference procedures are most often framed in terms of lower bounds on the marginal likelihood, we expect that Firefly Monte Carlo will benefit from developments in so-called “black box” variational methods (Wang and Blei, 2013; Ranganath et al., 2014). Second, we believe we have only scratched the surface of what is possible with efficient data structures and latent-variable update schemes. For example, the MH proposals we consider here for z_n have a fixed global $q_{d \rightarrow b}$, but clearly such a proposal should vary for each datum. Third, it is often the case that larger state spaces lead to slower MCMC mixing. In Firefly Monte Carlo, much like other auxiliary variable methods, we have expanded the state space significantly. We have shown empirically that the slower mixing can be more than offset by the faster per-transition computational time. In future work we hope to show that fast-mixing Markov chains on the parameter space will continue to mix fast in the Firefly auxiliary variable representation.

Firefly Monte Carlo is closely related to recent ideas in using pseudo-marginal MCMC (Andrieu and Roberts, 2009) for sampling from challenging target distributions. If we sampled each of the variables $\{z_n\}$ as a Bernoulli random variable with success probability 0.5, then the joint posterior we have been using becomes an unbiased estimator of the original posterior over θ , up to normalization. Running pseudo-marginal MCMC using this unbiased estimator would be a special case of FlyMC: namely FlyMC with z and θ updated simultaneously with Metropolis-Hastings updates.

Acknowledgements

We thank Andrew Miller, Jasper Snoek, Michael Gelbart, Brenton Partridge, Oren Rippel and Elaine Angelino for helpful discussions. We also thank Alan Aspuru-Guzik, Johannes Hachmann, and Roberto Olivares-Amaya for the use of the OPV data set and introduction to the cheminformatic feature set. Partial funding was provided by Analog Devices (Lyric Labs), DARPA Young Faculty Award N66001-12-1-4219 and Samsung Advanced Institute of Technology.

Abstract

Bayesian Optimisation has received considerable attention in recent years as a general methodology to find the maximum of costly-to-evaluate objective functions. Most existing BO work focuses on *where* to gather a set of samples without giving special consideration to the sampling sequence, or the costs or constraints associated with that sequence. However, in real-world sequential decision problems such as robotics, the order in which samples are gathered is paramount, especially when the robot needs to optimise a temporally non-stationary objective function. Additionally, the state of the environment and sensing platform determine the type and cost of samples that can be gathered. To address these issues, we formulate *Sequential Bayesian Optimisation* (SBO) with side-state information within a *Partially Observed Markov Decision Process* (POMDP) framework that can accommodate discrete and continuous observation spaces. We build on previous work using *Monte-Carlo Tree Search* (MCTS) and *Upper Confidence bound for Trees* (UCT) for POMDPs and extend it to work with continuous state and observation spaces. Through a series of experiments on monitoring a spatial-temporal process with a mobile robot, we show that our UCT-based SBO POMDP optimisation outperforms myopic and non-myopic alternatives.

1 INTRODUCTION

Bayesian Optimisation (BO) [1, 6, 10] is a global optimisation technique that has recently gained popularity in the machine learning community. BO possesses major advantages when used to find the maximum of partially observed objective functions that are costly to evaluate, lack gradient information, and can only be inferred indirectly from noisy

observations. BO is robust to this setting because it builds a statistical model over the objective. More specifically, it places a *prior* over the space of functions and combines it with noisy samples to produce an incremental prediction for the unknown function. The prior usually takes the form of a *Gaussian Process* (GP) [15], which has proved successful in modelling spatial-temporal data [4, 9, 17]. The key component for the effectiveness of BO is the use of an *Acquisition Function* (AF) that guides the search for the optimum by selecting the locations where samples are gathered based on the posterior in each iteration.

BO can be readily applied to scenarios where the objective function does not vary in time and sampling locations can be chosen freely within the input domain. In real-world robotics applications, functions are likely to change with time [11] indicating that *when* to sample is as important as *where* to sample. Another important aspect in realistic settings is that the state of the environment and sampling platform determines the reachable space for gathering the next sample. Combined, these issues create an imperative for finding optimal *sequences* of sampling locations.

Most of the existing work focuses on myopic decision-making by evaluating one-step lookahead for objective sampling. Non-myopic solutions have been proposed in [5, 12], but the authors acknowledge they are considerably expensive to evaluate and do not account for possible side-state presence due to external conditions. An optimal solution to non-myopic decision-making with side-state can be formalised in the *Partially Observed Markov Decision Process* (POMDP) framework. The key here is to consider the state as a tuple, consisting of the unknown function and the state of a sensing robot. However, this leaves open the question of how one can efficiently solve the resulting POMDP.

The *online* setting for POMDP planning has received increased attention in recent years for helping overcome perceived efficiency limitations of POMDP solutions [16]. Silver and Veness [18] show how to use UCT for large POMDPs, however, this does not extend to continuous observations (without sampling). Porta *et al* [14] present

Point-Based Value Iteration (PBVI) for continuous state, action and observation POMDPs, however, this approach aims for a closed-form value function that generalises over all states, which can only be computed in more restricted cases than the general sequential BO POMDP framework we would like to propose in this work. A first connection between BO and POMDPs has been noted by [20], that solved the two-step lookahead without any efficient strategies, or considering the side-state as we do. In this work we intend to build on both [18] and [20] to apply UCT to a general POMDP formulation of SBO with side-state and continuous observations.

We begin by briefly describing *Gaussian Processes* (GPs), BO and POMDPs. We show the connections between SBO and POMDPs, followed by possible online solutions for multi-step lookahead in POMDPs that aim to provide an optimal sequence of sampling locations. In section 4 we evaluate our model for spatial-temporal monitoring problems that clearly demonstrate the benefits of our UCT algorithm for non-myopic SBO optimisation.

2 BACKGROUND

We start with a brief description of Gaussian processes as the underlying regression technique for Bayesian optimisation. We then describe BO and define notation for our POMDP formulation.

2.1 GAUSSIAN PROCESSES

A GP is a collection of random variables with a joint Gaussian distribution. A GP places a Gaussian prior over the space of functions and is completely defined by a mean function, $m(\mathbf{x})$, and a positive semi-definite covariance function $k(\mathbf{x}, \mathbf{x}')$, where \mathbf{x} is an input in a D dimensional space, $\mathbf{x} \in \mathcal{R}^D$. A latent noisy function f can be represented as $f(\mathbf{x}) \sim \mathcal{GP}(m(\mathbf{x}), k(\mathbf{x}, \mathbf{x}'))$. Further, we assume an additive noise model $y = f(\mathbf{x}_i) + \epsilon$ for noisy observations y from f , where $\epsilon \stackrel{iid}{\sim} \mathcal{N}(0, \sigma_n^2)$ is an independent Gaussian noise.

Given a set of N training inputs $X = \{\mathbf{x}_i\}_{i=1}^N$ and corresponding outputs $\mathbf{y} = \{y_i\}_{i=1}^N$ we can calculate the predictive distribution of f at an unknown query location \mathbf{x}^* by computing the posterior $p(f(\mathbf{x}^*)|\mathbf{y}, X, \mathbf{x}^*)$. For a GP, this predictive distribution is Gaussian, $f(\mathbf{x}^*) \sim \mathcal{N}(\bar{f}^*, \text{cov}(f^*))$, where

$$\begin{aligned} \bar{f}^* &= K(\mathbf{x}^*, X)K_X^{-1}(\mathbf{y} - m(X)), \\ \text{cov}(f^*) &= K(\mathbf{x}^*, \mathbf{x}^*) - K(\mathbf{x}^*, X)K_X^{-1}K(X, \mathbf{x}^*), \end{aligned} \tag{1}$$

and $K(A, B)$ is a covariance matrix whose element (i, j) is calculated as $k_{i,j} = k(\mathbf{x}_i, \mathbf{x}_j)$, with $\mathbf{x}_i \in A$ and $\mathbf{x}_j \in B$. $K_X = K(X, X) + \sigma_n^2 I$ is the covariance matrix between observations, with identity matrix I .

The parameters of the mean and covariance functions can be estimated automatically by maximising the marginal likelihood of the data [15]. Since we will be dealing with space-time inputs, \mathbf{x} can be represented by space and time components, covariance functions can be separable [19] and learn periodic patterns [15, 21].

2.2 BAYESIAN OPTIMISATION

BO is an optimisation technique for finding the optimum $\hat{\mathbf{x}} \in \mathbb{R}^D$ of an unknown, costly to evaluate and noisy function $f : \mathbb{R}^D \rightarrow \mathbb{R}$,

$$\hat{\mathbf{x}} = \arg \max_{\mathbf{x}} f(\mathbf{x}). \tag{2}$$

In this setting f is not directly observable but we have available noisy samples from f , i.e. the i th observation can be seen as $y_i = f(\mathbf{x}_i) + \epsilon$, where $\epsilon \stackrel{iid}{\sim} \mathcal{N}(0, \sigma_n^2)$ is the noise associated to each independent observation. BO uses a GP to model f which is incrementally updated at every iteration, as new observations become available. The benefit of this approach is that for every optimum candidate location we can evaluate an analytical expression for the expected value of f and its variance (Equation 1). This information is used by an *Acquisition Function* (AF), $h(\mathbf{x})$, whose purpose is to guide the search for the optimum. At each iteration, one sample is gathered from f at a location selected by maximising $h(\mathbf{x})$, which is a simpler and faster optimisation procedure (compared to the original problem of optimising f). Algorithm 1 presents the BO algorithm.

Algorithm 1 Bayesian Optimisation

Inputs: f, h

Outputs: $\hat{\mathbf{x}}, f(\hat{\mathbf{x}})$

```

for  $j = 1, 2, 3, \dots$  {Max iterations} do
  Find  $\mathbf{x}_j = \arg \max_{\mathbf{x}} h(\mathbf{x})$ 
   $y_j \leftarrow f(\mathbf{x}_j)$  ▷ Gather sample from  $f$ 
  Augment training set with  $(\mathbf{x}_j, y_j)$ .
  Update GP
  if  $y_j > \mu(\hat{\mathbf{x}})$  then
     $\hat{\mathbf{x}} \leftarrow \mathbf{x}_j$  ▷ Update location of optimum
  end if
end for

```

Many AFs have been proposed on the literature [6–8, 12]. In this paper we use the *Upper Confidence Bound* (UCB) [3] acquisition function, however, none of the algorithms presented here are strongly linked to this specific AF.

2.3 PARTIALLY OBSERVABLE MDPs

POMDPs are a unified framework for sequential decision making under uncertainty when the state is not directly ob-

servable. A POMDP is fully represented by the following tuple $\langle S, A, T, R, Z, O \rangle$, where:

- S : Set of states $\{s_1, s_2, \dots, s_n\}$.
- A : Set of actions $\{a_1, a_2, \dots, a_n\}$.
- T : $S \times A \times S \rightarrow [0, 1]$ is a transition function that represents the probability of transition between states s and s' when executing action a , i.e. $T(s, a, s') = p(s'|s, a)$.
- R : $S \times A \rightarrow \mathbb{R}$ is a reward function that encodes the reward of executing action a on state s , i.e. $R(s, a)$.
- Z : Finite set of observations $\{z_1, z_2, \dots, z_n\}$.
- O : $S \times A \times Z \rightarrow [0, 1]$ is an observation function that represents the probability of observing o if action a is executed with resulting state s , i.e. $O(o, a, s) = p(o|a, s)$.

In POMDPs, it is well-known that a belief state summarises *all* relevant information in the observation history of a POMDP. Given a belief state $b_{t-1}(s)$, the belief at time t can be updated as:

$$b_t(s') \propto P(o|s') \int b_{t-1}(s) P(s'|s, a) ds. \quad (3)$$

where $b_0(s) = p(s)$ represents the initial belief state.

Solving a POMDP is equivalent to determining a policy π^* mapping belief states to actions which maximizes some objective criterion. An optimal policy over an infinite horizon can be found by maximising the expected cumulative discounted reward r_t (for discount $\gamma \in (0, 1]$) at time step t when executing π starting from belief state $b_0 := b_0(s)$,

$$\pi^* = \arg \max_{\pi} E \left[\sum_{t=0}^{\infty} \gamma^t \cdot r_t^{\pi} | b_0 \right]. \quad (4)$$

3 SEQUENTIAL BAYESIAN OPTIMISATION

With the definitions above we can now extend BO to a sequential setting. In order to apply BO to more realistic problems we expand the existing theory to a more generic framework and include the notion of state in the definition of the problem. This means that at every step a generic reward, r , can be obtained by sampling at \mathbf{x} . This reward depends on the state \mathbf{x} of a mobile robotic sensor and the expected value of the objective function $f(\mathbf{x})$. In the general case, because gathering each sample has an associated reward, the order in which they are gathered has a direct influence over the total accumulated reward for a specific lookahead. We call this kind of optimisation technique *Sequential Bayesian Optimisation* (SBO).

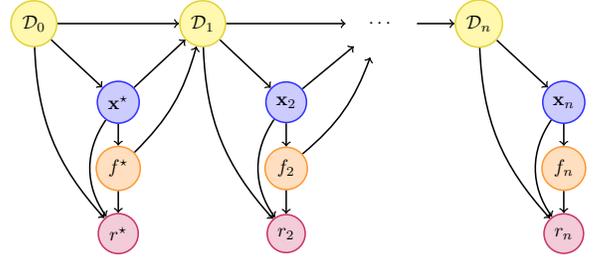

Figure 1: Bayesian network representation for SBO.

Sampling locations and their associated observations are grouped in \mathcal{D} , which is built incrementally as shown in Figure 1. Using a similar treatment to plain BO, the myopic expectation of the reward r (ER), can be obtained by marginalising out all unknown outcomes,

$$\text{ER}(\mathbf{x}^* | \mathcal{D}_0) = \mathbb{E}_{f^*} [r(\mathbf{x}^*, f^* | \mathcal{D}_0)] \quad (5)$$

$$= \int r(\mathbf{x}^*, f^* | \mathcal{D}_0) p(f^* | \mathbf{x}^*, \mathcal{D}_0) df^*. \quad (6)$$

The n -step lookahead expression is given by

$$\begin{aligned} \text{ER}_n(\mathbf{x}^* | \mathcal{D}_0) &= \int \dots \int \left(r(\mathbf{x}^*, f^* | \mathcal{D}_0) + \sum_{i=2}^n (r(\mathbf{x}_i, f_i | \mathcal{D}_{i-1})) \right) \\ &\quad p(f^* | \mathbf{x}^*, \mathcal{D}_0) \times \prod_{i=2}^n p(f_i | \mathbf{x}_i) p(\mathbf{x}_i | \mathcal{D}_{i-1}) \\ &\quad df^* df_2 \dots df_n d\mathbf{x}_2 \dots d\mathbf{x}_n, \end{aligned} \quad (7)$$

where we are marginalising out all future outcomes ($f^*, f_2 \dots f_n$) and locations ($\mathbf{x}_2 \dots \mathbf{x}_n$). This expression has been derived in [12], however, it presents a slight modification because we are considering the whole sequence of locations for reward calculation, not just the expected improvement for the last sample. It is important to note that within the BO algorithm, ER can be seen as the acquisition function $h(\mathbf{x})$ for selecting sampling locations. ER needs to be maximised w.r.t. \mathbf{x}^* in each iteration of the algorithm.

In real robotic deployments, decisions $\{\mathbf{x}_i\}$ can be represented as continuous paths followed by the robot. We represent these paths as parametrised curves, \mathcal{C} , over the input space, with each curve characterised by a set of parameters Θ . The following expression shows the expected reward for traversing a path with parameters Θ^* , and looking ahead for n steps, i.e. considering n paths in the future and

integrating all possible rewards,

$$\begin{aligned}
& \text{ER}_n(\Theta^*, \mathcal{D}_0) \\
&= \int_{f^*} \int_{f_2} \cdots \int_{f_n} \int_{\Theta_2} \cdots \int_{\Theta_n} \\
&\quad \left(r(\mathcal{C}_{\Theta^*} | \mathcal{D}_{N-1}) + \sum_{i=2}^n r(\mathcal{C}_{\Theta_i} | \mathcal{D}_{i-1}) \right) \\
&\quad p(f^* | \Theta^*, \mathcal{D}_{N-1}) \prod_{i=2}^n p(f_i | \Theta_i, \mathcal{D}_{i-1}) p(\Theta_i | \mathcal{D}_{i-1}) \\
&\quad df^* df_2 \cdots df_n d\Theta_2 \cdots d\Theta_n
\end{aligned} \tag{8}$$

In this expression we are marginalising out all possible observations and paths for n steps. Unfortunately, given the infinite number of possible paths, this integral does not have an analytical solution and can only be approximated. In the following section we illustrate how SBO can be represented in a POMDP formulation and solved using online decision making POMDP solvers.

3.1 SBO AS ONLINE POMDPs

Our SBO formulation is *state-aware*, i.e. it considers the state of a mobile robot for decision making. This problem can be formulated as a POMDP problem in a similar manner as described in [20] for regular BO. The main idea is to include the objective function, which is partially observable, together with the state of the robot, into the state definition. We assume the robot's pose is fully observable and part of the state as side information \mathbf{p} . The decision of where to sample f is encoded by the action space, which is limited by the possible actions that can be performed by the robot. In the discrete case, an action is represented by moving to a specific cell. For the continuous case an action means travelling along a continuous path. More formally, the elements of the POMDP definition for side-state SBO are:

- S : The state which is a tuple $\{f, \mathbf{p}\}$, where f is a latent (not directly observable) function defined over space and time representing the unknown process. Additionally, we include the state of the sensing robot, \mathbf{p} , which is fully observable, as the side information.
- A : The parametrised action space $a(\Theta)$. The actions can be described as move according to parameters Θ and gather a samples from f in the process. For the discrete sampling case, Θ represents a location in the spatial domain of f . For the continuous case, Θ are the parameters of a continuous curve defined over the domain of f .
- T : The transition function which is defined over the entire state $\{f, \mathbf{p}\}$. $T(\{f, \mathbf{p}\}, a(\Theta), \{f', \mathbf{p}'\})$ is the transition probability of resulting in state $\{f', \mathbf{p}'\}$ given that action $a(\Theta)$ was taken at state $\{f, \mathbf{p}\}$. Assuming that the robot does not affect or change the

objective function, the joint transition probability can be decomposed into the product of two independent transition functions:

$$\begin{aligned}
& T(\{f, \mathbf{p}\}, a(\Theta), \{f', \mathbf{p}'\}) \\
&= T_f(f, a(\Theta), f') T_{\mathbf{p}}(\mathbf{p}, a(\Theta), \mathbf{p}')
\end{aligned} \tag{9}$$

Since f is not affected by the actions in A , the transition function T_f is the identity.

$$T_f(f, a(\Theta), f') = \delta(f' - f). \tag{10}$$

The transition function $T_{\mathbf{p}}$ depends on the definition of the action space, and can often be modeled deterministically since robots can navigate with accurate positioning and path following controllers in many large-scale outdoor monitoring applications. When the action space is defined as a location, the action parameters Θ represent a location, and $T_{\mathbf{p}}$ can be calculated using

$$T_{\mathbf{p}}(\mathbf{p}, a(\Theta), \mathbf{p}') = \delta(\mathbf{p}' - \Theta) \tag{11}$$

- R : If the objective function f is sampled at Θ then the *expected* reward in an SBO POMDP belief state is the objective value w.r.t. beliefs $b(f)$ minus any application-specific action *cost* $\text{cost}(\mathbf{p}, \Theta)$ associated with moving from \mathbf{p} to Θ :

$$\text{ER}(\{f, \mathbf{p}\}, a(\Theta)) = \mathbb{E}_{b(f)}[f(\mathbf{x})] + \text{cost}(\mathbf{p}, a(\Theta)) \tag{12}$$

When the action space is parametrised as locations the reward can be evaluated directly. However, when the action space is parametrised by curves, the reward associated to an action is given by the sum of the rewards along the curve \mathcal{C} :

$$R(\{f, \mathbf{p}\}, \mathcal{C}(\Theta)) = \sum_{\mathbf{x} \in \mathcal{C}(\Theta)} R(\{f, \mathbf{p}\}, \mathcal{C}(\Theta)), \tag{13}$$

where the sum can be replaced by an integral when the sensing device allows continuous sampling along the curve.

- Z : In SBO, objective observations $z \in \mathbb{R}$ are simply noisy observations of $f(\Theta)$ as defined next.
- O : The observation function is defined according to the action space parametrisation. When the action space is defined as a sampling location Θ , f can be evaluated directly on Θ .

$$O(z, a(\Theta), \{f, \mathbf{p}\}) = p(z | f(\mathbf{x} = \Theta)) \tag{14}$$

We observe that for GPs, we can generate z by sampling from a GP marginal for f at location Θ . When the action space is a curve \mathcal{C} , f is evaluated at a number of sample locations within \mathcal{C} . The observation function for this set of observations $\{z_i\}$ is

$$O(\{z_i\}, \mathcal{C}(\Theta), \{f, \mathbf{p}\}) = \prod_{\mathbf{x}_i \in \mathcal{C}(\Theta)} p(z_i | f(\mathbf{x}_i)) \tag{15}$$

The belief is then the probability distribution over the space of functions f and updated as described in equation (3). If the model for f is a GP, the belief update for an action-observation pair can be computed directly. The action component can be ignored for purposes of updating a belief in f , since as stated earlier, the robot’s physical state does not affect or change the objective function, it only restricts the observations that can be made regarding f . Therefore, the belief update over f is simply computed by adding new location-observation pairs to the GP training data set.

Next, we present a methodology to solve this POMDP by sampling a subset of action primitives that the robot can execute in the environment. Action primitives and maximum likelihood observation selection are the key points to approximate Equation 8.

3.2 MCTS AND UCT FOR SBO

MCTS is a popular technique for solving large POMDPs [2, 18]. This method can turn a tedious search in decision trees into an efficient approximation using Monte-Carlo samples from the tree. MCTS efficiently searches reachable beliefs from a given initial belief state and is useful for real-time online planning. Its main advantage over other techniques, such as Point-Based Value Iteration is that it does not require the overhead of maintaining alpha-functions over all states nor choosing the states for which alpha-functions should be maintained.

[18] have shown how MCTS can reach impressive scalability through the use of UCT, which they call POMCP. In this work we conserve their idea of efficient tree search. However, we consider the case where the belief update is a GP update for f and use the maximum likelihood observation, as it is done by [13]. The maximum-likelihood observation assumption helps reducing the branching factor of the tree, which would grow uncontrollably when sampling observations.

For the SBO problem, each node in the tree consists of a belief representation for f and a side-state \mathbf{p} . We define the i th node by v_i . For each action-observation pair, the belief representation $b(f)$ and side state \mathbf{p} are updated easily since $b(f)$ is a GP prior and side-state transitions are deterministic and observable. Every new action-observation simulation creates a new node with the updated belief and side-state.

The tree is built incrementally starting with an initial node v_0 . Figure 2 shows an example of a small tree that has been expanded partially with two action primitives. Each ellipse represents a node, that consists of a belief over f , $b(f)$, and side-state \mathbf{p} . A node is expanded by simulating the outcomes of executing an action. The outcomes (noisy observations of f) are the maximum-likelihood observations. The branching factor of the tree will be the number of ac-

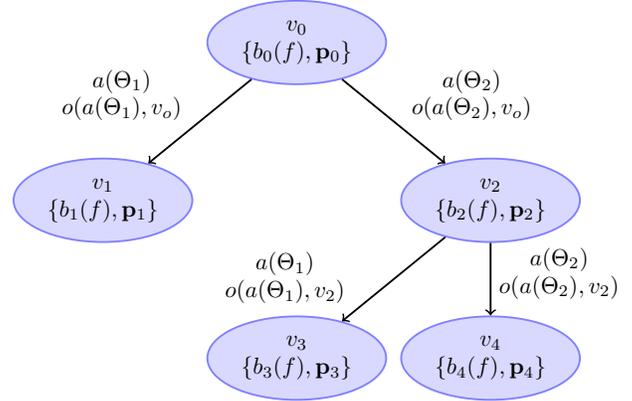

Figure 2: Example of a tree with depth 2, partially expanded from a set of two action primitives.

tion primitives. When a node is expanded, a new node is created using the updated belief and new side-state.

The first step in each iteration is to find a leaf node candidate for expansion/evaluation, which is done inside of the function TREEPOLICY. This search is guided by the function BESTCHILD, which uses the statistics stored for each node (accumulated reward and number of visitations) to select the most *promising* child. Starting from the chosen leaf node, a random action selection is conducted until the maximum depth is reached, executed within DEFAULTPOLICY. The total accumulated reward is then backed up in function BACKUP, that updates the statistics on all the nodes visited during the current iteration. Each iteration of the search algorithm simulates a sequence of up to n actions, where n is the maximum depth. When the iteration loop is completed, the best action is determined by picking the best child from the parent node v_0 . Algorithm 2 shows the full procedure for building a tree and returning the best immediate action.

4 EXPERIMENTS

In this section we present experiments where a robot attempts to learn the behaviour of a spatial-temporal process by choosing actions that maximise the expected reward. We show comparisons for two different problems, including one with time dependent behaviour.

For illustrative purposes we simulate 2D functions in space that can change with time, such that,

$$f : \quad \mathbb{R}^3 \quad \rightarrow \quad \mathbb{R} \\ (x_1, x_2, t) \rightarrow y.$$

In these experiments, the pose $\mathbf{p} = (x_{1r}, x_{2r}, \theta_r)$ of a robot is the side-state for the SBO formulation and f is the unknown function to be estimated. The belief $b(f)$ is represented by a GP using a separable space-time covariance function [19]. The structure of the GP’s covariance function can capture periodicity in f from the training data.

```

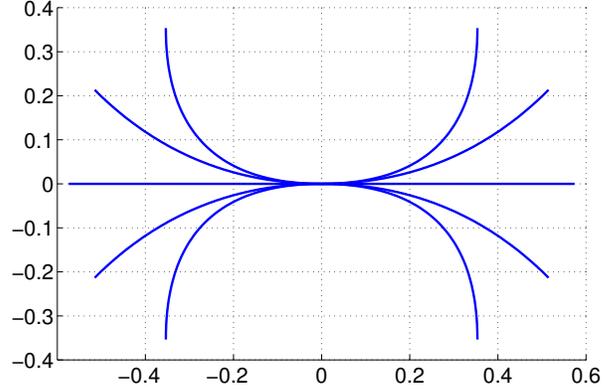

Figure 3: Motion primitives for a mobile robot. Axis in km.

Since the robot travels at a certain speed $\dot{\mathbf{p}}$, the reachable area for sampling f depends on the side-state \mathbf{p} .

The action space A is determined by a set of motion primitives parametrised as 2D cubic splines. A cubic spline \mathcal{C} is a continuous function mapping from \mathbb{R} to \mathbb{R}^2 , $\mathcal{C}(u|\Theta) = [\mathcal{C}_{x_1} \ \mathcal{C}_{x_2}]^T$, with $u \in [0, 1]$, defined as

$$\mathcal{C} = \Theta \begin{bmatrix} u^3 & u^2 & u^1 & 1 \end{bmatrix}^T, \quad (16)$$

where Θ are the parameters expressed as a 2×4 matrix for the 2D case. With appropriate parametrisation, the curves generate the ten primitives $A = \{\mathcal{C}_i\}_{i=1 \dots 10}$ shown in Figure 3 for $\mathbf{p} = \mathbf{p}_0 = (0, 0, 0)$. For values of $\mathbf{p} = (x_{1r}, x_{2r}, \theta_r)$ the curves are rotated and translated using translation and rotation matrices. We define a transition function $T_{\mathbf{p}}(\mathbf{p}, \mathcal{C}_i, \mathbf{p}') = 1$ for a cubic spline transformed from \mathbf{p} , with

$$\mathbf{p}' = \left(\mathcal{C}_i(u=1)_{x_1}, \mathcal{C}_i(u=1)_{x_2}, \frac{\partial \mathcal{C}_{x_1} / \partial u}{\partial \mathcal{C}_{x_2} / \partial u} \Big|_{u=1} \right). \quad (17)$$

Before an action (curve) is selected for execution, the robot computes the optimal action using the MCTS algorithm (Algorithm 2). The robot gathers noisy samples from f along \mathcal{C} while the action is being executed.

4.1 STATIC FUNCTION

In the first example, we simulate a static function, with expression

$$y = f(x_1, x_2, t) = e^{-(x_1-4)^2} e^{-(x_2-1)^2} + 0.8e^{-(x_1-1)^2} e^{-\left(\frac{x_2-4}{2.5}\right)^2} + 4e^{-\left(\frac{x_1-10}{5}\right)^2} e^{-\left(\frac{x_2-10}{5}\right)^2}, \quad (18)$$

where $x_1 \in [0, 5]$, $x_2 \in [0, 5]$, and $t \in [0, \infty]$. Figure 4 shows a plot for this function, where it is easy to distinguish two main peaks with different amplitudes. The robot is initially located at pose $\mathbf{p} = (0.5, 0.5, 0)$ and travels at a fixed speed of $0.2m/s$, gathering a sample every 5 minutes.

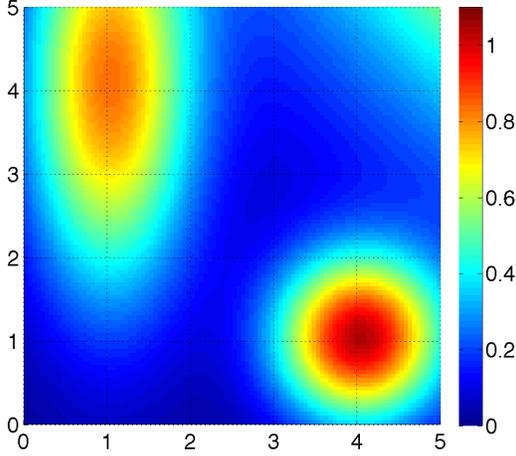

Figure 4: Static goal function. Axis in km.

We first want to evaluate how the definition of the reward function R within the POMDP context impacts the action selection properties of the algorithm. We compare four different reward functions based on the UCB acquisition function, $r(\mathbf{x}) = \mu(\mathbf{x}) + \kappa\sigma(\mathbf{x})$, where $\kappa_i \in \{1.0 \times 10^6, 200, 20, 10\}$. It is a well known fact that the value of κ affects the exploration-exploitation trade off and this is clearly reflected in the resulting paths followed by each robot, as shown in Figure 5. The most explorative path sequence corresponds to $\kappa = 1.0 \times 10^6$ (Figure 5a) and the least explorative is $\kappa = 10$ (Figure 5d). Between these two extremes there are intermediate solutions where exploitation is favoured more strongly for lower values of κ .

In the next experiment we focus on the depth of the action selection search, i.e. the number n of lookahead steps for decision making. This corresponds to the maximum depth allowed in the search tree. We first evaluated the entire decision tree, which means simulating all the possible combinations of actions. This approach, which we call *Full Tree* (FT) strategy, will need $|A|^n$ simulations which becomes impractical quickly. In fact, for this paper we only consider FT strategies with $n \leq 3$. We compare the performance of FT against MCTS (Algorithm 2) where the number of simulations is a parameter. Clearly, for a same depth, MCTS is bounded by FT, however MCTS can find near-optimal solutions much faster. For this reason we were able to experiment with depths up to $n \leq 5$. We compare six different combinations of depth and algorithm type as indicated in Table 1.

The reward function used for these simulations was $r(\mathbf{x}) = \mu(\mathbf{x}) + 1.0 \times 10^6 \sigma(\mathbf{x})$ for all cases. Therefore, the only difference in action selection is due to the number of lookahead steps. Figure 6 shows the paths followed by the robot at $t = 2.3$ days, when it had already gathered 616 samples from f . This figure does not show all cases, only the four most relevant ones. It is interesting to observe that

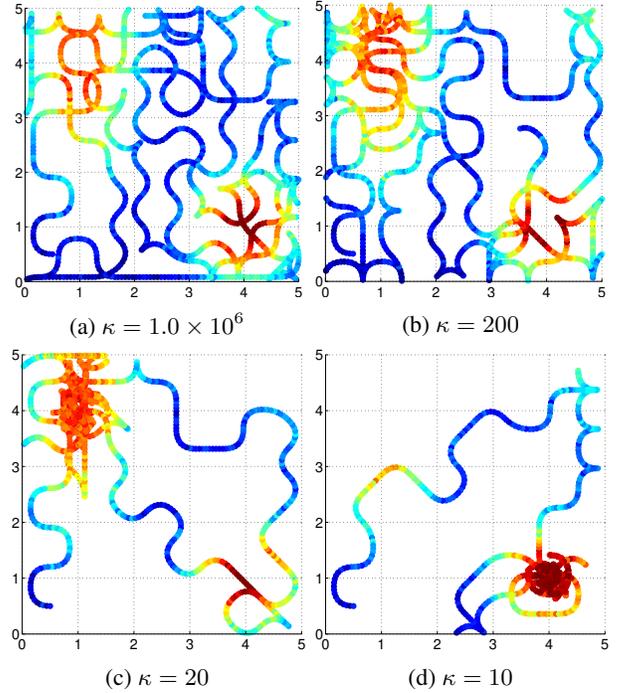

Figure 5: Comparison of followed paths for purely exploration behaviour using Full Tree and MCTS-UCT. Axis in km. Colour scale represents the value of sampled values.

Table 1: Experiment for Depth and Algorithm Type Comparison

Id	Algorithm	Max Depth	Iterations
1	FT	1	10
2	FT	2	110
3	FT	3	1110
4	MCTS	3	100
5	MCTS	4	150
6	MCTS	5	400

the search with FT Depth 1 (Figure 6a) has not achieved a full coverage of the area and is highly susceptible to get trapped and collide into the edges of the domain, which is clearly sub-optimal from an exploration point of view. On the other hand, the FT Depth 2 shows increased coverage capability, which is improved further for deeper search strategies. FT Depth 3 and MCTS Depth 3 show similar result, with the clear advantage that MCTS requires only 10% of the number of simulations of FT.

We also compare the accumulated reward over time for each case in Figure 7. This illustrates the advantage of using a multi-step lookahead strategy in increasing the total accumulated reward. However, it is not clear the advantage of using higher depths than two, as they do not show a clear improvement in accumulated reward. The main rea-

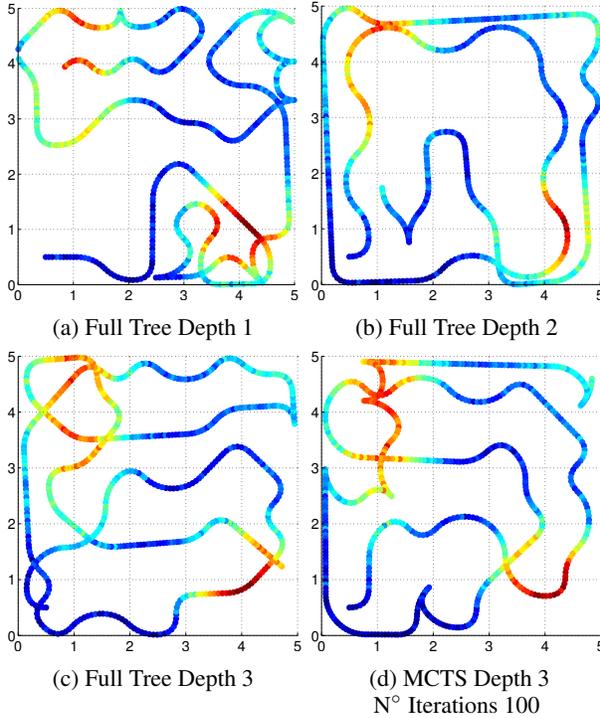

Figure 6: Comparison of paths for purely exploration behaviour using FT and MCTS-UCT. Axis in km. Colour scale represents the value of samples.

son behind this is that f does not change over time, thus making the problem simple enough such that any strategy with depth greater than 1 would be very close to the optimal solution.

4.2 DYNAMIC FUNCTION

In this second experiment we use a more complex function that changes over time,

$$y = f(x_1, x_2, t) = e^{-\left(\frac{x_1-2-f_1(t)}{0.7}\right)^2} e^{-\left(\frac{x_2-2-f_2(t)}{0.7}\right)^2}, \quad (19)$$

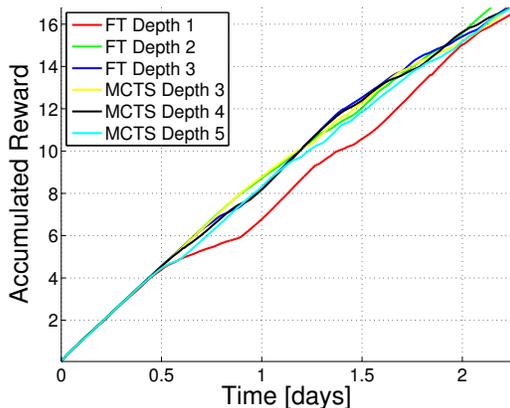

Figure 7: Accumulated reward for static goal function.

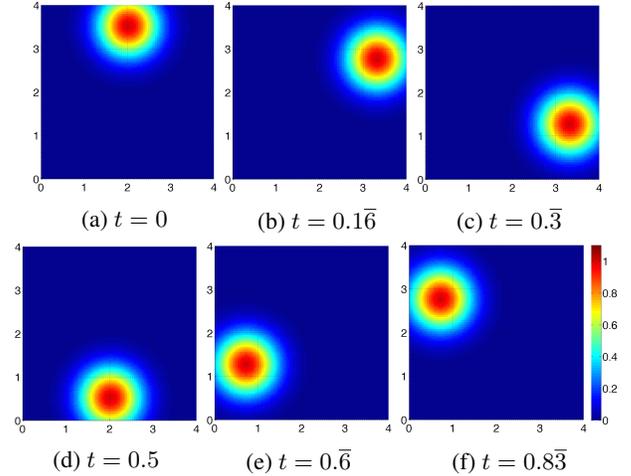

Figure 8: Dynamic goal function within one period. Axis in km.

with $f_1(t) = 1.5 \sin(2\pi t)$, $f_2(t) = 1.5 \cos(2\pi t)$, $x_1 \in [0, 5]$, $x_2 \in [0, 5]$, and $t \in [0, \infty]$. This expression generates a function where the peak moves over time. The peak circles clockwise around $(x_1, x_2) = (2, 2)$ periodically, with a period of 1 day. The motivation for this example comes from air pollution monitoring tasks where we are interested in following peaks of pollution through time while learning how the entire process evolves in space-time. Figure 8 shows the goal function for 6 time steps within one period.

Similarly to the previous experiment, the robot is initially located at pose $\mathbf{p} = (0.5, 0.5, 0)$, travels at a fixed speed of 0.12m/s and gathers a sample every 15 minutes. The goal in this experiment is to find and follow the maximum of f over time. Therefore, we select the reward function $r(\mathbf{x}) = \mu(\mathbf{x}) + 10\sigma(\mathbf{x})$, which according to Figure 5, should generate paths concentrated over the maximum values of f . Ideally, the robot should learn to follow the peak through time which would be possible for speeds greater than 0.109m/s . We try the same set of depth-algorithm pairs as in Section 4.1 and detailed in Table 1. We only show results for the extreme cases with the purpose of avoiding clutter in the figures.

Figure 9 illustrates the advantage of using multi-step lookahead strategies. The first row shows paths for FT Depth 1, where it can be seen that the robot does not learn how to follow the peak around a circle within 15 days. The second row, MCTS Depth 2, which only does 15 more simulations per iteration than FT Depth 1, the robot is already able to learn the circular pattern at $t = 12$ days. With deeper search strategies, the time required to learn the pattern decreases significantly indicating a better exploration and exploitation solution. In fact, for MCTS Depth 5 the pattern is learnt in $t = 8$ days.

Figure 10 shows the benefits of using non-myopic strategies for action selection. The cumulative reward is clearly

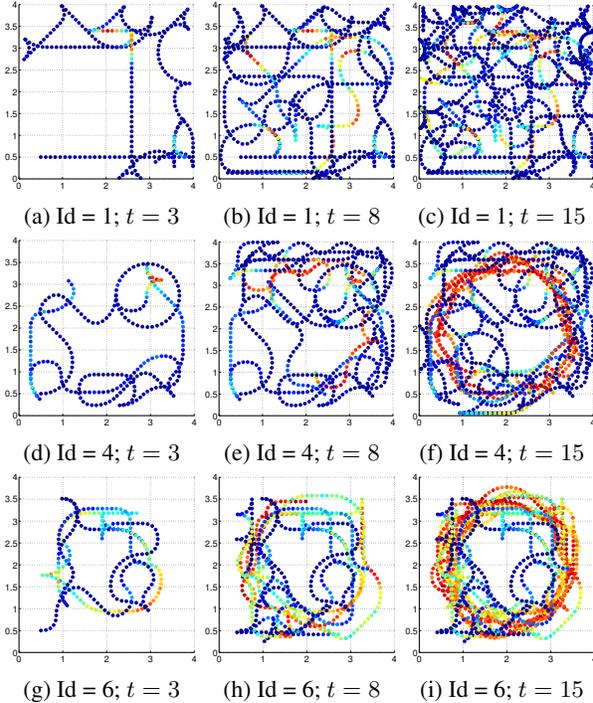

Figure 9: Comparison of followed paths for FT and MCTS-UCT in a dynamic function. First row shows the paths for FT, Depth 1; Second row shows the paths for MCTS, Depth 2; Third row shows the paths for MCTS, Depth 5. Colour scale represents the value of samples.

larger for multi-step lookahead decision making algorithms. The best solution is MCTS Depth 5, that is clearly superior for the entire duration of the simulation. A steeper slope for accumulated reward indicates that a method has learnt how to follow the peak. Then from this plot it is also clear that FT Depth 1 is not able to capture space-time dependencies properly.

It is important also to compare FT Depth 2 with MCTS Depth 2. The fact that FT is an upper bound for MCTS Depth 2 can be confirmed from Figure 10. In addition, it can be seen that both strategies accumulate similar rewards, which is a good indication that MCTS will approximate the FT solution, even with only 25% of the total tree.

Finally, Figure 11 shows how MCTS prioritises the search over promising paths. The pose of the robot at this instant is $\mathbf{p} = (1.5, 3, 0)$. Red paths are result of the function DEFAULTPOLICY that did not get further explored and blue paths are the paths present in the tree. In can be seen how the tree automatically grows towards potentially informative areas, i.e. where the reward is higher. The green curve is the best branch of the tree.

5 CONCLUSION

In this paper we proposed formulating the sequential BO problem as a POMDP. Our main contribution was to de-

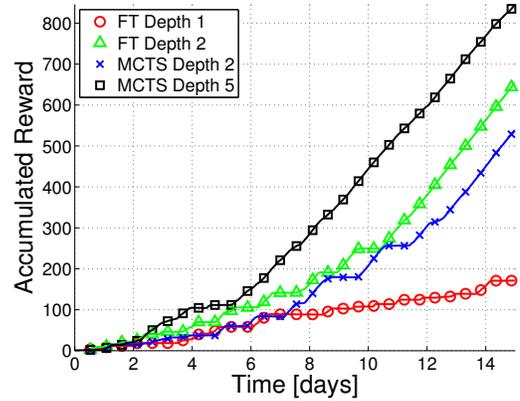

Figure 10: Accumulated reward for dynamic goal function.

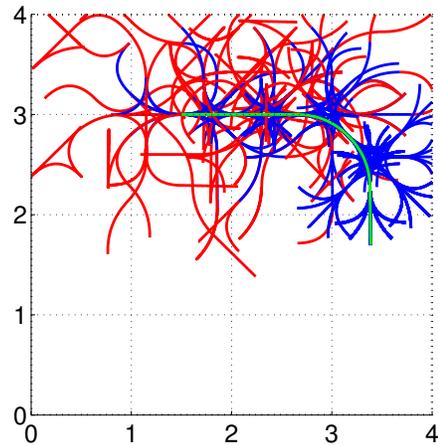

Figure 11: Example of tree built for MCTS Depth 5.

termine a non-myopic decision making solution that maximises reward and takes into account the belief of an unknown space time process and the state of a mobile robot acting as a sensor. We formulated the solution for the POMDP analogue of SBO using a modified version of the UCT algorithm for MCTS, which is a scalable and efficient way of finding asymptotically optimal decisions.

We demonstrate empirically the advantage of using non-myopic planning solutions, which becomes especially important when the objective function dynamically changes over time.

Even though long-term decision-making under uncertainty is a very complex problem, we solved it using a scalable method that works for realistic scenarios with state-dependent restrictions and time variation. We believe that using multi-step lookahead path planning is a convenient and practical way for solving many robotic problems requiring the accurate representation of real space-time phenomena, such as environment monitoring.

Abstract

Marginal MAP problems are known to be very difficult tasks for graphical models and are so far solved exactly by systematic search guided by a join-tree upper bound. In this paper, we develop new AND/OR branch and bound algorithms for marginal MAP that use heuristics extracted from weighted mini-buckets enhanced with message-passing updates. We demonstrate the effectiveness of the resulting search algorithms against previous join-tree based approaches, which we also extend to accommodate high induced width models, through extensive empirical evaluations. Our results show not only orders-of-magnitude improvements over the state-of-the-art, but also the ability to solve problem instances well beyond the reach of previous approaches.

1 INTRODUCTION

Graphical models provide a powerful framework for reasoning with probabilistic and deterministic information. These models use graphs to capture conditional independencies between variables, allowing a concise representation of knowledge as well as efficient graph-based query processing algorithms. Combinatorial maximization or maximum *a posteriori* (MAP) tasks arise in many applications and often can be efficiently solved by search schemes.

The marginal MAP problem distinguishes between maximization variables (called MAP variables) and summation variables (the others). Marginal MAP is NP^{PP} -complete [1]; it is difficult not only because the search space is exponential in the number of MAP variables, but also because evaluating the probability of any full instantiation of the MAP variables is PP-complete [2]. Algorithmically, this means that the variable elimination operations (max and sum) are applied in a constrained, often more costly order.

State-of-the-art exact algorithms for marginal MAP are

typically based on depth-first branch and bound search. A key component of branch and bound search is the heuristic function; while partitioning based heuristics such as *mini-bucket elimination* (MBE) [3] or *mini-cluster-tree elimination* (MCTE) [4, 5] can be applied to the constrained elimination order, the current state-of-the-art is to use a heuristic based on an *exact* solution to an *unconstrained* ordering, introduced by Park and Darwiche [6] and then refined by Yuan and Hansen [7]. These techniques appear to work well when the unconstrained ordering results in a small *induced width*. However, in many situations this is a serious limitation. As one contribution, we extend both algorithms to use mini-bucket partitionings schemes, enabling them to be applied to a wider variety of problem instances.

Importantly however, exact algorithms for pure max- or sum-inference problems have greatly improved in recent years. AND/OR branch and bound (AOBB) algorithms explore a significantly smaller search space, exploiting problem structure far more effectively [8]. The partition-based heuristics used by AOBB have also seen significant improvements – for MAP, cost-shifting [9] can be used to tighten the heuristic, while for summation, an extension of MBE called *weighted mini-bucket* (WMB) [10] uses Hölder’s inequality and cost-shifting to significantly enhance the likelihood bounds. WMB is closely related to variational bounds such as tree-reweighted belief propagation [11] and conditional entropy decompositions [12], and similar principles have also been used recently to develop message-passing approximations for marginal MAP [13].

Our contributions. In this paper, we develop AND/OR branch and bound search for marginal MAP, using a heuristic created by extending weighted mini-bucket to the constrained elimination order of marginal MAP. We evaluate both a single-pass heuristic, which uses cost-shifting by moment matching (WMB-MM) during construction, and an iterative version that passes messages on the corresponding join-graph (WMB-JG). We show empirically that the new heuristic functions almost always improve over standard mini-bucket, and in many cases give tighter bounds and faster searches than the unconstrained join-tree meth-

ods, yielding far more empowered search algorithms.

We demonstrate the effectiveness of the proposed search algorithms against the two previous methods at solving a variety of problem instances derived from the recent PASCAL2 Inference Challenge benchmarks. Our results show not only orders of magnitude improvements over the current state-of-the-art approaches but also the ability to solve many instances that could not be solved before.

Following background and brief overview of earlier work (Sections 2 and 3), Section 4 presents the AND/OR search approach for marginal MAP. Section 5 describes the weighted mini-bucket schemes, Section 6 is dedicated to our empirical evaluation and Section 7 concludes.

2 BACKGROUND

A *graphical model* is a tuple $\mathcal{M} = \langle \mathbf{X}, \mathbf{D}, \mathbf{F} \rangle$, where $\mathbf{X} = \{X_i : i \in V\}$ is a set of variables indexed by set V and $\mathbf{D} = \{D_i : i \in V\}$ is the set of their finite domains of values. $\mathbf{F} = \{\psi_\alpha : \alpha \in F\}$ is a set of discrete positive real-valued local functions defined on subsets of variables, where we use $\alpha \subseteq V$ and $\mathbf{X}_\alpha \subseteq \mathbf{X}$ to indicate the *scope* of function ψ_α , ie, $\mathbf{X}_\alpha = \text{var}(\psi_\alpha) = \{X_i : i \in \alpha\}$. The function scopes imply a *primal graph* whose vertices are the variables and which includes an edge connecting any two variables that appear in the scope of the same function. The graphical model \mathcal{M} defines a factorized probability distribution on \mathbf{X} , $P(\mathbf{X}) = \frac{1}{Z} \prod_{\alpha \in F} \psi_\alpha$. The *partition function*, Z , normalizes the probability to sum to one.

Let \mathbf{X}_S be a subset of \mathbf{X} and $\mathbf{X}_M = \mathbf{X} \setminus \mathbf{X}_S$ be the complement of \mathbf{X}_S . The *Marginal MAP* problem is to find the assignment x_M^* to variables \mathbf{X}_M that maximizes the value of the marginal distribution after summing out variables \mathbf{X}_S :

$$x_M^* = \operatorname{argmax}_{\mathbf{X}_M} \sum_{\mathbf{X}_S} \prod_{\alpha \in F} \psi_\alpha \quad (1)$$

We call \mathbf{X}_M “MAP variables”, and \mathbf{X}_S “sum variables”.

If $\mathbf{X}_S = \emptyset$ then the problem is also known as maximum *a posteriori* (MAP) inference. The marginal MAP problem is however significantly more difficult. The decision problem for marginal MAP was shown to be NP^{PP}-complete [1], while the decision problem for MAP is only NP-complete [14]. The main difficulty arises because the max and sum operators in Eq. (1) do not commute, which restricts efficient elimination orders to those in which all sum variables \mathbf{X}_S are eliminated before any max variables \mathbf{X}_M .

Bucket Elimination (BE) [15] solves the marginal MAP problem exactly by eliminating the variables in sequence. Given a *constrained elimination order* ensuring the sum variables are processed before the max variables, BE partitions the functions into buckets, each associated with a single variable. A function is placed in the bucket of its

argument that appears latest in the ordering. BE processes each bucket, from last to first, by multiplying all functions in the current bucket and eliminating the bucket’s variable (by summation for sum variables and by maximization for MAP variables), resulting in a new function which is placed in an earlier bucket. The complexity of BE is time and space exponential in the *constrained induced width* w_c^* of the primal graph given a constrained elimination order [15]. BE can be viewed as message passing in a join-tree whose nodes correspond to buckets and which connects nodes a, b if the function generated by a ’s bucket is placed in b ’s [16].

Mini-Bucket Elimination (MBE) [3] is an approximation algorithm designed to avoid the space and time complexity of full bucket elimination by partitioning large buckets into smaller subsets, called *mini-buckets*, each containing at most i (called i -bound) distinct variables. The mini-buckets are processed separately [3]. MBE processes sum buckets and the max buckets differently. Max mini-buckets (in \mathbf{X}_M) are eliminated by maximization, while for variables in \mathbf{X}_S , one (arbitrarily selected) mini-bucket is eliminated by summation, while the rest of the mini-bucket are eliminated by maximization. MBE outputs an upper bound on the optimal marginal MAP value. The complexity of the algorithm, which is parametrized by the i -bound, is time and space exponential in i only. When i is large enough (i.e., $i > w_c^*$), MBE coincides with full BE. MBE is often used to generate heuristics for branch and bound search.

Another related approximation with bounded complexity, more similar in structure to join-tree inference, is *Mini-Cluster-Tree Elimination* (MCTE) [5]. In MCTE, we pass messages along the structure of the join-tree, except that when computing a message, rather than combining all the functions in the cluster, we first partition it into mini-clusters, such that each mini-cluster has a bounded number of variables (the i -bound). Each mini-cluster is then processed separately to compute a set of outgoing messages. Like MBE, this procedure produces an upper bound on the results of exact inference, and increasing i typically provides tighter bounds, but at higher computational cost. Thus, both MBE and MCTE allow the user to trade upper bound accuracy for time and space complexity.

3 CURRENT SEARCH METHODS

The current state-of-the-art methods for marginal MAP are based on branch and bound search using specialized heuristics. In particular, Park and Darwiche [6] construct an upper bound on each subproblem using a modified join-tree algorithm along an *unconstrained* elimination order that interleaves the MAP and sum variables. During search, the join-tree is fully re-evaluated at each node in order to compute upper bounds for all uninstantiated MAP variables simultaneously, which allows the use of dynamic variable ordering. Although this approach provides effective bounds,

Algorithm 1: BBT for marginal MAP

Input: Graphical model $\mathcal{M} = \langle \mathbf{X}, \mathbf{D}, \mathbf{F} \rangle$, i -bound i , unassigned MAP variables \mathbf{X}_M , lower bound L , partial assignment to MAP variables \bar{x}

Output: Optimal marginal MAP value

```

1 if  $\mathbf{X}_M = \emptyset$  then
2    $\perp$  return  $\text{Solve}(\mathcal{M}|_{\bar{x}})$ ;
3 else
4    $X_k \leftarrow \text{SelectVar}(\mathbf{X}_M)$ ;
5   Update  $\text{MCTE}(i)$ ;
6   foreach value  $x_k \in D_k$  do
7     Assign  $X_k$  to  $x_k$ :  $\bar{x} \leftarrow \bar{x} \cup \{X_k = x_k\}$ ;
8      $U(\bar{x}) \leftarrow \text{extract}(\text{MCTE}(i))$ 
9     if  $U(\bar{x}) > L$  then
10       $\perp$   $L = \max(L, \text{BBT}(i, \mathbf{X}_M \setminus \{X_k\}, L, \bar{x})$ ;
11       $\bar{x} \leftarrow \bar{x} \cup \{X_k = x_k\}$ ;
12 return  $L$ ;
```

the computation can be quite expensive. More recently, Yuan and Hansen [7] proposed an incremental evaluation of the join-tree bounds which reduces significantly their computational overhead during search. However, this requires the search algorithm to follow a static variable ordering. In practice, Yuan and Hansen’s method proved to be cost effective, considerably outperforming [6]. However, both methods require that the induced width of the unconstrained join tree is small enough to be feasible, which often may not be the case.

3.1 ALGORITHM BBT

Our first two algorithms, then, can be viewed as generalizations of [6] and [7] schemes for models with high unconstrained induced width. In particular, we use $\text{MCTE}(i)$ to approximate the exact, unconstrained join-tree inference to accommodate a maximum clique size defined by the i -bound i . The resulting branch and bound with $\text{MCTE}(i)$ heuristics, abbreviated hereafter by BBT^1 , for marginal MAP is given in Algorithm 1.

The algorithm is called initially as $\text{BBT}(i, \mathbf{X}_M, 0, \emptyset)$, where \mathbf{X}_M are the MAP variables of the input graphical model, and i is the i -bound. The algorithm maintains the best solution found so far, giving a lower bound L on the optimal marginal MAP value. The algorithm searches the simple tree of all partial variable assignments (also called the OR tree). At each step, BBT uses $\text{MCTE}(i)$ to compute an upper bound $U(\bar{x})$ on the optimal marginal MAP extension of the current partial MAP assignment \bar{x} (lines 5-8). If $U(\bar{x}) \leq L$, then the current assignment \bar{x} cannot lead to a better solution and the algorithm can backtrack (line 9). Otherwise, BBT expands the current assignment by selecting the next MAP variable in a static or dynamic

¹For consistency with prior work, we use the name used in [17], (Branch and Bound with Bucket-Tree heuristic) to denote the same algorithm applied to pure MAP queries.

variable ordering (line 4) and recursively solves a set of subproblems, one for each un-pruned domain value. Notice that when \bar{x} is a complete assignment, BBT calculates its marginal MAP value by solving a summation task over $\mathcal{M}|_{\bar{x}}$, the subproblem defined by the sum variables conditioned on \bar{x} (line 2). Given sufficient resources (high enough i -bound), this can be done by variable elimination, but for consistency with our other algorithms, our implementation uses AND/OR search with caching [18] (see also Section 4). If a better new assignment is found then the lower bound L is updated (line 10).

If $\text{MCTE}(i)$ is fully re-evaluated at each iteration, it produces upper bounds for all uninstantiated MAP variables simultaneously. In this case, BBT can accommodate dynamic variable orderings and can thus be viewed as a generalization of Park and Darwiche [6]. Alternatively, $\text{MCTE}(i)$ can be done in an incremental manner as in [7]. In this case BBT requires a static variable ordering and can be viewed as a generalization of Yuan and Hansen.

4 AND/OR SEARCH

Significant improvements in search for pure MAP inference have been achieved by using AND/OR search spaces, which often capture problem structure far better than standard OR search methods [18]. In this section, we give an AND/OR search algorithm for marginal MAP. First, we define the *pseudo tree* of the primal graph, which defines the search space and captures problem decomposition.

DEFINITION 1 (pseudo tree) A pseudo tree of an undirected graph $G = (V, E)$ is a directed rooted tree $\mathcal{T} = (V, E')$ such that every arc of G not included in E' is a back-arc in \mathcal{T} , namely it connects a node in \mathcal{T} to one of its ancestors. The arcs in E' may not all be included in E .

The set of valid pseudo trees for marginal MAP is restricted to those for which the MAP variables form a *start pseudo tree*, a subgraph of pseudo tree \mathcal{T} that has the same root as \mathcal{T} . Given a graphical model $\mathcal{M} = \langle \mathbf{X}, \mathbf{D}, \mathbf{F} \rangle$ with primal graph G and pseudo tree \mathcal{T} of G , the AND/OR search tree $S_{\mathcal{T}}$ based on \mathcal{T} has alternating levels of OR nodes corresponding to the variables and AND nodes corresponding to the values of the OR parent’s variable, with edges weighted according to \mathbf{F} . Identical subproblems, identified by their *context* (the partial instantiation that separates the subproblem from the rest of the problem graph), can be merged, yielding an AND/OR search graph [18]. Merging all context-mergeable nodes yields the *context minimal AND/OR search graph*, denoted $C_{\mathcal{T}}$. The size of $C_{\mathcal{T}}$ is exponential in the induced width of G along a depth-first traversal of \mathcal{T} (i.e., the constrained induced width) [18].

A *solution tree* \hat{x} of $C_{\mathcal{T}}$ is a subtree that: (1) contains the root of $C_{\mathcal{T}}$; (2) if an internal OR node $n \in C_{\mathcal{T}}$ is in \hat{x} , then n is labeled by a MAP variable and exactly one of its

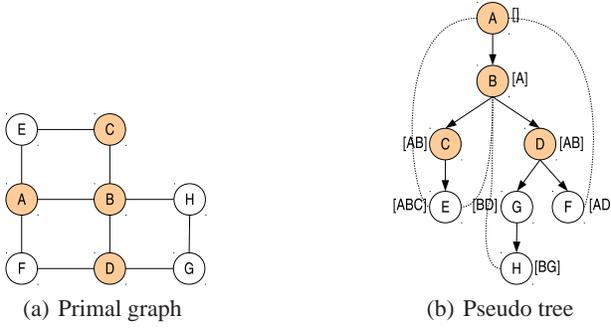

Figure 1: A simple graphical model.

children is in \hat{x} ; (3) if an internal AND node $n \in C_{\mathcal{T}}$ is in \hat{x} then all its OR children labeled by MAP variables are in \hat{x} .

Each node n in $C_{\mathcal{T}}$ can be associated with a value $v(n)$; for MAP variables, $v(n)$ captures the optimal marginal MAP value of the conditioned subproblem rooted at n , while for sum variables it is the conditional likelihood of the subproblem. Clearly, $v(n)$ can be computed recursively based on the values of n 's successors: OR nodes by maximization or summation (for MAP or sum variables, respectively), and AND nodes by multiplication.

Example 1 Figure 1(a) shows a simple graphical model with $\mathbf{X}_M = \{A, B, C, D\}$ and $\mathbf{X}_S = \{E, F, G, H\}$. Figure 2 displays the context minimal AND/OR search graph based on the constrained pseudo tree from Figure 1(b) (the contexts are shown next to the pseudo tree nodes). It is easy to see that the MAP variables form a start pseudo tree. A solution tree corresponding to the MAP assignment ($A = 0, B = 1, C = 1, D = 0$) is indicated in red.

Algorithm 2 describes the AND/OR Branch and Bound (AOBB) for marginal MAP. We use the notation that \bar{x} is the current partial solution and the table *Cache*, indexed by node contexts, holds the partial search results. The algorithm assumes that variables are selected statically according to a valid pseudo tree \mathcal{T} . A heuristic $f(\bar{x})$ calculates an upper bound on the optimal marginal MAP extension of \bar{x} .

If the set \mathbf{X} is empty, the result is trivially computed (line 1). Else, AOBB selects the next variable X_k in \mathcal{T} and if the corresponding OR node is not found in cache, it expands it and iterates over its domain values to compute the OR value $v(X_k)$ (lines 7-22). Notice that if X_k is a MAP variable, then AOBB attempts to prune unpromising domain values by comparing the upper bound $f(\bar{x})$ of the current partial solution tree \bar{x} to the current best lower bound L which is maintained by the root node of the search space (line 10). For each domain value x_k , the problem rooted at AND node $\langle X_k, x_k \rangle$ is decomposed into q independent subproblems $\mathcal{M}_l = \langle \mathbf{X}_l, \mathbf{D}_l, \mathbf{F}_l \rangle$, one for each child X_l of X_k in \mathcal{T} . These problems are then solved independently and their results accumulated by the AND node value $v(X_k, x_k)$ (lines 12-13 and 18-19). After trying all

```

possible values of variable X_k , the marginal MAP value of the subproblem rooted by X_k is $v(X_k)$ if X_k is a MAP variable, and is returned (line 21). If X_k is a sum variable, then $v(X_k)$ holds the likelihood value of that conditioned subproblem (line 22). The optimal marginal MAP value to the original problem is returned by the root node.

AOBB typically computes its heuristic $f(\cdot)$ using a mini-bucket bounding scheme (see Section 2), which can be pre-compiled along the reverse order of a depth-first traversal of the pseudo tree (which is a valid constrained elimination order). Unfortunately, our AOBB cannot use the joint-tree/MCTE(i) based heuristics of Section 3, since these are compiled along an unconstrained variable ordering which

is not compatible, in general, with the constrained pseudo tree that drives the AOBB search order. For this reason, we next turn to improving our mini-bucket bounds.

5 MINI-BUCKET FOR MARGINAL MAP

In this section, we develop improved, constrained order mini-bucket bounds compatible with AOBB search. MBE has been effective for pure MAP, but less so for marginal MAP; previously, its bounds appeared to be far less accurate than the unconstrained join-tree bounds [6, 7]. Therefore, we revisit the mini-bucket approach and enhance it with recent iterative cost-shifting schemes [10, 9, 13].

5.1 WEIGHTED MINI-BUCKETS

Weighted mini-bucket elimination (WMB) [10] is a recent algorithm developed for likelihood (summation) tasks that replaces the naïve mini-bucket bound with Hölder’s inequality. For a given variable X_k , the mini-buckets Q_{kr} associated with X_k are assigned a non-negative *weight* $w_{kr} \geq 0$, such that $\sum_r w_{kr} = 1$. Then, each mini-bucket r is eliminated using a weighted or power sum, $(\sum_{X_k} f(X)^{1/w_{kr}})^{w_{kr}}$. It is useful to note that w_{kr} can be interpreted as a “temperature”; if $w_{kr} = 1$, it corresponds to a standard summation, while if $w_{kr} \rightarrow 0$, it instead corresponds to a maximization over X_k . Thus, standard mini-bucket corresponds to choosing one mini-bucket r with $w_{kr} = 1$, and the rest with weight zero.

Weighted mini-bucket is closely related to variational bounds on the likelihood, such as conditional entropy decompositions [12] and tree-reweighted belief propagation (TRBP) [11]. The single-pass algorithm of Liu and Ihler [10] mirrors standard mini-bucket, except that within each bucket a cost-shifting (or reparameterization) operator is performed, which matches the marginal beliefs (or “moments”) across mini-buckets to improve the bound.

The temperature viewpoint of the weights enables us to apply a similar procedure for marginal MAP. In particular, for $X_k \in \mathbf{X}_S$, we enforce $\sum_r w_{kr} = 1$, while for $X_k \in \mathbf{X}_M$, we take $\sum_r w_{kr} = 0$ (so that $w_{kr} = 0$ for all r). The resulting algorithm, listed in Algorithm 3, treats MAP and sum variables differently: for sum variables it mirrors [10], while taking the zero-temperature limit for MAP variables we obtain the max-marginal matching operations described for pure MAP problems in [9]. This mirrors the result of Weiss et al. [19], that the linear programming relaxation for MAP corresponds to a zero-temperature limit of TRBP.

5.2 ITERATIVE UPDATES

While the single-pass algorithm is often very effective, we can further improve it using iterative updates. The iterative weighted mini-bucket algorithm [10], alternates be-

Algorithm 3: WMB-MM(i)

Input: Graphical model $\mathcal{M} = \langle \mathbf{X}, \mathbf{D}, \mathbf{F} \rangle$, MAP variables \mathbf{X}_M , constrained ordering $o = X_1, \dots, X_n$, i -bound i

Output: Upper bound on optimal marginal MAP value

```

1 foreach  $k \leftarrow n$  downto 1 do
  // Create bucket  $\mathbf{B}_k$  and mini-buckets  $Q_{kr}$ 
2  $\mathbf{B}_k \leftarrow \{\psi_\alpha | \psi_\alpha \in \mathbf{F}, X_k \in \text{var}(\psi_\alpha)\}; \mathbf{F} \leftarrow \mathbf{F} \setminus \mathbf{B}_k;$ 
3 Let  $\mathcal{Q} = \{Q_{k1}, \dots, Q_{kR}\}$  be an  $i$ -partition of  $\mathbf{B}_k$ ;
4 foreach  $r = 1$  to  $R$  do
5    $\psi_{kr} = \prod_{\psi \in Q_{kr}} \psi; \mathbf{Y}_r = \text{vars}(Q_{kr}) \setminus X_k;$ 
  // Moment Matching
6 if  $X_k \in \mathbf{X}_S$  then
7   Assign mini-bucket  $r$  weight  $w_{kr} > 0$ , st  $\sum_r w_{kr} = 1$ ;
8    $\mu_r = \sum_{\mathbf{Y}_r} (\psi_{kr})^{1/w_{kr}}; \mu = \prod_r (\mu_r)^{w_{kr}};$ 
9   Update  $\psi_{kr} = \psi_{kr} \cdot \left(\frac{\mu}{\mu_r}\right)^{w_{kr}};$ 
10 else
11    $\mu_r = \max_{\mathbf{Y}_r} \psi_{kr}; \mu = \left(\prod_r \mu_r\right)^{1/R};$ 
12   Update  $\psi_{kr} = \psi_{kr} \cdot \left(\frac{\mu}{\mu_r}\right);$ 
  // Downward Messages (eliminate  $X_k$ )
13 foreach  $r = 1$  to  $R$  do
14   if  $X_k \in \mathbf{X}_S$  then  $\lambda_{kr} \leftarrow \left(\sum_{X_k} (\psi_{kr})^{1/w_{kr}}\right)^{w_{kr}};$ 
15   else  $\lambda_{kr} \leftarrow \max_{X_k} \psi_{kr};$ 
16    $\mathbf{F} \leftarrow \mathbf{F} \cup \{\lambda_{kr}\};$ 
17 return  $\prod_{\psi \in \mathbf{F}} \psi$ 

```

tween downward passes, which look like standard mini-bucket with cost-shifting, and upward passes, which compute messages used to “focus” the cost shifting in the next downward pass. The algorithm can be viewed as message passing on a join graph defined by the mini-bucket cliques, and is listed in Algorithm 4.

Standard MBE computes “downward” messages $\lambda_{kr} = m_{a \rightarrow c}$ from each clique $a = (kr)$ (the r th mini-bucket for variable X_k) to a single child clique $c = \text{ch}(a)$. For the iterative version, we also compute “upward” messages $m_{c \rightarrow a}$ from clique c to its parent cliques $a \in \text{pa}(c)$. For $w_a > 0, w_c > 0$, these upward messages are given by [10]:

$$m_{c \rightarrow a} \propto \left[\sum_{Y_c \setminus Y_a} (\psi_c m_{\sim c})^{1/w_c} m_{a \rightarrow c}^{-1/w_a} \right]^{w_a}$$

where $\psi_c = \prod_{\psi \in Q_c} \psi$ are the model factors assigned to clique c , and $m_{\sim c}$ is the product of all messages into c .

These upward messages are used during the cost-shifting updates of X_k in later downward passes:

$$\forall r, \mu_{kr} \propto \sum_{Y_{kr}} (\psi_{kr} m_{\sim kr})^{1/w_{kr}}; \quad \mu = \left(\prod_r (\mu_{kr})^{w_{kr}} \right)^{1/w_k}$$

$$\forall r, \psi_{kr} \leftarrow \psi_{kr} \left(\frac{\mu}{\mu_{kr}} \right)^{\gamma w_{kr}}$$

in which we include the upward message $m_{\text{ch}(kr) \rightarrow kr}$ in the marginals μ_{kr} being matched, and define $w_k = \sum_r w_{kr}$. These fixed-point updates are not guaranteed to be monotonic; to assist convergence, we also include a “step size”

$\gamma \leq 1$. By initializing the upward messages $m_{\text{ch}(c) \rightarrow c} = 1$ and taking $\gamma = 1/t$, the first iteration of Alg. 4 corresponds exactly to WMB-MM (Alg. 3).

For marginal MAP, we can take the limit as some weights $w_a = \epsilon \rightarrow 0$; then, when both a and $c = \text{ch}(a)$ correspond to MAP variables we have

$$m_{c \rightarrow a} \propto \left[\max_{Y_c \setminus Y_a} (\psi_c m_{\sim c}) m_{a \rightarrow c}^{-1} \right]$$

$$\mu_a = \max_{Y_a} (\psi_a m_{\sim a}); \quad \mu = \left(\prod_a \mu_a \right)^{\frac{1}{|\mathcal{Q}|}}; \quad \psi_a \leftarrow \psi_a \left(\frac{\mu}{\mu_a} \right)^\gamma$$

When clique a corresponds to a sum variable and clique $c = \text{ch}(a)$ to a MAP variable, we take $w_c = \epsilon$ to give:

$$m_{c \rightarrow a} \propto \left[\sum_{Y_c \setminus Y_a} \sigma_\epsilon (\psi_c m_{\sim c}) m_{a \rightarrow c}^{-1/w_a} \right]^{w_a}$$

$$\sigma_\epsilon (f(X)) = (f(X) / \max_x f(x))^{1/\epsilon}$$

When $\epsilon \rightarrow 0$, σ_ϵ becomes an indicator function of the maximizing arguments of f , “focusing” the matching step at parent a on configurations relevant to the max values of child c . The resulting algorithm is also closely related to a (tree-reweighted) mixed-product belief propagation algorithm for marginal MAP [13]. Unfortunately, directly taking $\epsilon = 0$ can cause the objective function to be highly non-smooth, and lead to undesirable, non-monotonic fixed-point updates. To alleviate this, in practice we use a schedule $\epsilon = 1/t$ to decrease the temperature over iterations.

6 EXPERIMENTS

We empirically evaluate the proposed branch and bound algorithms on problem instances derived from benchmarks used in the PASCAL2 Inference Challenge [20] as well as the original instances from [7].

Algorithms. We consider three AND/OR branch and bound search algorithms (Section 4): AOBB guided by basic MBE(i) heuristics (denoted AOBB), AOBB guided by heuristics from WMB-MM(i) (denoted AOBB-MM), and AOBB guided by heuristics from WMB-JG(i) (denoted by AOBB-JG), respectively. All of the mini-bucket heuristics were generated in a pre-processing phase, prior to search. The weighted schemes used uniform weights. In addition, we also tested two OR branch and bound schemes guided by MCTE(i) heuristics, denoted BBBTi and BBBTd, respectively. BBBTi performs MCTE(i) incrementally, while BBBTd fully re-evaluates MCTE(i) at each iteration.

We compare all five algorithms against each other and against the current state-of-the-art branch and bound with incremental join-tree upper bounds [7], denoted by YUAN, along with the original approach by Park and Darwiche [6], denoted by PARK. Algorithms BBBTd and PARK

```

use a dynamic variable ordering and select the next MAP variable whose domain values have the most asymmetric bounds. Algorithms BBBTi and YUAN are restricted to a static variable ordering that corresponds to a post-order traversal of the underlying join-tree. The pseudo trees guiding the AND/OR algorithms were obtained by a modified min-fill heuristic [18] that constrained the MAP variables to form a start pseudo tree. All algorithms were implemented in C++ (64-bit) and the experiments were run on a 2.6GHz 8-core processor with 80 GB of RAM.

Benchmarks. Our problem instances were derived from three PASCAL2 benchmarks: *segbin* (image segmentation), *protein* (protein side-chain interaction) and *promedas* (medical diagnosis expert system). For each

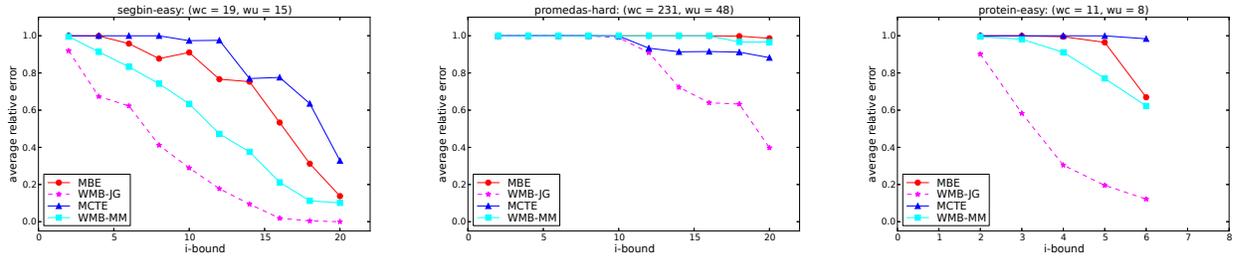

Figure 3: Average relative error (w.r.t. tightest upper bound) as a function of i -bound. WMB-JG(i) ran for 10 iterations.

network, we generated two marginal MAP problem instances with m MAP variables, as follows: an *easy* instance such that the MAP variables were selected as the first m variables from a breadth-first traversal of a pseudo tree obtained from a hypergraph decomposition of the primal graph (ties were broken randomly) [8], and a *hard* instance where the MAP variables were selected uniformly at random. The *easy* instances were designed such that problem decomposition is maximized and the constrained and unconstrained elimination orders are relatively close to each other, thus having comparable induced widths. In contrast, the *hard* instances tend to have very large constrained induced widths. We selected 30% of the variables as MAP variables. In total we evaluated 120 problem instances (20 *easy* and 20 *hard* instances per benchmark).

In all experiments we report total CPU time in seconds and number of nodes visited during search. We also record the problem parameters: number of variables (n), max domain size (k), number of MAP variables (m), and the constrained (w_c^*) and unconstrained (w_u^*) induced widths. The best performance points are highlighted. In each table, 'oom' stands for out-of-memory, while '-' denotes out-of-time.

Results: quality of the upper bounds. We compare the accuracy of the upper bounds obtained by the mini-bucket schemes MBE(i), WMB-MM(i) and WMB-JG(i) against those produced by the unconstrained join-tree scheme, denoted JT, and its generalization MCTE(i).

Table 1 shows results on a typical set of problem instances from both *easy* (top 3) and *hard* (bottom 3) categories, for two values of i -bound: $i = 10, 20$. For every problem instance, for each algorithm we report the upper bound ob-

tained (lower values are better) and CPU time in seconds. The iterative scheme WMB-JG(i) ran for 5, 10 or 100 iterations, respectively. We see clearly that for all instances WMB-MM(i) provides significantly tighter upper bounds than the corresponding pure MBE(i) in a comparable CPU time (see also Figure 3). On the other hand, WMB-JG(i) is able to converge to the most accurate bounds in 4 out of 6 cases, but at a much higher computational cost. JT bounds are typically tighter than those produced by MCTE(i) and MBE(i) which is consistent with previous studies [6, 7].

In Figure 3 we plot the average relative error with respect to the tightest upper bound obtained, as a function of the i -bound. Since, the JT bounds were available only on a relatively small fraction of the instances tested, they are omitted for clarity. We observe that if given enough time WMB-JG(i) is superior to all its competitors, especially for larger i -bounds. However, if time is bounded, then WMB-MM(i) provides a cost-effective alternative. Notice also that when the gap between the constrained and unconstrained induced width is very large, then MCTE(i) provides more accurate bounds than MBE(i) and WMB-MM(i) (eg, *promedas hard*), because MCTE(i) does less partitioning in this case. When the gap is relatively small, then the mini-bucket based bounds are often superior to the MCTE(i) ones for the same i -bound (eg, *segbin easy*).

Results: comparison with state-of-the-art search. Tables 2 and 3 report CPU time in seconds and number of nodes expanded by each search algorithm on a subset of instances from the protein and *promedas* benchmarks. The columns are indexed by the i -bound and the time limit was set to 1 hour. WMB-JG(i) ran for 10 iterations. We can

see clearly that AOBB-JG(i) is the overall best performing algorithm, especially for relatively small i -bounds. For example, on the `pd1a62`, AOBB-JG(3) proves optimality in 13 seconds while AOBB(3) and AOBB-MM(3) finish in 1533 and 169 seconds, respectively. The search space explored by AOBB-JG(3) is also dramatically smaller than those explored by AOBB(3) or AOBB-MM(3). Therefore, the much stronger heuristics generated by WMB-JG(i) translate into impressive time savings. When the i -bound increases, the accuracy ceases to offset the computational overhead and the running time of AOBB-JG(i) increases (e.g., `pd1aho`). In this case, AOBB-MM(i) is a cost-effective alternative, with reduced overhead for pre-compiling the heuristic (see also Figure 4 for a profile of the

CPU time of the algorithms across all benchmarks). The performance of algorithms YUAN and PARK is quite poor in this domain due to the relatively large unconstrained induced widths, which prevent computation of their heuristic. In contrast, BBBTi/BBBTd with relatively higher i -bounds are sometimes competitive and are able to solve more problem instances than YUAN/PARK.

For completeness, we also tested on the Bayesian networks from [7] (results omitted for space). We observed that all of our proposed algorithms were competitive with YUAN/PARK, but due to the relatively small unconstrained induced widths on these problems, very accurate join-tree heuristics could be computed. Thus, there was very little room for improvement by the new methods.

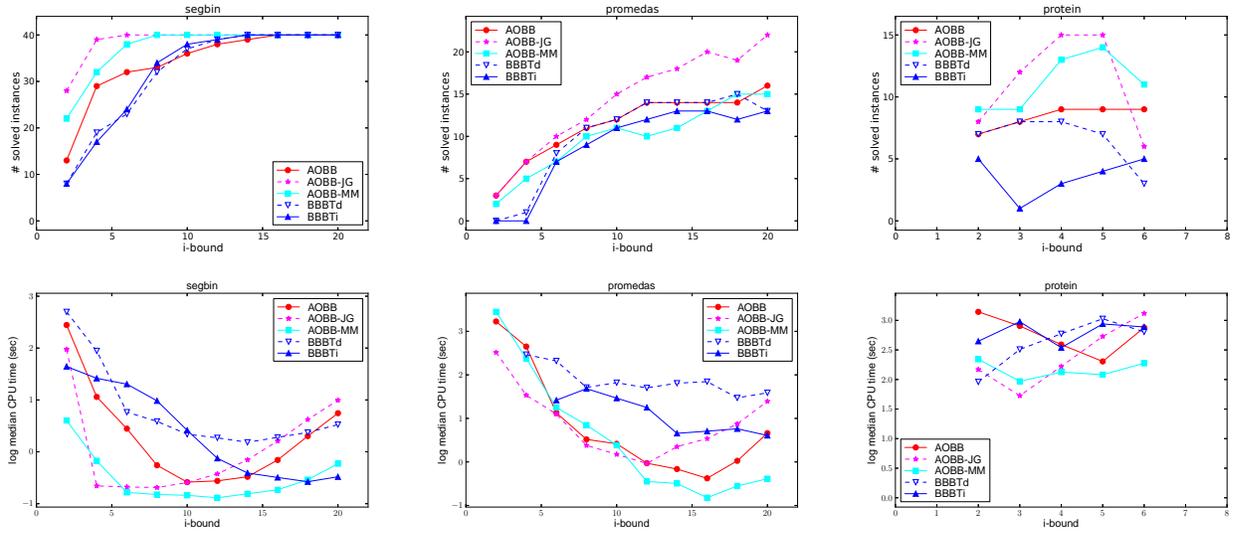

Figure 4: Number of instances solved (top) and median CPU time (bottom) as a function of i -bound for the segbin, promedas and protein instances. Time limit 1 hour. WMB-JG(i) ran for 10 iterations.

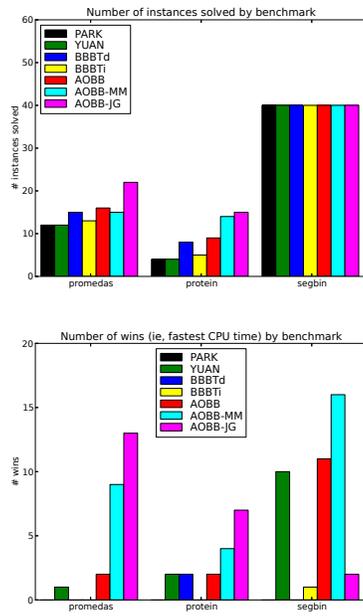

Figure 5: Number of instances solved (top) and number of wins (bottom) by benchmark.

Summary of the experiments. Figure 4 plots the number of problem instances solved from each benchmark (top) and the median CPU time (bottom) as a function of the i -bound. Clearly, AOBB-JG solves the largest number of instances across i -bounds. Moreover, the running time profile shows that AOBB-JG is faster at lower i -bounds due to more accurate heuristics, while AOBB-MM is faster at higher i -bounds due to reduced overhead. Figure 5 summarizes the total number of instances solved as well as the total number of wins (defining a ‘win’ as the fastest time) across the benchmarks, for all competing algorithms. Over-

all, we see that the proposed search algorithms consistently solve more problems and in many cases are significantly faster than the current approaches.

In summary, based on our empirical evaluation, we can conclude that:

- Cost-shifting (especially the iterative version) tightened significantly the MBE bounds for marginal MAP. This yielded considerably faster AOBB search.
- The AOBB algorithms with improved mini-bucket heuristics outperformed in many cases the previous search methods guided by join-tree based heuristics.

7 CONCLUSION

In this paper, we develop AND/OR branch and bound search algorithms for marginal MAP that use heuristics extracted from weighted mini-buckets with cost-shifting. We evaluate both a single-pass version of the heuristic with cost-shifting by moment matching as well as an iterative version that passes messages on the corresponding join-graph. We demonstrate the effectiveness of our proposed search algorithms against previous unconstrained join-tree based methods, which we also extend to apply to high induced-width models, through extensive empirical evaluations on a variety of benchmarks. Our results show not only orders of magnitude improvements over the current state-of-the-art, but also the ability to solve many instances that could not be solved before.

Abstract

Stochastic discriminative EM (sdEM) is an online-EM-type algorithm for discriminative training of probabilistic generative models belonging to the natural exponential family. In this work, we introduce and justify this algorithm as a stochastic *natural gradient* descent method, i.e. a method which accounts for the information geometry in the parameter space of the statistical model. We show how this learning algorithm can be used to train probabilistic generative models by minimizing different discriminative loss functions, such as the negative conditional log-likelihood and the Hinge loss. The resulting models trained by sdEM are always generative (i.e. they define a joint probability distribution) and, in consequence, allows to deal with missing data and latent variables in a principled way either when being learned or when making predictions. The performance of this method is illustrated by several text classification problems for which a multinomial naive Bayes and a latent Dirichlet allocation based classifier are learned using different discriminative loss functions.

1 INTRODUCTION

Online learning methods based on stochastic approximation theory [19] have been a promising research direction to tackle the learning problems of the so-called Big Data era [1, 10, 12]. Stochastic gradient descent (SGD) is probably the best known example of this kind of techniques, used to solve a wide range of learning problems [9]. This algorithm and other versions [27] are usually employed to train discriminative models such as logistic regression or SVM [10].

There also are some successful examples of the use of SGD for discriminative training of probabilistic generative models, as is the case of deep belief networks [18]. However,

this learning algorithm cannot be used directly for the discriminative training of general generative models. One of the main reasons is that statistical estimation or risk minimization problems of generative models involve the solution of an optimization problem with a large number of *normalization constraints* [24], i.e. those which guarantee that the optimized parameter set defines a valid probabilistic model. Although successful solutions to this problem have been proposed [16, 20, 24, 31], they are based on ad-hoc methods which cannot be easily extended to other statistical models, and hardly scale to large data sets.

Stochastic approximation theory [19] has also been used for maximum likelihood estimation (MLE) of probabilistic generative models with latent variables, as is the case of the online EM algorithm [13, 29]. This method provides efficient MLE estimation for a broad class of statistical models (i.e. exponential family models) by sequentially updating the so-called *expectation parameters*. The advantage of this approach is that the resulting iterative optimization algorithm is fairly simple and amenable, as it does not involve any normalization constraints.

In this paper we show that the derivation of Sato's online EM [29] can be extended for the discriminative learning of generative models by introducing a novel interpretation of this algorithm as a natural gradient algorithm [3]. The resulting algorithm, called stochastic discriminative EM (sdEM), is an online-EM-type algorithm that can train generative probabilistic models belonging to the natural exponential family using a wide range of discriminative loss functions, such as the negative conditional log-likelihood or the Hinge loss. In opposite to other discriminative learning approaches [24], models trained by sdEM can deal with missing data and latent variables in a principled way either when being learned or when making predictions, because at any moment they always define a joint probability distribution. sdEM could be used for learning using large scale data sets due to its stochastic approximation nature and, as we will show, because it allows to compute the *natural gradient* of the loss function with no extra cost [3]. Moreover, if allowed by the generative model and the discriminative

loss function, the presented algorithm could potentially be used interchangeably for classification or regression or any other prediction task. But in this initial work, sdEM is only experimentally evaluated in classification problems.

The rest of this paper is organized as follows. Section 2 provides the preliminaries for the description of the sdEM algorithm, which is detailed in Section 3. A brief experimental evaluation is given in Section 4, while Section 5 contains the main conclusions of this work.

2 PRELIMINARIES

2.1 MODEL AND ASSUMPTIONS

We consider generative statistical models for prediction tasks, where Y denotes the random variable (or the vector-value random variable) to be predicted, X denotes the predictive variables, and y^* denotes a prediction, which is made according to $y^* = \arg \max_y p(y, x|\theta)$.

Assumption 1. *The generative data model belongs to a natural exponential family*

$$p(y, x|\theta) \propto \exp(\langle s(y, x), \theta \rangle - A_l(\theta))$$

where θ is the so-called natural parameter which belongs to the so-called natural parameter space $\Theta \in \mathbb{R}^K$, $s(y, x)$ is the vector of sufficient statistics belonging to a convex set $\mathcal{S} \subseteq \mathbb{R}^K$, $\langle \cdot, \cdot \rangle$ denotes the dot product and A_l is the log partition function.

Assumption 2. *We are given a conjugate prior distribution $p(\theta|\alpha)$ of the generative data model*

$$p(\theta|\alpha) \propto \exp(\langle s(\theta), \alpha \rangle - A_g(\alpha))$$

where the sufficient statistics are $s(\theta) = (\theta, -A_l(\theta))$ and the hyperparameter α has two components $(\bar{\alpha}, \nu)$. ν is a positive scalar and $\bar{\alpha}$ is a vector also belonging to \mathcal{S} [6].

2.2 DUAL PARAMETERIZATION AND ASSUMPTIONS

The so-called *expectation parameter* $\mu \in \mathcal{S}$ can also be used to parameterize probability distributions of the natural exponential family. It is a dual set of the model parameter θ [2]. This *expectation parameter* μ is defined as the expected vector of sufficient statistics with respect to θ :

$$\begin{aligned} \mu &\triangleq E[s(y, x)|\theta] = \int s(y, x)p(y, x|\theta)dydx \\ &= \partial A_l(\theta)/\partial \theta \end{aligned} \quad (1)$$

The transformation between θ and μ is one-to-one: μ is a dual set of the model parameter θ [2]. Therefore, Equation (1) can be inverted as: $\theta = \theta(\mu)$. That is to say, for each $\theta \in \Theta$ we always have an associated $\mu \in \mathcal{S}$ and both parameterize the same probability distribution.

For obtaining the *natural parameter* θ associated to an *expectation parameter* μ , we need to make use of the negative of the entropy,

$$\begin{aligned} H(\mu) &\triangleq \int p(y, x|\theta(\mu)) \ln p(y, x|\theta(\mu)) dydx \\ &= \sup_{\theta \in \Theta} \langle \mu, \theta \rangle - A_l(\theta) \end{aligned} \quad (2)$$

Using the above function, the natural parameter θ can be explicitly expressed as

$$\theta = \theta(\mu) = \partial H(\mu)/\partial \mu \quad (3)$$

Equations (1), (2), (3) define the Legendre-Fenchel transform.

Another key requirement of our approach is that it should be possible to compute the transformation from μ to θ in closed form:

Assumption 3. *The transformation from the expectation parameter μ to the natural parameter θ , which can be expressed as*

$$\theta(\mu) = \arg \max_{\theta \in \Theta} \langle \mu, \theta \rangle - A_l(\theta) \quad (4)$$

is available in closed form.

The above equation is also known as the *maximum likelihood function*, because $\theta(\frac{1}{n} \sum_{i=1}^n s(y_i, x_i))$ gives the maximum likelihood estimation θ^* for a data set with n observations $\{(y_1, x_1), \dots, (y_n, x_n)\}$.

For later convenience, we show the following relations between the Fisher Information matrices $I(\theta)$ and $I(\mu)$ for the probability distributions $p(y, x|\theta)$ and $p(y, x|\theta(\mu))$, respectively [23]:

$$I(\theta) = \frac{\partial^2 A_l(\theta)}{\partial \theta \partial \theta} = \frac{\partial \mu}{\partial \theta} = I(\mu)^{-1} \quad (5)$$

$$I(\mu) = \frac{\partial^2 H(\mu)}{\partial \mu \partial \mu} = \frac{\partial \theta}{\partial \mu} = I(\theta)^{-1} \quad (6)$$

2.3 THE NATURAL GRADIENT

Let $\mathcal{W} = \{w \in \mathbb{R}^K\}$ be a parameter space on which the function $L(w)$ is defined. When \mathcal{W} is a Euclidean space with an orthonormal coordinate system, the negative gradient points in the direction of steepest descent. That is, the negative gradient $-\partial L(w)/\partial w$ points in the same direction as the solution to:

$$\arg \min_{dw} L(w + dw) \quad \text{subject to} \quad \|dw\|^2 = \epsilon^2 \quad (7)$$

for sufficiently small ϵ , where $\|dw\|^2$ is the squared length of a small increment vector dw connecting w and $w + dw$. This justifies the use of the classical gradient descent method for finding the minimum of $L(w)$ by taking steps (of size ρ) in the direction of the negative gradient:

$$w_{t+1} = w_t - \rho \frac{\partial L(w_t)}{\partial w} \quad (8)$$

However, when \mathcal{W} is a Riemannian space [4], there are no orthonormal linear coordinates, and the squared length of vector dw is defined by the following equation,

$$\|dw\|^2 = \sum_{ij} g_{ij}(w) dw_i dw_j \quad (9)$$

where the $K \times K$ matrix $G = (g_{ij})$ is called the Riemannian metric tensor, and it generally depends on w . G reduces to the identity matrix in the case of the Euclidean space [4].

In a Riemannian space, the steepest descent direction is not anymore the traditional gradient. That is, $-\partial L(w)/\partial w$ is not the solution of Equation (7) when the squared length of the distance of dw is defined by Equation (9). Amari [3] shows that this solution can be computed by pre-multiplying the traditional gradient by the inverse of the Riemannian metric G^{-1} ,

Theorem 1. *The steepest descent direction or the natural gradient of $L(w)$ in a Riemannian space is given by*

$$-\frac{\tilde{\partial}L(w)}{\tilde{\partial}w} = -G^{-1}(w) \frac{\partial L(w)}{\partial w} \quad (10)$$

where $\tilde{\partial}L(w)/\tilde{\partial}w$ denotes the *natural gradient*.

As argued in [3], in statistical estimation problems we should use gradient descent methods which account for the natural gradient of the parameter space, as the parameter space of a statistical model (belonging to the exponential family or not) is a Riemannian space with the Fisher information matrix of the statistical model $I(w)$ as the tensor metric [2], and this is the only invariant metric that must be given to the statistical model [2].

2.4 SATO'S ONLINE EM ALGORITHM

Sato's online EM algorithm [29] is used for maximum likelihood estimation of missing data-type statistical models. The model defines a probability distribution over two random or vector-valued variables X and Z , and is assumed to belong to the natural exponential family:

$$p(z, x|\theta) \propto \exp(\langle s(z, x), \theta \rangle - A_t(\theta))$$

where (z, x) denotes a so-called *complete data* event. The key aspect is that we can only observe x , since z is an unobservable event. In consequence, the loss function $\ell(x, \theta)$ ¹ is defined by marginalizing z : $\ell(x, \theta) = -\ln \int p(z, x) dz$.

The online setting assumes the observation of a non-finite data sequence $\{(x_t)\}_{t \geq 0}$ independently drawn according to the unknown data distribution π . The objective function that EM seeks to minimize is given by the following expectation: $L(\theta) = E[\ell(x, \theta)|\pi]$.

¹We derive this algorithm in terms of minimization of a loss function to highlight its connection with sdEM.

Sato [29] derived the stochastic updating equation of online EM by relying on the free energy formulation, or lower bound maximization, of the EM algorithm [22] and on a discounting averaging method. Using our own notation, this updating equation is expressed as follows,

$$\begin{aligned} \mu_{t+1} &= (1 - \rho_t)\mu_t + \rho_t E_z[s(z, x_t|\theta(\mu_t))] \\ &= \mu_t + \rho_t (E_z[s(z, x_t|\theta(\mu_t))] - \mu_t) \\ &= \mu_t + \rho_t \frac{\partial \ell(x_t, \theta(\mu_t))}{\partial \theta} \end{aligned} \quad (11)$$

where $E_z[s(z, x_t|\theta(\mu_t))]$ denotes the expected sufficient statistics, $E_z[s(z, x_t|\theta(\mu_t))] = \int s(z, x_t) p(z|x_t, \theta(\mu_t)) dz$.

He proved the convergence of the above iteration method by casting it as a second order stochastic gradient descent using the following equality,

$$\frac{\partial \ell(x, \theta)}{\partial \theta} = \frac{\partial \mu}{\partial \theta} \frac{\partial \ell(x, \theta(\mu))}{\partial \mu} = I(\mu)^{-1} \frac{\partial \ell(x, \theta(\mu))}{\partial \mu} \quad (12)$$

This equality is obtained by firstly applying the chain rule, followed by the equality shown in Equation (5). It shows that online EM is equivalent to a stochastic gradient descent with $I(\mu_t)^{-1}$ as coefficient matrices [9].

Sato noted that that the third term of the equality in Equation (12) resembles a natural gradient (see Theorem 1), but he did not explore the connection. But the key insights of the above derivation, which were not noted by Sato, is that Equation (12) is also valid for other loss functions different from the marginal log-likelihood; and that the convergence of Equation (11) does not depend on the formulation of the EM as a "lower bound maximization" method [22].

3 STOCHASTIC DISCRIMINATIVE EM

3.1 THE sdEM ALGORITHM

We consider the following supervised learning setup. Let us assume that we are given a data set D with n observations $\{(y_1, x_1), \dots, (y_n, x_n)\}$. We are also given a *discriminative loss function*² $\ell(y_i, x_i, \theta)$. For example, it could be the negative conditional log-likelihood (NCLL) $\ell(y_i, x_i, \theta) = -\ln p(y_i, x_i|\theta) + \ln \int p(y, x_i|\theta) dy = -\ln p(y_i|x_i, \theta)$. Our learning problem consists in minimizing the following objective function:

$$\begin{aligned} L(\theta) &= \sum_{i=1}^n \ell(y_i, x_i, \theta) - \ln p(\theta|\alpha) \\ &= E[\ell(y, x, \theta)|\pi] - \frac{1}{n} \ln p(\theta|\alpha) \end{aligned} \quad (13)$$

where π is now the empirical distribution of D and $E[\ell(y, x, \theta)|\pi]$ the empirical risk. Although the above

²The loss function is assumed to satisfy the mild conditions given in [9]. E.g., it can be a non-smooth function, such as the Hinge Loss.

loss function is not standard in the machine learning literature, we note that when ℓ is the negative log-likelihood (NLL), we get the classic *maximum a posterior estimation*. This objective function can be seen as an extension of this framework.

sdEM is presented as a generalization of Sato’s online EM algorithm for finding the minimum of an objective function in the form of Equation (13) (i.e. the solution to our learning problem). The stochastic updating equation of sdEM can be expressed as follows,

$$\mu_{t+1} = \mu_t - \rho_t I(\mu_t)^{-1} \frac{\partial \bar{\ell}(y_t, x_t, \theta(\mu_t))}{\partial \mu} \quad (14)$$

where (y_t, x_t) denotes the t -th sample, randomly generated from π , and the function $\bar{\ell}$ has the following expression: $\bar{\ell}(y_t, x_t, \theta(\mu_t)) = \ell((y_t, x_t, \theta(\mu_t))) + 1/n \ln p(\theta(\mu_t))$. We note that this loss function satisfies the following equality, which is the base for a stochastic approximation method [19], $E[\bar{\ell}(y_t, x_t, \theta(\mu)) | \pi] = L(\theta(\mu))$.

Similarly to Amari’s natural gradient algorithm [3], the main problem of sdEM formulated as in Equation (14) is the computation of the inverse of the Fisher information matrix at each step, which becomes even prohibitive for large models. The following result shows that this can be circumvented when we deal with distributions of the natural exponential family:

Theorem 2. *In a natural exponential family, the natural gradient of a loss function with respect to the expectation parameters equals the gradient of the loss function with respect to the natural parameters,*

$$I(\mu)^{-1} \frac{\partial \bar{\ell}(y, x, \theta(\mu))}{\partial \mu} = \frac{\partial \bar{\ell}(y, x, \theta)}{\partial \theta}$$

Sketch of the proof. We firstly need to prove that $I(\mu)$ is a valid Riemannian tensor metric and, hence, the expectation parameter space has a Riemannian structure defined by the metric $I(\mu)$ and the definition of the natural gradient makes sense. This can be proved by the invariant property of the Fisher information metric to one-to-one reparameterizations or, equivalently, transformations in the system of coordinates [2, 4]. $I(\mu)$ is a Riemannian metric because it is the Fisher information matrix of the reparameterized model $p(y, x | \theta(\mu))$, and the reparameterization is one-to-one, as commented in Section 2.2.

The equality stated in the theorem follows directly from Sato’s derivation of the online EM algorithm (Equation (12)). This derivation shows that we can avoid the computation of $I(\mu)^{-1}$ by using the natural parameters instead of the expectation parameters and the function $\theta(\mu)$. \square

Theorem 1 simplifies the sdEM’s updating equation to,

$$\mu_{t+1} = \mu_t - \rho_t \frac{\partial \bar{\ell}(y_t, x_t, \theta(\mu_t))}{\partial \theta} \quad (15)$$

sdEM can be interpreted as a stochastic gradient descent algorithm iterating over the *expectation parameters* and guided by the natural gradient in this Riemannian space.

Algorithm 1 Stochastic Discriminative EM (sdEM)

Require: D is randomly shuffled.

- 1: $\mu_0 = \bar{\alpha}$; (initialize according to the prior)
 - 2: $\theta_0 = \theta(\mu_0)$;
 - 3: $t = 0$;
 - 4: **repeat**
 - 5: **for** $i = 1, \dots, n$ **do**
 - 6: **E-Step:** $\mu_{t+1} = \mu_t - \frac{1}{(1+\lambda t)} \frac{\partial \bar{\ell}(y_i, x_i, \theta_i)}{\partial \theta}$;
 - 7: **Check-Step:** $\mu_{t+1} = \text{Check}(\mu_{t+1}, \mathcal{S})$;
 - 8: **M-Step:** $\theta_{t+1} = \theta(\mu_{t+1})$;
 - 9: $t = t + 1$;
 - 10: **end for**
 - 11: **until** convergence
 - 12: **return** $\theta(\mu_t)$;
-

An alternative proof to Theorem 2 based on more recent results on information geometry has been recently given in [25]. The results of that work indicate that sdEM could also be interpreted as a mirror descent algorithm with a Bregman divergence as a proximity measure. It is beyond the scope of the paper to explore this relevant connection.

3.2 CONVERGENCE OF sdEM

In this section we do not attempt to give a formal proof of the convergence of sdEM, since very careful technical arguments would be needed for this purpose [9]. We simply go through the main elements that define the convergence of sdEM as a stochastic approximation method [19].

According to Equation (14), sdEM can be seen as a stochastic gradient descent method with the inverse of the Fisher information matrix $I(\mu)^{-1}$ as a coefficient matrix [9]. As we are dealing with natural exponential families, these matrices are always positive-definite. Moreover, if the gradient $\partial \bar{\ell}(y, x, \theta) / \partial \theta$ can be computed exactly (in Section 3.4 we discuss what happens when this is not possible), from Theorem 2, we have that it is an unbiased estimator of the natural gradient of the $L(\theta(\mu))$ defined in Equation 13,

$$E \left[\frac{\partial \bar{\ell}(y, x, \theta)}{\partial \theta} \Big| \pi \right] = I(\mu)^{-1} \frac{\partial L(\theta(\mu))}{\partial \mu} \quad (16)$$

However, one key difference in terms of convergence between online EM and sdEM can be seen in Equation (11): μ_{t+1} is a convex combination between μ_t and the expected sufficient statistics. Then, $\mu_{t+1} \in \mathcal{S}$ during all the iterations. As will be clear in the next section, we do not have this same guarantee in sdEM, but we can take advantage

Table 1: sdEM updating equations for fully observed data (Section 3.3) .

Loss	sdEM equation
NLL	$\mu_{t+1} = (1 - \rho_t(1 + \frac{\nu}{n}))\mu_t + \rho_t (s(y_t, x_t) + \frac{1}{n}\bar{\alpha})$
NCLL	$\mu_{t+1} = (1 - \rho_t\frac{\nu}{n})\mu_t + \rho_t (s(y_t, x_t) - E_y[s(y, x_t) \theta(\mu_t)] + \frac{1}{n}\bar{\alpha})$
Hinge	$\mu_{t+1} = (1 - \rho_t\frac{\nu}{n})\mu_t + \rho_t \begin{cases} \frac{1}{n}\bar{\alpha} & \text{if } \ln \frac{p(y_t, x_t \theta)}{p(\bar{y}_t, x_t \theta)} > 1 \\ s(y_t, x_t) - s(\bar{y}_t, x_t) + \frac{1}{n}\bar{\alpha} & \text{otherwise} \end{cases}$ <p style="text-align: right;">where $\bar{y}_t = \arg \max_{y \neq y_t} p(y, x_t \theta)$</p>

of the log prior term of Equation (13) to avoid this problem. This term plays a dual role as both “regularization” term and log-barrier function [30] i.e. a continuous function whose value increases to infinity as the parameter approaches the *boundary of the feasible region* or the support of $p(\theta(\mu)|\alpha)$ ³. Then, if the step sizes ρ_t are small enough (as happens near convergence), sdEM will always stay in the feasible region \mathcal{S} , due to the effect of the log prior term. The only problem is that, in the initial iterations, the step sizes ρ_t are large, so one iteration can jump out of the boundary of \mathcal{S} . The method to avoid that depends on the particular model, but for the models examined in this work it seems to be a simple check in every iteration. For example, as we will see in the experimental section when implementing a multinomial Naive Bayes, we will check at every iteration that each sufficient statistic or “word count” is always positive. If a “word count” is negative at some point, we will set it to a very small value. As mentioned above, this does not hurt the convergence of sdEM because in the limit this problem disappears due the effect of the log-prior term.

The last ingredient required to assess the convergence of a stochastic gradient descent method is to verify that the sequence of step sizes satisfies: $\sum \rho_t = \infty$, $\sum \rho_t^2 < \infty$.

So, if the sequence $(\mu_t)_{t \geq 0}$ converges, it will probably converge to the global minimum $(\mu^*, \theta^* = \theta(\mu^*))$ if $L(\theta)$ is convex, or to a local minimum if $L(\theta)$ is not convex [9].

Finally, we give an algorithmic description of sdEM in Algorithm 1. Following [11], we consider steps sizes of the form $\rho_t = (1 + \lambda t)^{-1}$, where λ is a positive scalar⁴. As mentioned above, the “Check-Step” is introduced to guarantee that μ_t is always in \mathcal{S} . Like the online EM algorithm [29, 13], Algorithm 1 resembles the classic *expecta-*

tion maximization algorithm [15] since, as we will see in the next section, the gradient is computed using *expected sufficient statistics*. Assumption 3 guarantees that the maximization step can be performed efficiently. This step differentiates sdEM from classic stochastic gradient descent methods, where such a computation does not exist.

3.3 DISCRIMINATIVE LOSS FUNCTIONS

As we have seen so far, the derivation of sdEM is complete except for the definition of the loss function. We will discuss now how two well known *discriminative loss functions* can be used with this algorithm.

Negative Conditional Log-likelihood (NCLL)

As mentioned above, this loss function is defined as follows:

$$\ell_{CL}(y_t, x_t, \theta) = -\ln p(y_t, x_t|\theta) + \ln \int p(y, x_t|\theta) dy$$

And its gradient is computed as

$$\frac{\partial \ell_{CL}(y_t, x_t, \theta)}{\partial \theta} = -s(y_t, x_t) + E_y[s(y, x_t)|\theta]$$

where the sufficient statistic $s(y_t, x_t)$ comes from the gradient of the $\ln p(y_t, x_t|\theta)$ term in the NCLL loss, and the expected sufficient statistic $E_y[s(y, x_t)|\theta] = \int s(y, x_t)p(y|x_t, \theta)dy$, comes from the gradient of the $\ln \int p(y, x_t|\theta)dy$ term in the NCLL loss. As mentioned above, the computation of the gradient is similar to the *expectation step* of the classic EM algorithm.

The iteration equation of sdEM for the NCLL loss is detailed in Table 1. We note that in the case of multi-class prediction problems the integrals of the updating equation are replaced by sums over the different classes of the class variable Y . We also show the updating equation for the negative log-likelihood (NLL) loss for comparison purposes.

³The prior p would need to be suitably chosen.

⁴Our experiments suggest that trying $\lambda \in \{1, 0.1, 0.01, 0.001, \dots\}$ suffices for obtaining a quick convergence.

Table 2: sdEM updating equations for partially observed data (Section 3.4)

Loss	sdEM equation
NLL	$\mu_{t+1} = (1 - \rho_t(1 + \frac{\nu}{n}))\mu_t + \rho_t (E_z[s(y_t, z, x_t) \theta(\mu_t)] + \frac{1}{n}\bar{\alpha})$
NCLL	$\mu_{t+1} = (1 - \rho_t\frac{\nu}{n})\mu_t + \rho_t (E_z[s(y_t, z, x_t) \theta(\mu_t)] - E_{y_z}[s(y, z, x_t) \theta(\mu_t)] + \frac{1}{n}\bar{\alpha})$
Hinge	$\mu_{t+1} = (1 - \rho_t\frac{\nu}{n})\mu_t + \rho_t \begin{cases} \frac{1}{n}\bar{\alpha} & \text{if } \ln \frac{\int p(y_t, z, x_t \theta)dz}{\int p(\bar{y}_t, z, x_t \theta)dz} > 1 \\ E_z[s(y_t, z, x_t) \theta(\mu_t)] - E_z[s(\bar{y}_t, z, x_t) \theta(\mu_t)] + \frac{1}{n}\bar{\alpha} & \text{otherwise} \end{cases}$ <p style="text-align: center;">where $\bar{y}_t = \arg \max_{y \neq y_t} \int p(y, z, x_t \theta)dz$</p>

The Hinge loss

Unlike the previous loss which is valid for continuous and discrete (and vector-valued) predictions, this loss is only valid for binary or multi-class classification problems.

Margin-based loss functions have been extensively used and studied by the machine learning community for binary and multi-class classification problems [5]. However, in our view, the application of margin-based losses (different from the negative conditional log-likelihood) for discriminative training of probabilistic generative models is scarce and based on ad-hoc learning methods which, in general, are quite sophisticated [24]. In this section, we discuss how sdEM can be used to minimize the empirical risk of one of the most used margin-based losses, the Hinge loss, in binary and multi-class classification problems. But, firstly, we discuss how Hinge loss can be defined for probabilistic generative models.

We build on LeCun et al.'s ideas [21] about energy-based learning for prediction problems. LeCun et al. [21] define the Hinge loss for energy-based models as follows,

$$\max(0, 1 - (E(\bar{y}_t, x_t, w) - E(y_t, x_t, w)))$$

where $E(\cdot)$ is the energy function parameterized by a parameter vector w , $E(y_t, x_t, w)$ is the energy associated to the correct answer y_t and $E(\bar{y}_t, x_t, w)$ is the energy associated to the most offending incorrect answer, $\bar{y}_t = \arg \min_{y \neq y_t} E(y, x_t, w)$. Predictions y^* are made using $y^* = \arg \min_y E(y, x_t, w^*)$ when the parameter w^* that minimizes the empirical risk is found.

In our learning settings we consider the minus logarithm of the joint probability, $-\ln p(y_t, x_t|\theta)$, as an energy function. In consequence, we define the hinge loss as follows

$$\ell_{hinge}(y_t, x_t, \theta) = \max(0, 1 - \ln \frac{p(y_t, x_t|\theta)}{p(\bar{y}_t, x_t|\theta)}) \quad (17)$$

where \bar{y}_t denotes here too the most offending incorrect answer, $\bar{y}_t = \arg \max_{y \neq y_t} p(y, x_t|\theta)$.

The gradient of this loss function can be simply computed as follows

$$\frac{\partial \ell_{hinge}(y_t, x_t, \theta)}{\partial \theta} = \begin{cases} 0 & \text{if } \ln \frac{p(y_t, x_t|\theta)}{p(\bar{y}_t, x_t|\theta)} > 1 \\ -s(y_t, x_t) + s(\bar{y}_t, x_t) & \text{otherwise} \end{cases}$$

and the iteration equation for minimizing the empirical risk of the Hinge loss is also given in Table 1.

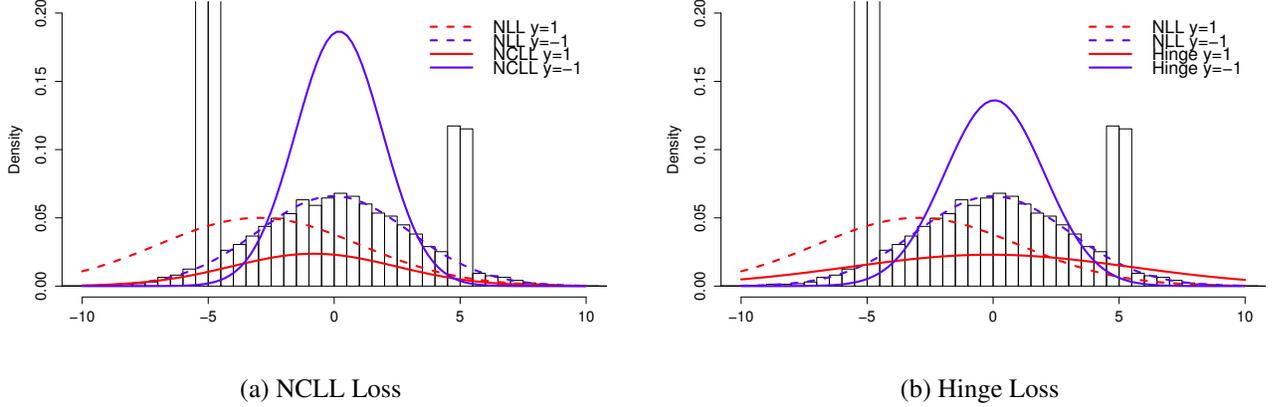

3.4 PARTIALLY OBSERVABLE DATA

The generalization of sdEM to partially observable data is straightforward. We denote by Z the vector of non-observable variables. sdEM will handle statistical models which define a probability distribution over (y, z, x) which belongs to the natural exponential family (Assumption 1). Assumption 2 and 3 remain unaltered.

The tuple (y, z, x) will denote the complete event or complete data, while the tuple (y, x) is the observed event or the observed data. So we assume that our given data set D with n observations is expressed as $\{(y_1, x_1), \dots, (y_n, x_n)\}$. So sdEM's Equation (14) and (15) are the same, with the only difference that the natural gradient is now defined using the inverse of the Fisher information matrix for the statistical model $p(y, z, x|\theta(\mu))$. The same happens for Theorem 2.

The NCLL loss and the Hinge loss are equally defined as in Section 3.3, with the only difference that the computation of $p(y_t, x_t|\theta)$ and $p(x_t|\theta)$ requires marginalization over z , $p(y_t, x_t|\theta) = \int p(y_t, z, x_t|\theta)dz$, $p(x_t|\theta) = \int p(y, z, x_t|\theta)dydz$. The updating equations for sdEM under partially observed data for the NCLL and Hinge loss are detailed in Table 2. New expected sufficient statistics need to be computed,

Figure 1: Toy example (Section 4.1). The result using the NLL loss (i.e. MLE estimation) is plotted with dashed lines which represent the densities $p(y = k)N(x, \mu^{(k)}, \sigma^{(k)})$ for both classes (i.e. when the red line is higher than the blue line we predict the red class and vice versa). The estimated prediction accuracy of the MLE model is 78.6%. Solid lines represent the same estimation but using the NCLL and the Hinge loss. Their estimated prediction accuracies are 90.4% and 90.6%, respectively.

$E_z[s(y_t, z, x_t)|\theta] = \int s(y_t, z, x_t)p(z|y_t, x_t, \theta)dz$ and $E_{yz}[s(y, z, x_t)|\theta] = \int s(y, z, x_t)p(y, z|x_t, \theta)dydz$. As previously, we also show the updating equation for the negative log-likelihood (NLL) loss for comparison purposes.

3.5 sdEM AND APPROXIMATE INFERENCE

For many interesting models [8], the computation of the expected sufficient statistics in the iteration equations shown in Table 1 and 2 cannot be computed in closed form. This is not a problem as far as we can define *unbiased estimators* for these expected sufficient statistics, since the equality of Equation (16) still holds. As it will be shown in the next section, we use sdEM to discriminatively train *latent Dirichlet allocation* (LDA) models [8]. Similarly to [26], for this purpose we employ collapsed Gibbs sampling to compute the expected sufficient statistics, $E_z[s(y_t, z, x_t)|\theta]$, as it guarantees that at convergence samples are i.i.d. according to $p(z|y_t, x_t, \theta)$.

4 EXPERIMENTAL ANALYSIS

4.1 TOY EXAMPLE

We begin the experimental analysis of sdEM by learning a very simple Gaussian naive Bayes model composed by a binary class variable Y and a single continuous predictor X . Hence, the conditional density of the predictor given the class variable is assumed to be normally distributed. The interesting part of this toy example is that the training data is generated by a different model: $\pi(y = -1) = 0.5$, $\pi(x|y = -1) \sim N(0, 3)$ and $\pi(x|y = 1) \sim$

$0.8 \cdot N(-5, 0.1) + 0.2 \cdot N(5, 0.1)$. Figure 1 shows the histogram of the 30,000 samples generated from the π distribution. The result is a mixture of 3 Gaussians, one in the center with a high variance associated to $y = -1$ and two narrow Gaussians on both sides associated to $y = 1$.

sdEM can be used by considering 6 (non-minimal) sufficient statistics: $N^{(-1)}$ and $N^{(1)}$ as “counts” associated to both classes, respectively; $S^{(-1)}$ and $S^{(1)}$ as the “sum” of the x values associated to classes $y = -1$ and $y = 1$, respectively; and $V^{(-1)}$ and $V^{(1)}$ as the “sum of squares” of the x values for each class. We also have five parameters which are computed from the sufficient statistics as follows: Two for the prior of class $p(y = -1) = p^{(-1)} = N^{(-1)}/(N^{(-1)} + N^{(1)})$ and $p^{(1)} = N^{(1)}/(N^{(-1)} + N^{(1)})$; and four for the two Gaussians which define the conditional of X given Y , $\mu^{(-1)} = S^{(-1)}/N^{(-1)}$, $\sigma^{(-1)} = \sqrt{V^{(-1)}/N^{(-1)} - (S^{(-1)}/N^{(-1)})^2}$, and equally for $\mu^{(1)}$ and $\sigma^{(1)}$.

The sdEM’s updating equations for the NCLL loss can be written as follows

$$\begin{aligned} N_{t+1}^{(k)} &= N_t^{(k)} + \rho_t(I[y_t = k] - p_t(k|x_t)) + \frac{\rho_t}{n} \\ S_{t+1}^{(k)} &= (1 - \frac{\rho_t}{n})S_t^{(k)} + \rho_t x_t (I[y_t = k] - p_t(k|x_t)) \\ V_{t+1}^{(k)} &= (1 - \frac{\rho_t}{n})V_t^{(k)} + \rho_t x_t^2 (I[y_t = k] - p_t(k|x_t)) + \frac{\rho_t}{n} \end{aligned}$$

where k indexes both classes, $k \in \{-1, 1\}$, $I[\cdot]$ denotes the indicator function, $p_t(k|x_t)$ is an abbreviation of $p(y = k|x_t, \theta_t)$, and θ_t is the parameter vector computed from the sufficient statistics at the t -th iteration.

Figure 2: Convergence trade-off of the Hinge loss versus the NCLL loss and the perplexity for a multinomial naive Bayes model trained minimizing the Hinge loss using sdEM. Circle-lines, triangle-lines and cross-lines correspond to the results with 20NewsGroup, Cade and Reuters-R52 datasets, respectively.

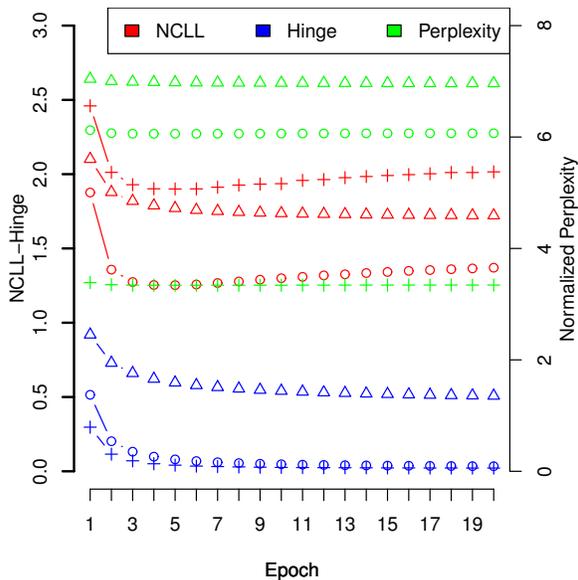

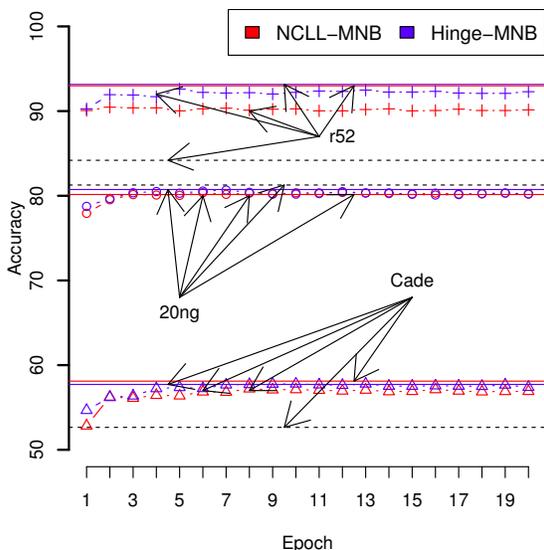

Figure 3: Convergence of the classification accuracy for a multinomial naive Bayes model trained minimizing the NCLL loss (NCLL-MNB) and the Hinge loss (Hinge-MNB) using sdEM. Red circle-lines, red triangle-lines and red cross-lines correspond to the results of NCLL-MNB with 20NewsGroup, Cade and Reuters-R52 datasets, respectively. Same for Hinge-MNB. The three blue and the three red solid lines detail the accuracy of logistic regression and SVM, respectively. The three dashed black lines detail the accuracy of plain MNB with a Laplace prior.

Similarly, the sdEM’s updating equations for the Hinge loss can be written as follows,

$$N_{t+1}^{(k)} = N_t^{(k)} + ky_t \rho_t I[\ln \frac{p_t(y_t|x_t)}{p_t(\bar{y}_t|x_t)} < 1] + \frac{\rho_t}{n}$$

$$S_{t+1}^{(k)} = (1 - \frac{\rho_t}{n})S_t^{(k)} + ky_t \rho_t x_t I[\ln \frac{p_t(y_t|x_t)}{p_t(\bar{y}_t|x_t)} < 1]$$

$$V_{t+1}^{(k)} = (1 - \frac{\rho_t}{n})V_t^{(k)} + ky_t \rho_t x_t^2 I[\ln \frac{p_t(y_t|x_t)}{p_t(\bar{y}_t|x_t)} < 1] + \frac{\rho_t}{n}$$

where the product ky_t is introduced in the updating equations to define the sign of the sum, and the indicator function $I[\cdot]$ defines when the hinge loss is null.

In the above set of equations we have considered as a conjugate prior for the Gaussians a three parameter Normal-Gamma prior, $\nu = 1$ and $\bar{\alpha}_1 = 0$ for $S^{(k)}$ and $\bar{\alpha}_2 = 1$ for $V^{(k)}$ [6, page 268], and a Beta prior with $\nu = 0$ and $\bar{\alpha} = 1$ for $N^{(k)}$. We note that these priors assign zero probability to “extreme” parameters $p^{(k)} = 0$ (i.e. $N^{(k)} = 0$) and $\sigma^{(k)} = 0$ (i.e. $V^{(k)}/N^{(k)} - (S^{(k)}/N^{(k)})^2 = 0$).

Finally, the “Check-step” (see Algorithm 1) performed before computing θ_{t+1} , and which guarantees that all sufficient statistics are correct, is implemented as follows:

$$N_{t+1}^{(k)} = \max(N_{t+1}^{(k)}, \frac{\rho_t}{n})$$

$$V_{t+1}^{(k)} = \max(V_{t+1}^{(k)}, \frac{(S_{t+1}^{(k)})^2}{N_{t+1}^{(k)}} + \frac{\rho_t}{n})$$

I.e., when the $N^{(k)}$ “counts” are negative or too small or when the $V^{(k)}$ values lead to negative or null deviations $\sigma^{(k)} \leq 0$, they are fixed with the help of the prior term.

The result of this experiment is given in Figure 1 and clearly shows the different trade-offs of both loss functions compared to *maximum likelihood estimation*. It is interesting to see how a generative model which does not match the underlying distribution is able to achieve a pretty high prediction accuracy when trained with a discriminative loss function (using the sdEM algorithm).

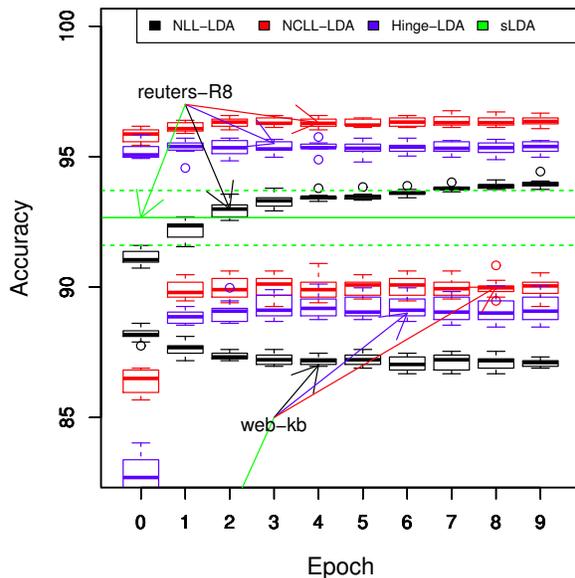

4.2 sdEM FOR TEXT CLASSIFICATION

Next, we briefly show how sdEM can be used to discriminatively train some generative models used for text classification, such as multinomial naive Bayes and a similar classifier based on latent Dirichlet allocation models [8]. Supplementary material with full details of these experiments and the Java code used in this evaluation can be download at: <http://sourceforge.net/projects/sdem/>

Multinomial Naive Bayes (MNB)

MNB assumes that words in documents with the same class or label are distributed according to an independent multinomial distribution. sdEM can be easily applied to train this

Figure 4: Convergence of the classification accuracy of LDA classification models trained by sdEM using different loss functions (NLL, NCLL and Hinge) over 10 different random initializations. The two dashed lines and the single solid line detail the maximum, minimum and mean accuracy of sLDA, respectively, over 10 random initializations.

model. The sufficient statistics are the “prior class counts” and the “word counts” for each class. The updating equations and the check step are the same as those of $N_t^{(k)}$ in the previous toy example. Parameters of the MNB are computed simply through normalization operations. Two different conjugate Dirichlet distributions were considered: A “Laplace prior” where $\bar{\alpha}_i = 1$; and a “Log prior” where $\bar{\alpha}_i =$ “logarithm of the number of words in the corpus”. We only report analysis for “Laplace prior” in the case of NCLL loss and for “Log prior” in the case of Hinge loss. Other combinations show similar results, although NCLL was more sensitive to the chosen prior.

We evaluate the application of sdEM to MNB with three well-known multi-class text classification problems: 20Newsgroup (20 classes), Cade (12 classes) and Reuters21578-R52 (52 classes). Data sets are stemmed. Full details about the data sets and the train/test data sets split used in this evaluation can be found in [14].

Figure 2 shows the convergence behavior of sdEM with $\lambda = 1e-05$ when training a MNB by minimizing the Hinge loss (Hinge-MNB). In this figure, we plot the evolution of the Hinge loss but also the evolution of the NCLL loss and the normalized perplexity (i.e. the perplexity measure [8] divided by the number of training documents) at each epoch. We can see that there is a trade-off between the different losses. E.g., Hinge-MNB decreases the Hinge loss (as expected) but tends to increase the NCLL loss, while it

only decreases perplexity at the very beginning.

Figure 3 displays the evolution of the classification accuracy of two MNBs trained minimizing the NCLL loss and the Hinge loss using sdEM. We compare them to: the standard MNB with a “Laplace prior”; the L2-regularized Logistic Regression; and the primal L2-regularized SVM. The two later methods were taken from the Liblinear toolkit v.18 [17]. As can be seen, sdEM is able to train simple MNB models with a performance very close to that provided by highly optimized algorithms.

Latent Dirichlet Allocation (LDA)

We briefly show the results of sdEM when discriminatively training LDA models. We define a classification model equal to MNB, but where the documents of the same class are now modeled using an independent LDA model. We implement this model by using, apart from the “prior class counts”, the standard sufficient statistics of the LDA model, i.e. “words per hidden topic counts”, associated to each class label. Similarly to [26], we used an online Collapsed Gibbs sampling method to obtain, at convergence, unbiased estimates of the expected sufficient statistics (see Table 2).

This evaluation was carried out using the standard train/test split of the Reuters21578-R8 (8 classes) and web-kb (4 classes) data sets [14], under the same preprocessing than in the MNB’s experiments. Figure 4 shows the results of this comparison using 2-topics LDA models trained with the NCLL loss (NCLL-LDA), the Hinge loss (Hinge-LDA), and also the NLL loss (NLL-LDA) following the updating equations of Table 2. We compared these results with those returned by supervised-LDA (sLDA) [7] using the same prior, but this time with 50 topics because less topics produced worse results. We see again how a simple generative model trained with sdEM outperforms much more sophisticated models.

5 CONCLUSIONS

We introduce a new learning algorithm for discriminative training of generative models. This method is based on a novel view of the online EM algorithm as a stochastic *natural gradient* descent algorithm for minimizing general discriminative loss functions. It allows the training of a wide set of generative models with or without latent variables, because the resulting models are always generative. Moreover, sdEM is comparatively simpler and easier to implement (and debug) than other ad-hoc approaches.

Abstract

Kullback Leibler (KL) control problems allow for efficient computation of optimal control by solving a principal eigenvector problem. However, direct applicability of such framework to continuous state-action systems is limited. In this paper, we propose to embed a KL control problem in a probabilistic graphical model where observed variables correspond to the continuous (possibly high-dimensional) state of the system and latent variables correspond to a discrete (low-dimensional) representation of the state amenable for KL control computation. We present two examples of this approach. The first one uses standard hidden Markov models (HMMs) and computes exact optimal control, but is only applicable to low-dimensional systems. The second one uses factorial HMMs, it is scalable to higher dimensional problems, but control computation is approximate. We illustrate both examples in several robot motor control tasks.

1 INTRODUCTION

Recent research in stochastic optimal control theory has identified a class of problems known as Kullback-Leibler (KL) control problems (Kappen et al., 2012) or linearly solvable Markov decision problems (LSMDPs) (Todorov, 2006). For these (discrete) problems, the set of actions and the cost function are restricted in a way that makes the Bellman equation linear and thus more efficiently solvable, for instance, by solving the principal eigenvector of a certain linear operator (Todorov, 2009a).

However, direct applicability of this framework to continuous state-action systems, such as robot motor control, is limited. The main problem is the curse of

dimensionality, which appears because discretization quickly leads to a combinatorial explosion. This problem has been addressed using function approximation methods in (Todorov, 2009b). Instead of directly solving a discrete-state LSMDP, these methods approximate the so-called desirability function, which is defined in the continuous-state space. Kinjo et al. (2013) combined this function approximation scheme with system identification on a real robot navigation task. However, approaches based on the continuous-state formulation of KL control problems have several limitations: they require to solve a quadratic programming problem, a more computationally demanding problem than computing the principal eigenvector. Also, there is no guarantee of convergence to a positive solution. Alternative formulations that address these limitations have been recently proposed (Zhong and Todorov, 2011a,b). Zhong and Todorov (2011a) used a soft aggregation method to solve KL-control problems in an aggregated space. Both approaches, however, require the model of system dynamics, which is often not available in real-world applications (Kinjo et al., 2013).

In this paper, we propose to embed a KL-control problem in a probabilistic graphical model with mixed continuous and discrete variables. The continuous variables correspond to the (possibly high-dimensional) state of the system and the discrete variables correspond to a latent (low-dimensional) representation of the state which is amenable for KL control computation. The model parameters are first learned using data from the real system running with exploring controls. The control input to the real system is then computed as a filtering step combined with the solution of the KL-control problem in the latent space.

We present two examples of this approach: the first one uses a standard hidden Markov model (HMM) in which inference can be computed exactly, but is only applicable to low-dimensional continuous systems. The second one uses factorial HMMs (FHMMs)

and is applicable to higher dimensional problems, although optimal control can only be approximated. We illustrate both examples in several robot motor control tasks. In particular, we experimentally demonstrate that the second example with FHMMs is scalable to high-dimensional problems (e.g., 25 dimensional problem) that may not be solvable by other approaches.

2 KULLBACK LEIBLER CONTROL PROBLEMS

We briefly summarize the class of KL control problems introduced by Todorov (2006) in the infinite-horizon average-cost formulation (see also Todorov, 2009a).

Let $\mathcal{X} = \{1, \dots, N\}$ be a finite set of states and $\mathcal{U}(x)$ be a set of admissible control actions at state $x \in \mathcal{X}$. Consider the transition probability $p(x'|x)$ that describes the system dynamics in the absence of control. Such *uncontrolled dynamics* assigns zero probability for physically forbidden state transitions. Denote the transition probability given action $u \in \mathcal{U}(x)$ as $p(x'|x, u)$ and the immediate cost for being in state x and taking action u as $\ell(x, u) \geq 0$.

For infinite-horizon problems, the objective is to find a control law $u = \pi(x)$ that minimizes the average cost

$$\lim_{n \rightarrow \infty} \frac{1}{n} \mathbb{E} \left[\sum_{t=0}^{n-1} \ell(x_t, \pi(x_t)) \right] = \sum_x \Pi(x) \ell(x, \pi(x)) \quad (1)$$

where n is the number of time-steps and $\Pi(x) = \lim_{t \rightarrow \infty} p(x_t = x | x_0, \pi)$ is the stationary distribution of states under control law π , which we assume exists and is independent of x_0 , i.e., $p(x_t = x | x_0, \pi)$ is assumed ergodic.

The following Bellman equation defined for the (differential) cost-to-go function $v(x)$ minimizes Eq. (1)

$$c + v(x) = \min_{u \in \mathcal{U}(x)} \left\{ \ell(x, u) + \mathbb{E}_{x' \sim p(\cdot|x, u)} [v(x')] \right\}, \quad (2)$$

where c is the average cost that does not depend on the starting state.

Minimizing Eq. (2) is in general hard, but in some cases it can be done efficiently. KL control problems are a class of problems for which Eq. (2) becomes linear under the following assumptions:

(i) the controls directly specify state transition probabilities, i.e. $p(x'|x, u) = u(x'|x)$. The action vector $u(\cdot|x)$ is a probability distribution over next states given the current state x .

(ii) the immediate cost function has the following form

$$\ell(x, u) = \alpha q(x) + \text{KL}(u(\cdot|x) \parallel p(\cdot|x)),$$

where $q(x) \geq 0$ is an arbitrary state-dependent cost and KL is the Kullback Leibler divergence between the controlled and the uncontrolled dynamics, reflecting how much the control changes the normal behavior of the system. Parameter α allows to balance the two cost terms.

Define the exponentiated cost-to-go (desirability) function $z(x) = \exp(-v(x))$ and the linear operator

$$\mathcal{G}[z](x) = \sum_{x'} p(x'|x) z(x') = \mathbb{E}_{x' \sim p(\cdot|x, u)} [z(x')].$$

The resulting minimization takes the form

$$\min_{u \in \mathcal{U}(x)} \left\{ \alpha q(x) + \text{KL} \left(u(\cdot|x) \parallel \frac{p(\cdot|x)z(\cdot)}{\mathcal{G}[z](x)} \right) - \log \mathcal{G}[z](x) \right\}.$$

At the global minimum, the Bellman equation becomes

$$\exp(-c)z(x) = \exp(-\alpha q(x))\mathcal{G}[z](x)$$

or in matrix form

$$\lambda \mathbf{z} = \mathbf{G} \mathbf{P} \mathbf{z} \quad (3)$$

where \mathbf{G} is a $N \times N$ diagonal matrix with elements $\exp(-\alpha q(x))$ and $\lambda = \exp(-c)$. From Eq. (3), it follows that \mathbf{z} is any eigenvector of the matrix $\mathbf{G} \mathbf{P}$ with eigenvalue λ . The optimal average cost becomes $c = -\ln \lambda$. Thus, the minimal solution is given by the principal eigenvector of $\mathbf{G} \mathbf{P}$: the eigenvector \mathbf{z}^* with largest eigenvalue, which can be efficiently computed using the power iteration method (Todorov, 2006). The optimal control is given by

$$u^*(x'|x) = \frac{p(x'|x)\mathbf{z}^*(x')}{\mathcal{G}[\mathbf{z}^*](x)}. \quad (4)$$

3 LATENT KULLBACK LEIBLER CONTROL

The previously described framework is not directly applicable for continuous systems. For such cases, we propose to learn a discrete hidden representation and dynamics amenable for efficient computation from the observed continuous variables. Our approach can be summarized in the following three steps:

1. Learn a probabilistic graphical model from data samples obtained for the real system
2. Solve the KL control problem in the latent space of the probabilistic graphical model
3. Compute control in the observed space

This general method is directly applicable to arbitrary continuous state-action systems, while in this paper we focus on the following deterministic control-affine systems that typically describe discrete-time robot dynamics:

$$\mathbf{y}_{t+1} = \mathbf{y}_t + \Delta t (\mathbf{f}(\mathbf{y}_t) + \mathbf{B}(\mathbf{y}_t)\boldsymbol{\tau}_t), \quad (5)$$

where $\mathbf{y}_t \in \mathbb{R}^D$ is the state variable of the system, $\boldsymbol{\tau}_t \in \mathbb{R}^d$ is the control input, $\mathbf{f}(\mathbf{y}_t) \in \mathbb{R}^D$ is the uncontrolled dynamics, $\mathbf{B}(\mathbf{y}_t) \in \mathbb{R}^{D \times d}$ is the control matrix and Δt is the discrete-time step-size.

Two particular realizations of this general approach are described in the next section. The first one uses standard HMMs, which are the most natural way to model sequences of observations. However, it is only applicable to systems in which the relevant region of the state-space is small, such as low-dimensional systems, or largely constrained high-dimensional systems. The second one uses factorial HMMs, which assume factorized uncontrolled dynamics and can scale up to higher dimensional problems.

4 EXACT CONTROL COMPUTATION USING HIDDEN MARKOV MODELS

In this section, we describe an example of latent KL control based on standard hidden Markov models.

4.1 LEARNING HMMS FOR KL CONTROL

Consider the hidden Markov model with hidden states $x_t \in \{1, \dots, N\}$, stochastic state transition matrix \mathbf{P} with entries $P_{ij} = p(x_{t+1} = j | x_t = i)$ and Gaussian observation model $p(\mathbf{y}_t | x_t = k) = \mathcal{N}(\mu_k, \Sigma_k)$.

We generate sample trajectories $\mathcal{D} = \{\mathbf{y}_t, \dots, \mathbf{y}_T\}$ from the real system driven solely by exploration noise (uncontrolled dynamics) and use them to learn the parameters $\boldsymbol{\theta}_{\text{HMM}} = \{\mathbf{P}, \mu_{1:N}, \Sigma_{1:N}\}$. After learning, the matrix \mathbf{P} encodes a coarse description of the observed dynamics in a latent space and the Gaussian means and variances capture the relevant regions in this space. More precisely, considering the system of Eq. (5), we set exploration noise as $\boldsymbol{\tau}_t = \epsilon_t$ for $t = 1 \dots T$, where $\epsilon_t \in \mathbb{R}^d \sim \mathcal{N}(0, \Sigma_\epsilon)$. The choice of such a zero-mean Gaussian distribution is motivated by the relationship between the KL action cost and the input-norm cost: in the continuous setting the KL cost reduces to a quadratic energy cost (Todorov, 2009a; Kappen et al., 2012), which coincides with a commonly used input-norm cost for energy-efficient or smooth motor control behavior (Mitrovic et al., 2010).

The covariance matrix Σ_ϵ is a free parameter. For low exploration noise, one would expect the learned model to be a poor approximation since only a small fraction of the state space is visited. Conversely, large noise values would result in too flexible models with unrealistic state transitions. The correct noise value is therefore a trade-off between these two scenarios.

Given \mathcal{D} , the parameters $\boldsymbol{\theta}_{\text{HMM}}$ can be learned, for instance, using the standard Expectation-Maximization (EM) algorithm (Baum-Welch algorithm).

4.2 CONTROL COMPUTATION IN LATENT SPACE

To define a KL control problem in the latent space, we first need a state-dependent cost function expressed in terms of the latent variable x . Let $\tilde{q}(\mathbf{y}_t)$ and $q(x_t)$ be the cost functions in observation and latent spaces, respectively. We define $q(x_t)$ given $\tilde{q}(\mathbf{y}_t)$ using $\exp(-q(x_t)) = \int_{\mathbf{y}_t} \exp(-\alpha \tilde{q}(\mathbf{y}_t)) p(\mathbf{y}_t | x_t) d\mathbf{y}_t$. Furthermore, if $\tilde{q}(\mathbf{y}_t)$ is given in quadratic form $\tilde{q}(\mathbf{y}_t) = (\mathbf{y}_t - \mu_q)^T \Sigma_q^{-1} (\mathbf{y}_t - \mu_q) = \|\mathbf{y}_t - \mu_q\|_{\Sigma_q^{-1}}^2$ and the observation model is Gaussian $p(\mathbf{y}_t | x_t) = \mathcal{N}(\mu_x, \Sigma_x)$, we can obtain $q(x_t)$ analytically:

$$\begin{aligned} q(x_t) &= -\ln \left\{ \int_{\mathbf{y}_t} \exp(-\alpha \tilde{q}(\mathbf{y}_t)) p(\mathbf{y}_t | x_t) d\mathbf{y}_t \right\} \\ &= -\ln \left\{ \frac{|\mathbf{S}|^{1/2}}{|\Sigma_x|^{1/2}} \exp \left[-\frac{1}{2} \|\mu_q - \mu_x\|_{\mathbf{M}^{-1}}^2 \right] \right\} \end{aligned}$$

where, $\mathbf{S} = (\alpha \Sigma_q^{-1} + \Sigma_x^{-1})^{-1}$ and $\mathbf{M} = \alpha^{-1} \Sigma_q + \Sigma_x$.

The (latent) KL control problem can now be formulated using state cost $q(x_t)$ and uncontrolled dynamics \mathbf{P} as in Eq. (3). The optimal state transition $u^*(x_{t+1} | x_t)$ under controlled dynamics is given by Eq. (4).

4.3 CONTROL COMPUTATION IN OBSERVED SPACE

We are now ready to describe how to use latent KL control in the real system. Given an observation sequence $\mathbf{y}_{1:t}$ until time t , we can compute predictive distributions of the next observation \mathbf{y}_{t+1} under both the uncontrolled dynamics $p(x_{t+1} | x_t)$ and the optimally controlled dynamics $u^*(x_{t+1} | x_t)$ in the latent space as:

$$\begin{aligned} p(\mathbf{y}_{t+1} | \mathbf{y}_{1:t}) &= \sum_{x_{t:t+1}} p(\mathbf{y}_{t+1} | x_{t+1}) p(x_{t+1} | x_t) u(x_t | \mathbf{y}_{1:t}) \\ u(\mathbf{y}_{t+1} | \mathbf{y}_{1:t}) &= \sum_{x_{t:t+1}} p(\mathbf{y}_{t+1} | x_{t+1}) u^*(x_{t+1} | x_t) u(x_t | \mathbf{y}_{1:t}) \end{aligned}$$

where $u(x_t | \mathbf{y}_{1:t})$ denotes the filtered state at time t following the controlled process that evolves according to

$u^*(x'|x)$. Since we keep the previous filtered estimate $u(x_{t-1}|\mathbf{y}_{1:t-1})$, this computation is simply as

$$u(x_t|\mathbf{y}_{1:t}) = \frac{p(\mathbf{y}_t|x_t) \sum_{x_{t-1}} u^*(x_t|x_{t-1})u(x_{t-1}|\mathbf{y}_{1:t-1})}{u(\mathbf{y}_t|\mathbf{y}_{1:t-1})}.$$

We finally compute the control input command to the system such that the “difference” between the uncontrolled and optimal behaviors is reduced

$$\boldsymbol{\tau}_t = \mathbf{K}(\bar{\mathbf{y}}_{t+1|1:t}^u - \bar{\mathbf{y}}_{t+1|1:t}^p), \quad (6)$$

where $\bar{\mathbf{y}}_{t+1|1:t}^u$ and $\bar{\mathbf{y}}_{t+1|1:t}^p$ are the expectations of \mathbf{y} over $u(\mathbf{y}_{t+1}|\mathbf{y}_{1:t})$ and $p(\mathbf{y}_{t+1}|\mathbf{y}_{1:t})$ respectively and \mathbf{K} is a gain matrix to be tuned. The gain \mathbf{K} can be optimally computed if the model of system dynamics is available (Todorov, 2009b), however, in this paper we focus on the model-free scenario and leave it as a free parameter.

5 APPROXIMATE CONTROL USING FACTORIAL HIDDEN MARKOV MODELS

For high-dimensional problems that require to cover large regions of the state space, the previous approach becomes infeasible, since the cardinality required for the latent variable grows exponentially. In this section, we consider an alternative model with a multi-dimensional latent variable and constrained state transitions. We consider each dimension independent from the rest in the absence of control. These assumptions are naturally expressed using factorial HMMs. The advantage is that we can capture complex latent dynamics more efficiently. The price to pay is that exact optimal control computation in the latent space is no longer feasible and different approximation schemes have to be used. We describe this approach in the following sections.

5.1 FACTORIAL HIDDEN MARKOV MODELS

FHMM is a special type of HMM to model sequences of observations originated from multiple latent dynamical processes that interact to generate a single output (Ghahramani and Jordan, 1997; Murphy, 2012). The state is represented by a collection of variables $\mathbf{x}_t = \{x_t^{(1)}, \dots, x_t^{(m)}, \dots, x_t^{(M)}\}$ each of them having K possible values. The latent state \mathbf{x}_t is thus a M -dimensional variable with K^M possible values.

We will use a 1-of- K encoding, such that each state component $\mathbf{x}_t^{(m)}$ will be denoted using a $K \times 1$ vector, where each of the K discrete values corresponds to a 1 in one position and 0 elsewhere.

The assumption is that the transition model factorizes among the individual components

$$p(\mathbf{x}_t|\mathbf{x}_{t-1}) = \prod_{m=1}^M p^{(m)}(\mathbf{x}_t^{(m)}|\mathbf{x}_{t-1}^{(m)}), \quad (7)$$

where $p^{(m)}(\mathbf{x}_t^{(m)}|\mathbf{x}_{t-1}^{(m)})$ is the state transition matrix $\mathbf{P}^{(m)}$ for the m -th chain. We assume the Gaussian observation model, which is defined as

$$p(\mathbf{y}_t|\mathbf{x}_t) = \mathcal{N}\left(\sum_{m=1}^M \mathbf{W}^{(m)} \mathbf{x}_t^{(m)}, \Sigma\right) \quad (8)$$

where $\mathbf{W}^{(m)}$ is a $D \times K$ weight matrix that contains in its columns the contributions to the means for each of the possible configurations of $\mathbf{x}_t^{(m)}$. The marginal over \mathbf{y}_t is thus a Gaussian mixture model, with K^M Gaussian mixture components, each having a constant covariance matrix Σ .

The parameters $\boldsymbol{\theta}_{\text{FHMM}} = \{\mathbf{P}^{1:M}, \mathbf{W}^{1:M}, \Sigma\}$ can be learned using EM, as before. In this case, however, the E-step becomes intractable, since the forward-backward step has time complexity $O(TMK^{M+1})$. An alternative approximation that works well in practice is the structured mean field approximation, which has time complexity $O(TMK^2I)$, where I is the number of mean field iterations (see Ghahramani and Jordan, 1997; Murphy, 2012, for details).

5.2 CONTROL COMPUTATION IN LATENT SPACE

In a similar way as in Section 4.2, we need first to define a cost function in the latent space $q(\mathbf{x}_t)$ to be able to formulate a KL control problem. A natural way to define $q(\mathbf{x}_t)$ given the observation model of Eq. (8) and the cost function in observation space $\tilde{q}(\mathbf{y}_t)$ is

$$q(\mathbf{x}_t) = \alpha \tilde{q}\left(\sum_{m=1}^M \mathbf{W}^{(m)} \mathbf{x}_t^{(m)}\right). \quad (9)$$

Computing the exact optimal control using Eq. (3) in FHMMs requires to transform the model into a single chain model with K^M states, which is intractable. We assume approximate controlled dynamics $u_{\text{ap}}(\mathbf{x}_t|\mathbf{x}_{t-1})$ and associated stationary distribution $\Pi_{\text{ap}}(\mathbf{x}_t)$ that factorize in its components:

$$u_{\text{ap}}(\mathbf{x}_t|\mathbf{x}_{t-1}) = \prod_{m=1}^M u_{\text{ap}}^{(m)}(\mathbf{x}_t^{(m)}|\mathbf{x}_{t-1}^{(m)})$$

$$\Pi_{\text{ap}}(\mathbf{x}_t) = \prod_{m=1}^M \Pi_{\text{ap}}^{(m)}(\mathbf{x}_t^{(m)}).$$

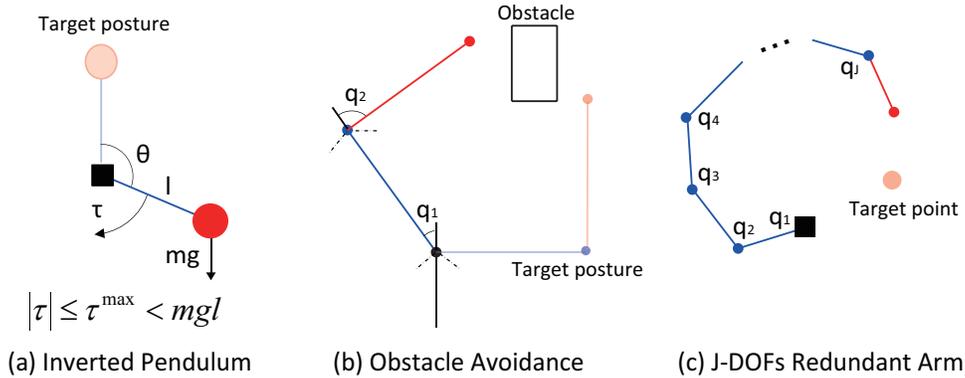

Figure 1: Motor control problems with simulated robots: **(a) Pendulum swing up with limited torque.** The state variable is $\mathbf{y} = [\theta, \omega]^T$ where $\omega = \dot{\theta}$, $|\theta| \leq \pi$, $|\omega| \leq 4\pi$. The control input is the torque at the joint τ . Uncontrolled dynamics and control matrix are given as $\mathbf{f}(\mathbf{y}) = [0 \ 1; g \sin(\theta)/l \ \mu/\omega]$, $\mathbf{B}(\mathbf{y}) = 1/ml^2$, respectively. Parameters values are $m = l = 1$, $g = 9.8$, $\mu = 0.25$ and $\tau^{\max} = 5.0$ that satisfies $\tau^{\max} < mgl$; **(b) Robot arm control with obstacle.** The state variable is $\mathbf{y} = [q_1, q_2]^T \in \mathcal{S}$ where \mathcal{S} is the state space that satisfies the joint angle limits and no collisions with the obstacle. The control input is $\boldsymbol{\tau} = \dot{\mathbf{y}}$. The uncontrolled dynamics and control matrix are $\mathbf{f}(\mathbf{y}) = [0, 0]^T$ and $\mathbf{B}(\mathbf{y}) = I_D$; **(c) Multi-DOF redundant arm reaching task.** The state variable is $\mathbf{y}_t = [q_1(t), \dots, q_J(t)]^T$, $q_i(t) \in \mathcal{S}$ is the i -th joint angle and \mathcal{S} is the state space that satisfies the joint angle limit $-0.5\pi \leq q_i(t) \leq 0.5\pi$. The control input, uncontrolled dynamics and control matrix are as in (b), but for J dimensions. In all examples we use first-order Euler method for numerical integration.

These assumptions imply that the KL cost term can also be decomposed such that Eq. (1) becomes

$$\sum_{\mathbf{x}_t} \prod_{m=1}^M \Pi_{\text{ap}}^{(m)}(\mathbf{x}_t^{(m)}) \times \left(q(\mathbf{x}_t) + \sum_{m=1}^M \text{KL} \left(u_{\text{ap}}^{(m)}(\cdot | \mathbf{x}_t^{(m)}) \parallel p^{(m)}(\cdot | \mathbf{x}_t^{(m)}) \right) \right). \quad (10)$$

We can minimize Eq. (10) iteratively using sequential updates: for each chain m , update the parameters $u_{\text{ap}}^{(m)}$ and $\Pi_{\text{ap}}^{(m)}$ assuming the parameters for the other chains fixed so that it minimizes the marginal state-dependent cost

$$Q^{(m)}(\mathbf{x}_t^{(m)}) = \sum_{\mathbf{x}_t^{(i)}, i \neq m} \prod_{i \neq m} \Pi_{\text{ap}}^{(i)}(\mathbf{x}_t^{(i)}) q(\mathbf{x}_t) \quad (11)$$

and the corresponding KL cost. Each update corresponds to a sub-problem of the type of Eq. (3) and can be solved as a principal eigenvector problem. The average cost monotonically decreases at each iteration and its convergence is guaranteed. We call this scheme *Variational KL minimization (VKL)*.

Note however, **VKL** requires summing over all the values of the $M - 1$ chains to obtain the marginal state-dependent cost, and thus it has time complexity $O(K^{M-1})$, which is still intractable. We further

approximate this computation by taking the expected state of the other chains according to their individual stationary distributions

$$Q^{(m)}(\mathbf{x}_t^{(m)}) \approx \alpha \tilde{q} \left(\mathbf{W}^{(m)} \mathbf{x}_t^{(m)} + \sum_{i \neq m} \mathbf{W}^{(i)} \Pi_{\text{ap}}^{(i)} \right), \quad (12)$$

where $\Pi_{\text{ap}}^{(i)}$ is a K -dimensional vector with the stationary distribution of chain i . Evaluation of Eq. (12) only requires $O(KM)$ steps, and it is therefore tractable. We refer this approximation as *Approximate Variational KL minimization (AVKL)*.

We refer to the control computed using either **VKL** and **AVKL** as u_{ap}^* in the rest of this section.

5.3 CONTROL COMPUTATION IN OBSERVED SPACE

Having approximated our optimal control law in the latent space, we need to define a control law for the real (observed) system given sequence of observations $\mathbf{y}_{1:t}$. We follow the same approach as in Section 4.3. First, we obtain estimates for the expected values of the next observed state under both controlled and uncontrolled dynamics as $\bar{\mathbf{y}}_{t+1|1:t}^u$ and $\bar{\mathbf{y}}_{t+1|1:t}^p$, respectively. Second, we apply the controller of Eq. (6).

The first step requires to solve a filtering problem to obtain $u(\mathbf{x}_t|\mathbf{y}_{1:t})$, which is intractable for this model. We use an approximate approach based on structured mean field, as in the model learning step (Section 5.1, E-step). However, instead of keeping the last filtered estimate $u(\mathbf{x}_{t-1}|\mathbf{y}_{1:t-1})$ as before, we keep the filtered estimate at time-step $t-H$, i.e. $u(\mathbf{x}_{t-H}|\mathbf{y}_{1:t-H})$ and perform *offline* structured mean field using the last H observations $\mathbf{y}_{t-H:t}$. This approach improves considerably the accuracy of the filtered estimates $u(\mathbf{x}_t|\mathbf{y}_{1:t}) = \prod_m u^{(m)}(\mathbf{x}_t^{(m)}|\mathbf{y}_{1:t})$ and at the same time, it is more efficient than structured mean field on the entire sequence of past observations.

Once we have filtered estimates of the latent state, the expectation of \mathbf{y}_{t+1} over predictive distribution $u(\mathbf{y}_{t+1}|\mathbf{y}_{1:t})$ can be approximated using samples

$$\begin{aligned} \bar{\mathbf{y}}_{t+1|1:t}^u &= \int \mathbf{y}_{t+1} u(\mathbf{y}_{t+1}|\mathbf{y}_{1:t}) d\mathbf{y}_{t+1} \\ &\approx \frac{1}{L} \sum_{\mu=1}^L \sum_{m=1}^M \mathbf{W}^{(m)} \hat{\mathbf{x}}_{\mu}^{(m)} \end{aligned}$$

where $\hat{\mathbf{x}}_{\mu}^{(m)}$ are samples drawn from the posterior distribution of the latent component according to the approximated controlled dynamics

$$\begin{aligned} \hat{\mathbf{x}}_{\mu}^{(m)} &\sim u^{(m)}(\mathbf{x}_{t+1}^{(m)}|\mathbf{y}_{1:t}) \\ &= \sum_{\mathbf{x}_t^{(m)}} u_{\text{ap}}^{*,(m)}(\mathbf{x}_{t+1}^{(m)}|\mathbf{x}_t^{(m)}) u^{(m)}(\mathbf{x}_t^{(m)}|\mathbf{y}_{1:t}). \end{aligned} \quad (13)$$

Similarly, we can estimate $\bar{\mathbf{y}}_{t+1|1:t}^p$ using samples from

$$p^{(m)}(\mathbf{x}_{t+1}^{(m)}|\mathbf{y}_{1:t}) = \sum_{\mathbf{x}_t^{(m)}} p^{(m)}(\mathbf{x}_{t+1}^{(m)}|\mathbf{x}_t^{(m)}) u^{(m)}(\mathbf{x}_t^{(m)}|\mathbf{y}_{1:t}).$$

We show in the next section that for relatively small values of the window length H and the number of samples L , the resulting controls are satisfactory.

6 SIMULATION RESULTS

In this section, we apply our method to three benchmark (simulated) robot motor control problems: (a) pendulum swing-up with limited torque (Doya, 2000), (b) robot arm control with obstacles (Sugiyama et al., 2007), and (c) multi-degrees of freedom (DOF) redundant arm reaching task (Theodorou et al., 2010). Figure 1 illustrates these problems. The first two examples correspond to the approach using HMMs of Section 4 whereas the third shows an application using FHMMs as described in Section 5.

For learning the HMM parameters, we use identical and independent exploration noise in all controlled dimensions parameterized by σ_{ϵ}^2 , i.e. $(\Sigma_{\epsilon})_{ij} = \delta_{ij}\sigma_{\epsilon}^2$.

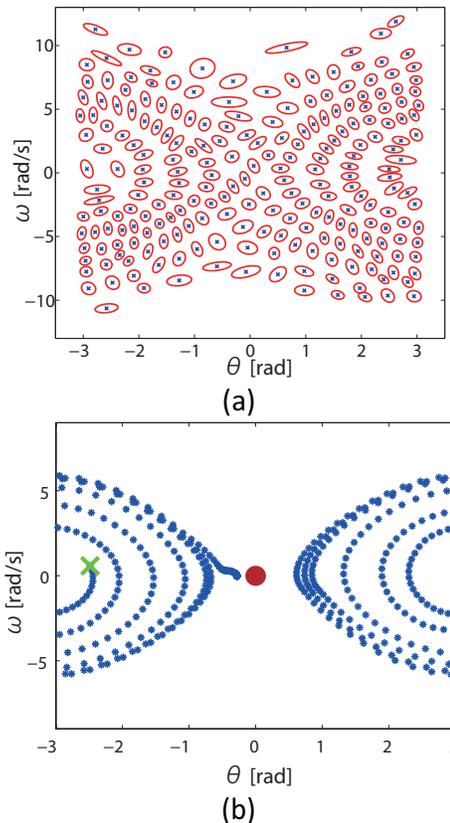

Figure 2: Pendulum swing-up task results: (a) Observation model after learning the HMM with $N = 225$ hidden states and $\sigma_{\epsilon} = 1.5$. Each hidden state corresponds to a two-dimensional Gaussian distribution with mean indicated by a cross and contour with equal probability density shown as an ellipse. (b) Typical controlled behaviour in the phase plane. The cross and the circle show initial and target states respectively.

Both tasks consider a two-dimensional observed continuous state and a one-dimensional latent variable. The complexity of the method strongly depends on the number of hidden values N . For this experiments, we simply choose N large enough ($N = 255$ in both scenarios) to obtain a model that accurately describes the system dynamics. We learn the full parameter vector θ_{HMM} using EM with K-means initialization for the Gaussian means.

6.1 PENDULUM SWING-UP TASK

This is a non-trivial problem when the maximum torque τ^{\max} is smaller than the maximal load torque mgl . The optimal control requires to take an energy-efficient strategy: swing the pendulum several times to build up momentum and also decelerate the pendulum early enough to prevent it from falling over.

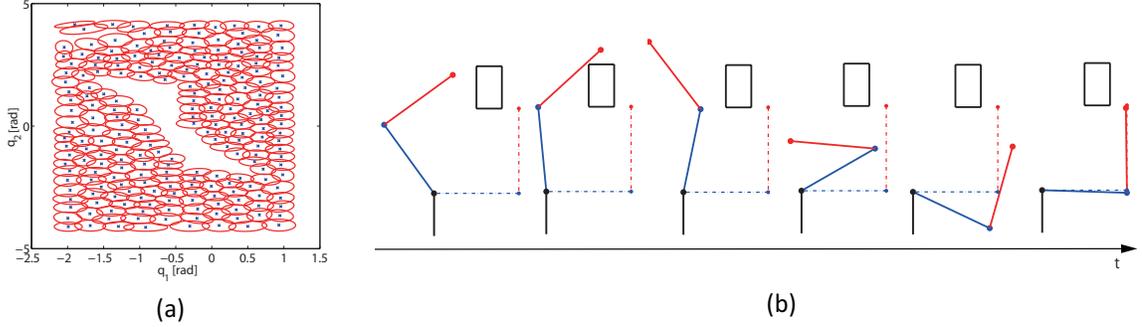

Figure 3: Results on the robot arm with an obstacle. **(a)** Learned HMM with $N = 225$, $\Sigma_\epsilon = \text{diag}\{1.5, 1.5\}$ and $T = 3 \cdot 10^4$ samples. **(b)** Controlled robot arm behavior at different time steps. The robot successfully reaches the target posture avoiding the obstacle.

Fig. 2(a) shows the 2-dimensional observation model after learning with exploration noise $\sigma_\epsilon^2 = 1.5$. We can see that the HMM is able to capture a discrete, coarse representation of the continuous state.

For control computation, we define a quadratic cost $\tilde{q}(\mathbf{y}_t) = \mathbf{y}^T \Sigma_q^{-1} \mathbf{y}$, where $\Sigma_q = \text{diag}\{0.005, 0.02\}$, and set the scale parameter $\alpha = \alpha_0 \Delta t / \sigma_\epsilon^2$ to prevent the scaling effect of the exploration noise variance σ_ϵ^2 in the KL cost ($\alpha_0 = 0.2$). The gain matrix is $\mathbf{K} = \text{diag}\{50, 10\}$. The eigenvector computation only takes $3 \cdot 10^{-2}$ seconds¹. The computation of control input (see Section 4.3) takes $3 \cdot 10^{-3}$ seconds per time-step. The resulting controller successfully maintains the pendulum in a region of $|\theta| \leq 0.5$ continuously in all tested random initializations and it is optimal in terms of energy-efficiency. A typical controlled behavior of the pendulum is shown in Fig. 2(b).

For comparison, we also implemented standard value iteration (VI) (Sutton and Barto, 1998), which requires knowledge of the true pendulum dynamics and uses a fully discretized state-action space. For consistency, we choose as a cost function $r(\mathbf{y}, \mathbf{u}) = \alpha \tilde{q}(\mathbf{y}_t) + \frac{1}{2} \|\mathbf{u}\|^2$ and the same error tolerance 10^{-8} for both value iteration method and power method. VI requires a very fine discretization ($N \geq 1225$ states) and at least 20 seconds of CPU-time, which are roughly an order of magnitude larger than the values obtained using the proposed method.

6.2 ROBOT ARM CONTROL WITH OBSTACLE

In this second task, we aim to control a two-joint robot arm from an initial posture to the target posture while avoiding an obstacle. The presence of the obstacle

makes this task difficult to solve using standard trajectory interpolation methods, see Fig. 1(b) for details.

Fig. 3(a) shows the 2D observation model learned using the same setup as before. As the empty region in the middle of the plot indicates, the model successfully captures the physically impossible state transitions that would bring the robot arm through the obstacle.

For this problem, we set the cost function as $\tilde{q}(\mathbf{y}_t) = (\mathbf{y} - \mathbf{g})^T \Sigma_q^{-1} (\mathbf{y} - \mathbf{g})$, where $\Sigma_q = \text{diag}\{0.01, 0.01\}$ and $\mathbf{g} = [-\pi/2, \pi/2]^T$. In this case, we use $\alpha_0 = 0.05$ and $\mathbf{K} = \text{diag}\{3.0, 0.5\}$ to set the scale parameter and the gain matrix, respectively. Computation time of the optimal control is approximately 0.03 seconds using the same specifications as in the previous example. Fig. 3(b) illustrates the typical controlled robot behavior. The robot arm first decreases the angle q_2 and then modifies q_1 reaching the target posture while successfully avoiding the obstacle.

6.3 REACHING TASK

The third task consists of a multi-DOF planar robot arm with J joints and joint-limit constraints as shown in Fig. 1(c). The J joints are of equal length $l = 1$ and connected to a fixed base. Each joint dynamics of this robot model is decoupled, and therefore suitable for our method using FHMMs.

The goal is to control the joint angles to reach a target position $\mathbf{t}^{\text{target}}$ with the end-effector of the robot arm. For $J \gg 2$ the control policy has to make a choice among many possible trajectories in the joint space. Moreover, considering joint-limit constraints limits direct application of standard methods for inverse kinematic, e.g. Jacobian inverse techniques (Yoshikawa,

¹Core-i7 2.8GHz-CPU, 8GB memory and MATLAB.

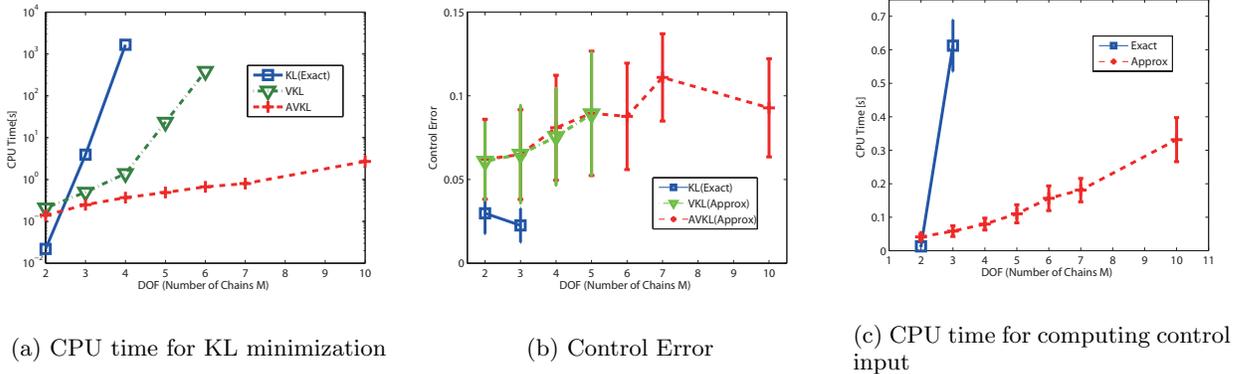

Figure 4: **Multi-DOF robot reaching task:** Comparison between **KL(exact)**, **VKL** and **AVKL**. **VKL** and **AVKL** can efficiently compute near optimal controller comparable to exact KL minimization. **AVKL** scales to high-dimensional problems. **KL(exact)** and **VKL** are only feasible for $J < 4$ and $J < 6$, respectively.

1990). The cost function for this task is

$$\tilde{q}(\mathbf{y}) = \|\mathbf{t}^{\text{target}} - \mathbf{T}(\mathbf{y})\|, \quad (14)$$

where $\mathbf{T}(\cdot)$ is the forward kinematics model that maps a joint angle vector to the corresponding end-effector position in the task space

$$\mathbf{T}(\mathbf{y}) = \begin{bmatrix} \sum_{n=1}^J \cos\left(\sum_{j=1}^n y_j\right) \\ \sum_{n=1}^J \sin\left(\sum_{j=1}^n y_j\right) \end{bmatrix}.$$

Although the dynamics decouples for each joint, the cost function couples all the joint angles making the problem difficult.

We analyze the scaling properties with the number J of degrees of freedom, comparing the different strategies described in Section 5.2: **KL(exact)** minimization, **VKL** and **AVKL**. The exact solution uses K^M states and performs exact inference. For approximate methods, we use as many latent dimensions (chains) as joints $M = J$, with $K = 20$ and $H = 2J$ time-steps for approximate filtering. Note that M could be smaller than J , as long as the learned hidden representation captures well the underlying structure and dynamics. We set $M = J$ to simplify the evaluation.

Convergence of variational eigen-computations **VKL** and **AVKL** is reached after approximately 10 iterations in this task (each iteration requires an update of all the parameters of the J joints). Learning the parameters of the FHMM is sensitive to local minima. In practice, we choose $\mathbf{W}^{(m)}$ so that each factored state represents each joint dynamics and only learn the uncontrolled dynamics (transition probabilities). Also, $\mathbf{t}^{\text{target}}$ is set to one of the $\mathbf{w}_i^{(m)}$ to prevent space quantization errors in this comparison.

Fig. 4 illustrates the comparison. Whereas **KL(exact)** and **VKL** are only feasible for $J < 5$ and $J < 7$ respectively, **AVKL** is applicable to a larger number of joints. Fig. 4(a) shows CPU-time for control computation in the latent space (Section 5.2), which scales exponentially for both **KL(exact)** and **VKL** and approximately linear for **AVKL**.

Fig. 4(b) shows the error Eq. (14) averaged over 200 trials with randomly initialized joints. Although exact control computation can be performed for $M < 5$, exact inference is only possible for $M < 4$. We can observe that the resulting controls are satisfactory and errors do not differ significantly between **VKL** and **AVKL**. Notice that the **AVKL** error remains approximately constant as a function of M .

Fig. 4(c) shows CPU-time for the control computation in the observed space (Section 5.3). While CPU-time for exact computation quickly increases, our approximate approach results in a roughly linear increase.

Examples of controlled robot behaviors for a different number of degrees of freedom are shown in Fig. 5. In all cases, the robot successfully reaches the goal while satisfying the joint-limit constraints starting from several initial postures.

From these results we can conclude that it is feasible to learn FHMMs for high-dimensional systems with uncoupled uncontrolled dynamics and that latent KL control is an effective method to near-optimally control such systems.

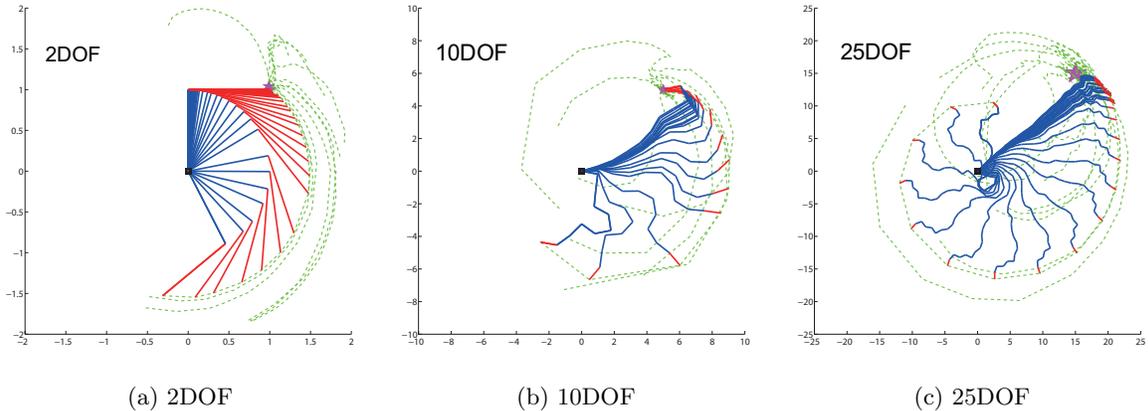

Figure 5: **Multi-DOF robot reaching task:** Examples of robot trajectories. The arm successfully reaches the target position while satisfying the joint-limit constraints from several initializations. Green lines show end-effector trajectories for different initializations. Blue and red lines indicate intermediate and end links.

7 DISCUSSION

We have proposed a novel solution that combines the KL control framework with probabilistic graphical models in the infinite horizon, average cost setting. Our approach learns a coarse, discrete representation amenable for efficient computation to near-optimally control continuous-state systems. We have presented two examples, using hidden Markov models (HMMs) and factorial HMMs (FHMMs), and we have shown evidence that our proposed method is feasible in three robotic tasks. In particular, we have demonstrated that the second example with FHMMs is scalable to higher dimensional problems.

The presented latent KL control approach (with HMMs) resembles the one of Zhong and Todorov (2011a) which considers an “aggregated” space similar to the latent space of the HMM. However, note that whereas for Zhong and Todorov (2011a) the real model is *required in the observed space*, in our case we *learn an approximate* model in which observations are coupled through the latent variables. Their main computational bottleneck is the “double” numerical integration over the observed space for computing the “aggregated” state transition probability. In our case, we replace such a problem by a probabilistic graphical model learning problem.

The control performance strongly depends on the quality of the learned model, which requires choosing a proper exploration noise and a proper initialization of the graphical model parameters. Current work is focused in alternative learning methods that efficiently sample interesting regions of the state space and exploit the ergodic nature of the problems. Extension to more complex scenarios is also being considered.

Abstract

Scientists often express their understanding of the world through a computationally demanding simulation program. Analyzing the posterior distribution of the parameters given observations (the inverse problem) can be extremely challenging. The Approximate Bayesian Computation (ABC) framework is the standard statistical tool to handle these likelihood free problems, but they require a very large number of simulations. In this work we develop two new ABC sampling algorithms that significantly reduce the number of simulations necessary for posterior inference. Both algorithms use confidence estimates for the accept probability in the Metropolis Hastings step to adaptively choose the number of necessary simulations. Our GPS-ABC algorithm stores the information obtained from every simulation in a Gaussian process which acts as a surrogate function for the simulated statistics. Experiments on a challenging realistic biological problem illustrate the potential of these algorithms.

1 Introduction

The morphogenesis of complex biological systems, the birth of neutrons stars, and weather forecasting are all natural phenomena whose understanding relies deeply upon the interaction between simulations of their underlying processes and their naturally observed data. Hypotheses that posit the generation of observations evolve after critical evaluation of the match between simulation and observation.

This hypothesis–simulation–evaluation cycle is the foundation of *simulation-based modeling*. For all but the most trivial phenomena, this cycle is grossly inefficient. A typical simulator is a complex computer program with a potentially large number of interacting parameters that not

only drive the simulation program, but are also often the variables of scientific interest because they play a role in explaining the natural phenomena. Choosing an optimal value setting for these parameters can be immensely expensive.

While a single, optimal parameter setting may be useful to scientists, often they are more interested in the *distribution* of parameter settings that provide accurate simulation results [20, 3, 18]. The interaction between parameters can provide insight regarding not only the properties of the simulation program, but more importantly, the underlying phenomena of interest. The main challenges that we address in this paper are 1) simulation-based modeling in a *likelihood-free* setting (we do not have a model in the typical machine learning sense, and therefore we do not have a standard likelihood function), and 2) running simulations is very expensive.

The first challenge is partly addressed by the *approximate Bayesian computation* (ABC) approach to sampling in likelihood-free scenarios [25, 5]. The ABC approach will be described in a later section, but in short it uses the distance between simulated and observed data as a proxy for the likelihood term in the parameter posterior. ABC provides the necessary framework to make progress in simulation-based modeling, but it is a very inefficient approach, even on simple problems.

The second challenge is approached with a surrogate model in mind. This means that every simulation (parameters and result) is stored and used to maintain a surrogate of the mapping from parameters to result. By carefully constructing an approximate Markov chain Monte Carlo (MCMC) sampler, we are able to sample from the parameter distribution in such a way that our sampling error is controlled and decreases over time. The main advantage of this approach is that by accepting some bias, we are able to very efficiently sample from the approximate posterior because parameters can sometimes be accepted within MCMC with high confidence by relying on the surrogate and thus avoiding expensive simulations.

In this paper we present a procedure for approximate Bayesian inference using a Gaussian process surrogate for expensive simulation-based models. In our approach, simulations that are run over the course of the inference procedure are incorporated into a GP model, gradually improving the surrogate over time. Using MCMC with a Metropolis-Hastings (MH) accept/reject rule, our method uses the surrogate and its uncertainty to make all MH decisions. The key insight is that the uncertainty in the acceptance probability is used to determine if simulations are required to confidently proceed to the MH step. If the uncertainty is high, and we are likely to make an error, then more simulations are run.

2 Approximate Bayesian Computation

The current state-of-the-art for simulation-based model inference is *likelihood-free* or *approximate Bayesian computation* methods [23, 15]. In this section we briefly introduce likelihood-free inference with a focus on MCMC inference procedures as our modeling approach will extend naturally from this work.

In likelihood-free sampling, we do not have a model in the typical sense. Instead, we have access to a simulator that generates pseudo-data that, given an accurate model of the world, look like the observations. The goal is to infer the parameters of the simulator which produce accurate pseudo-data. Importantly, we do not have access to a tractable likelihood function. We now describe in detail the likelihood-free set-up and in particular MCMC sampling techniques.

One of the primary goals of Bayesian inference is to infer the posterior distribution of latent variables θ using its prior $\pi(\theta)$ and its data likelihood $\pi(\mathbf{y}|\theta)$:

$$\pi(\theta|\mathbf{y}) = \frac{\pi(\theta)\pi(\mathbf{y}|\theta)}{\int \pi(\theta)\pi(\mathbf{y}|\theta)d\theta} \quad (1)$$

where θ is a vector of latent parameters and \mathbf{y} is the observed data set. In simulation-based modeling, we do not have access to the likelihood $\pi(\mathbf{y}|\theta)$. Instead our model of the world consists of a simulator that generates samples $\mathbf{x} \stackrel{\text{sim}}{\sim} \pi(\mathbf{x}|\theta)$ (where we indicate that the simulator was run with parameters θ and returns pseudo-data \mathbf{x}). Simulation results \mathbf{x} are then compared with the observations \mathbf{y} through a distribution $\pi_\epsilon(\mathbf{y}|\mathbf{x}, \theta)$, which measures how similar \mathbf{x} is to \mathbf{y} . The distribution is parameterized by ϵ which controls the acceptable discrepancy between \mathbf{x} and \mathbf{y} . We can thus approximately infer the posterior distribution as

$$\pi_\epsilon(\theta|\mathbf{y}) = \frac{\pi(\theta)}{\pi(\mathbf{y})} \int \pi_\epsilon(\mathbf{y}|\mathbf{x})\pi(\mathbf{x}|\theta)d\mathbf{x} \quad (2)$$

This approximate posterior is only equal to the true posterior for $\pi_{\epsilon=0}(\mathbf{y}|\mathbf{x}) = \delta(\mathbf{y}, \mathbf{x})$ where $\delta(\cdot)$ is the delta-

function. For the exact posterior, one could apply a rejection sampling procedure that would repeatedly sample $\theta \sim \pi(\theta)$, run a simulation $\mathbf{x} \stackrel{\text{sim}}{\sim} \pi(\mathbf{x}|\theta)$, then accept θ only if it equals \mathbf{y} . For continuous data, ϵ acts as a slack variable because equality cannot be achieved. However, we prefer small ϵ because this will improve our approximation to the true posterior. Unfortunately, there remains an unavoidable trade-off between approximation bias (large for large ϵ) and rejection rate (large for small ϵ).

2.1 Marginal and Pseudo-Marginal ABC

Instead of the rejection sampler described in the previous section (which is hopeless in high dimensions), we now describe two MCMC procedures, the marginal sampler and the pseudo-marginal sampler [2]. At every iteration of MCMC we propose a new $\theta' \sim q(\theta'|\theta)$. Next we generate S samples $\mathbf{x}'_s \stackrel{\text{sim}}{\sim} \pi(\mathbf{x}'|\theta')$, $s = 1..S$ from the simulator. From these samples we approximate the marginal likelihood as follows,

$$\pi_\epsilon(\mathbf{y}|\theta') = \int \pi_\epsilon(\mathbf{y}|\mathbf{x})\pi(\mathbf{x}|\theta')d\mathbf{x} \approx \frac{1}{S} \sum_{s=1}^S \pi_\epsilon(\mathbf{y}|\mathbf{x}^{(s)}, \theta') \quad (3)$$

We accept the proposed parameter θ' with probability equal to,

$$\alpha(\theta'|\theta) = \min \left(1, \frac{\pi(\theta') \sum_s \pi_\epsilon(\mathbf{y}|\mathbf{x}^{(s)}, \theta') q(\theta|\theta')}{\pi(\theta) \sum_s \pi_\epsilon(\mathbf{y}|\mathbf{x}^{(s)}, \theta) q(\theta'|\theta)} \right) \quad (4)$$

where the estimate of the marginal likelihood in the denominator (based on $\{\mathbf{x}_s, \theta\}$) is carried over from the previous iteration. It can be shown that this algorithm is an instance of the more general pseudo-marginal procedure [2] because the estimate of the marginal likelihood is unbiased. From this we can immediately infer that this Markov chain converges to the posterior $\pi_\epsilon(\theta|\mathbf{y})$. Interestingly, there is an alternative view of this sampler [22] that interprets it as a Markov chain over the extended state $\{\theta, \mathbf{x}_1, \dots, \mathbf{x}_S\}$ which also leads to the conclusion that the samples θ will asymptotically follow the distribution $\pi_\epsilon(\theta|\mathbf{y})$.

Unfortunately, it is well known that pseudo-marginal samplers can suffer from slow mixing. In particular, when through a ‘‘lucky’’ draw our marginal likelihood estimate in Eqn. 3 attains a large value, then it is very difficult for the sampler to mix away from that state. To avoid this behavior it is sometimes beneficial to re-estimate the denominator (as well as the numerator) in every iteration. This procedure is more expensive and does not guarantee convergence to $\pi_\epsilon(\theta|\mathbf{y})$ (unless $S \rightarrow \infty$), but can result in much better mixing. We will call this the marginal LF MCMC method [2].

While for the pseudo-marginal approach we can interpret the fluctuations induced by estimating the $\pi(\mathbf{y}|\theta)$ from a

finite sample set as part of randomly proposing a new state, this is no longer true for the approximate marginal MCMC. For the latter it is instructive to study the uncertainty in the acceptance probability $\alpha(\theta'|\theta)$ due to these fluctuations: repeatedly estimating $\pi(\mathbf{y}|\theta)$ with S samples will produce a distribution over α . Clearly for small S the distribution will be wider while for very large S it will approach a delta peak. Our approach uses this distribution directly to determine the confidence in the MH accept step, allowing it to implicitly set S based on the local uncertainty. This will be discussed further in next sections.

Besides the marginal and pseudo-marginal approaches to ABC, there is a large body of work using sequential Monte Carlo sampling to approach this problem [21, 4, 26].

3 The Synthetic Likelihood

We next discuss the approximation introduced by Wood [29], who models the simulated pseudo-data $\{\mathbf{x}_1, \dots, \mathbf{x}_S\}$ at θ using a normal distribution, i.e. $\pi(\mathbf{x}|\theta) \approx \mathcal{N}(\mathbf{x}|\hat{\boldsymbol{\mu}}_\theta, \hat{\boldsymbol{\Sigma}}_\theta)$. We will later replace this with a Gaussian process. The procedure is very simple: we draw S samples from our simulator and compute first and second order statistics,

$$\hat{\boldsymbol{\mu}}_\theta = \frac{1}{S} \sum_s \mathbf{x}^{(s)} \quad (5)$$

$$\hat{\boldsymbol{\Sigma}}_\theta = \frac{1}{S-1} \sum_s (\mathbf{x}^{(s)} - \hat{\boldsymbol{\mu}}_\theta) (\mathbf{x}^{(s)} - \hat{\boldsymbol{\mu}}_\theta)^T \quad (6)$$

Using estimators $\hat{\boldsymbol{\mu}}_\theta$ and $\hat{\boldsymbol{\Sigma}}_\theta$ we set $\pi(\mathbf{x}|\theta) = \mathcal{N}(\hat{\boldsymbol{\mu}}_\theta, \hat{\boldsymbol{\Sigma}}_\theta)$. Moreover, if we use a Gaussian kernel, then

$$\pi_\epsilon(\mathbf{y}|\mathbf{x}) = K_\epsilon(\mathbf{y}, \mathbf{x}) = \frac{1}{(2\pi\epsilon)^{J/2}} e^{-\frac{1}{2\epsilon^2}(\mathbf{x}-\mathbf{y})^T(\mathbf{x}-\mathbf{y})} \quad (7)$$

where J is the dimension of \mathbf{y} , we can then analytically integrate over \mathbf{x} in Eqn 2 giving the *synthetic-ABC* likelihood:

$$\pi(\mathbf{y}|\theta) = \int K_\epsilon(\mathbf{y}, \mathbf{x}) \mathcal{N}(\hat{\boldsymbol{\mu}}_\theta, \hat{\boldsymbol{\Sigma}}_\theta) d\mathbf{x} \quad (8)$$

$$= \mathcal{N}(\hat{\boldsymbol{\mu}}_\theta, \hat{\boldsymbol{\Sigma}}_\theta + \epsilon^2 \mathbf{I}) \quad (9)$$

which has the satisfying result that likelihood of $\mathbf{y}|\theta$ is the density under a Gaussian model at each simulation parameter setting θ .

This approximation has two advantages. First, we can take the limit $\epsilon \rightarrow 0$.¹ This implies that the bias introduced by the need to use a distribution $\pi_\epsilon(\mathbf{y}|\theta)$ to measure the similarity between simulations \mathbf{x} and observations \mathbf{y} is now

¹We may not always want to do this as ϵ^2 acts both as a prior over and a smoother of the likelihood. In practice, smoothing the likelihood may be necessary for mixing, and likewise, we may have access to a prior which could make the sampler more robust.

removed. But this is traded off with the bias introduced by modeling the simulations from $\pi(\mathbf{x}|\theta)$ with a normal distribution. The second advantage was the main motivation in [29], namely that this procedure is more robust for extremely irregular probability distributions as encountered in chaotic or near chaotic simulation dynamics.

A marginal sampler based on a Gaussian approximation (Algorithm 1) has the following acceptance probability:

$$\alpha(\theta'|\theta) = \min \left(1, \frac{\pi(\theta') \mathcal{N}(\hat{\boldsymbol{\mu}}_{\theta'}, \hat{\boldsymbol{\Sigma}}_{\theta'} + \epsilon^2 \mathbf{I}) q(\theta|\theta')}{\pi(\theta) \mathcal{N}(\hat{\boldsymbol{\mu}}_\theta, \hat{\boldsymbol{\Sigma}}_\theta + \epsilon^2 \mathbf{I}) q(\theta'|\theta)} \right) \quad (10)$$

As with the marginal sampler of Section 2, the fact that we estimate first and second order statistics from a finite sample set introduces uncertainty in the accept probability $\alpha(\theta'|\theta)$: another run of S simulations would have resulted in different values for these statistics and hence of the accept probability. See Figure 1 for an illustration. In the following section we will analyze the distribution over $\alpha(\theta'|\theta)$ and develop a method to decide how many simulations S we need in order to be sufficiently confident that we are making the correct accept/reject decision. Random acceptance probability distributions have been studied in general [16] and for the specific case of Gaussian log-energy estimates [9].

3.1 MCMC with a Random Acceptance Probability

We now make explicit the role of randomness in the MCMC sampler with synthetic (normal) likelihoods. At each iteration of the MCMC sampler, we compute estimators $\{\hat{\boldsymbol{\mu}}_\theta, \hat{\boldsymbol{\Sigma}}_\theta, \hat{\boldsymbol{\mu}}_{\theta'}, \hat{\boldsymbol{\Sigma}}_{\theta'}\}$ as before using Eqns 5 and 6. To estimate the distribution over accept probabilities we would need M sets of S simulations, which would be too expensive. Instead, we use our Gaussian assumption to derive that the variance of the mean is $1/S$ times the variance in the sample $\{\mathbf{x}_1, \dots, \mathbf{x}_S\}$,

$$\boldsymbol{\mu}_\theta \sim \mathcal{N}(\hat{\boldsymbol{\mu}}_\theta, \hat{\boldsymbol{\Sigma}}_\theta/S) \quad (11)$$

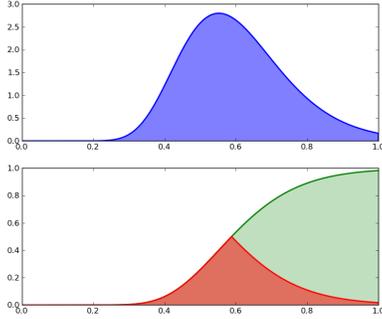

Figure 1: An example of $p(\alpha)$, the distribution over acceptance probabilities (**top**) and its CDF shown folded at its median (**bottom**).

and similarly for $\mu_{\theta'}$. This shortcut is important because it allows us to avoid a significant number of expensive simulations and replace them with samples from a normal distribution.

Given our M samples of $(\mu_{\theta}, \mu_{\theta'})$, we can compute M samples of $\alpha(\theta'|\theta)$ by inserting them into the expression for the randomized MH accept probability:

$$\alpha^{(m)} = \min \left(1, \frac{\pi(\theta') \mathcal{N}(\mathbf{y} | \mu_{\theta'}^{(m)}, \hat{\Sigma}_{\theta'} + \epsilon^2 \mathbf{I}) q(\theta|\theta')}{\pi(\theta) \mathcal{N}(\mathbf{y} | \mu_{\theta}^{(m)}, \hat{\Sigma}_{\theta} + \epsilon^2 \mathbf{I}) q(\theta'|\theta)} \right) \quad (12)$$

We now derive a procedure to estimate the probability of making an error in an accept/reject decision ($\mathcal{E}(\alpha)$, the *Metropolis-Hastings error*) and a threshold τ for actually making the decision. The error of making an incorrect decision can either be measured conditioned on $u \sim \mathcal{U}(0, 1)$ (the uniformly distributed draw used in the MH decision), or unconditionally, by integrating over $\mathcal{U}(0, 1)$. First we start with the conditional error which trivially extends to the unconditional error by averaging.

If $u \leq \tau$, then we accept the MH proposal and move to the proposed state. The probability of making an error in this case is $P(\alpha < u)$ (i.e. the probability we should actually reject):

$$P(\alpha < u) = \frac{1}{M} \sum_m [\alpha^{(m)} < u] \quad (13)$$

Similarly, if $u > \tau$ then we reject, and the error is $P(\alpha > u)$ (i.e. the probability we should actually accept):

$$P(\alpha > u) = \frac{1}{M} \sum_m [\alpha^{(m)} \geq u] \quad (14)$$

The total conditional error is therefore:

$$\mathcal{E}_u(\alpha) = [u \leq \tau] P(\alpha < u) + [u > \tau] P(\alpha \geq u) \quad (15)$$

and the total unconditional error is:

$$\mathcal{E}(\alpha) = \int \mathcal{E}_u(\alpha) \mathcal{U}(0, 1) du \quad (16)$$

which can again be estimated by Monte Carlo or grid values of u . The analytic calculation of $\mathcal{E}(\alpha)$ is the area under the cumulative distribution function of $p(\alpha)$ folded at τ (see Figure 1). This integral is also known as the *mean absolute deviation* [30] which is minimized at the median of $p(\alpha)$ (the value of α where the CDF equals 1/2), justifying our decision threshold $\tau = \text{median}(\alpha)$ (also determined by samples $\alpha^{(m)}$).

With this in hand, we now have the necessary tools to construct an adaptive synthetic-likelihood MCMC algorithm that uses $\mathcal{E}(\alpha)$ as a guide for running simulations (Algorithm 2). At the start of each MH step, S_0 simulations are run for both θ and θ' ; estimators are computed; then M $\alpha^{(m)}$ are sampled. Based on these samples, the median and $\mathcal{E}(\alpha)$ is computed. Note that this phase of the algorithm is very cheap; here we are sampling from J bivariate Gaussian distributions to compute Monte Carlo estimates of τ and $\mathcal{E}(\alpha)$, so M can be set high without a computational hit, though in practice $M < 100$ should be fine. While $\mathcal{E}(\alpha) > \xi$, ΔS new simulations are run and the estimators updated, along with new draws of $\alpha^{(m)}$, etc. The user-defined error threshold ξ is a knob which controls both the accuracy and computational cost of the MCMC. New simulations can be run at either θ or θ' ; we run simulations at both locations, though selecting one over the other based on the higher individual mean uncertainty could result in fewer simulations. As S increases, the uncertainty around $p(\alpha)$ decreases such that $\mathcal{E}(\alpha) < \xi$; once this occurs, the MH is now *confident* and it proceeds using the usual acceptance test, with τ as the acceptance threshold.

In many cases, the actual number of simulations required at each step can be quite small, for example when one parameter setting is clearly better than another (where the median is at or close to 0 or 1). Nevertheless, there remains a serious drawback to this algorithm for expensive simulations: all simulations are discarded after each MH step; a great waste considering the result is a single binary decision. Using a Gaussian process surrogate, described in the next section, we will remember all simulations and use them to gradually improve the surrogate and as a consequence, eventually eliminate the need to run simulations.

4 Gaussian Process Surrogate ABC

As mentioned in the introduction, in many scientific disciplines simulations can be extremely expensive. The algorithms up till now all have the downside that at each MCMC update a minimum number of simulations needs to be conducted. This seems unavoidable unless we store the information of previous simulations and use them to make accept/reject decisions in the future. In particular, we can *learn* the mean and covariance $\mu_{\theta}, \Sigma_{\theta}$ of the synthetic likelihood as a function of θ and as such avoid hav-

ing to perform simulations to compute them. There is a very natural tool that provides exactly this functionality, namely the Gaussian process (GP). For our purposes, the GP will “store” the simulation runs θ_n, \mathbf{x}_n for all simulations conducted during the MCMC run. We will use the GP as a “surrogate” function for the simulated statistics from which will be able to estimate the marginal likelihood values away from regions where actual simulations were run. Importantly, the GP provides us with uncertainty estimates of the marginal likelihood which will inform us of the need to conduct additional experiments in order to make confident accept/reject decisions. Going from the synthetic likelihood model to the GP represents a change from frequentist statistics in favor of (nonparametric) Bayesian statistics. Gaussian processes have recently also become a popular tool in the machine learning literature as surrogates of expensive regression surfaces, such as log-likelihoods [17]; optimization surfaces [8, 24]; simulations of physical systems [6]; emulation of computer codes [10]; and for accelerating ABC [28].

Similar in spirit to our own work, [28] uses GP surrogates to model the ABC log-likelihood surface in successive waves of inference, each eliminating regions of implausibility and producing more and more accurate models of the log-likelihood. There are two important differences. Space-filling design points are used by [28] to train their GP models, whereas we control the simulations with ξ , and we model all J simulation outputs versus a single log-likelihood, which is a much larger overhead for our approach, but has advantages, e.g. enabling posterior analysis and evaluation of the simulator.

Our surrogate model and algorithm follow directly from the synthetic-ABC approximation and randomized acceptance algorithm. The main difference between the two is that in this paper, we model the J statistics as J independent Gaussian processes (recall J is the dimensionality of \mathbf{y}). We note that it would be better to model the J statistics using a single joint Gaussian process. This can be done using “co-Kriging” or variants thereof [12, 7]. Although the independence assumption may lead to overconfidence (because it is assuming—falsely— independent evidence), it is also more robust in high-dimensions where the estimator of the full output covariance has high variance (it overfits). It may be that the mentioned multi-output GPs can provide an appropriate solution by tying the covariance structure across parameter space using a small number of kernel hyperparameters. For our experiments we found that independent GPs worked well enough to illustrate the algorithm’s potential. For high-dimensional outputs, modeling the log-likelihood directly may be more appropriate [28].

For each statistic j , the surrogate provides the following conditional predictive distribution of the expected value of statistic j :

$$\mu_{\theta j} \sim \mathcal{N}(\bar{\mu}_{\theta j}, \sigma_{\theta j}^2) \quad (17)$$

where the mean and covariance are determined by the set of N training inputs $\{\theta_n\}$ and N training outputs $\{\mathbf{x}_n\}$ (using only statistic j). They are given by the usual expressions for the GP mean and covariance,

$$\bar{\mu}_{\theta j} = \mathbf{k}_{\theta\Theta_j} [\mathbf{K}_{\Theta\Theta_j} + \sigma_j^2 \mathbf{I}]^{-1} \mathbf{X}[:, j] \quad (18)$$

and

$$\sigma_{\theta j}^2 = k_{\theta\theta j} - \mathbf{k}_{\theta\Theta_j} [\mathbf{K}_{\Theta\Theta_j} + \sigma_j^2 \mathbf{I}]^{-1} \mathbf{k}_{\Theta\theta j}$$

where $\mathbf{k}_{\theta\Theta_j}$ is a 1 by N vector of kernel evaluations for the j ’th Gaussian process between θ and the input training set Θ , $\mathbf{K}_{\Theta\Theta_j}$ is the j th kernel matrix evaluated on the training data; σ_j^2 is the data noise term for the j ’th statistic (used below in the acceptance ratio), \mathbf{X} is the N by J training output data set and $\mathbf{X}[:, j]$ is column j from the training data, and $k_{\theta\theta j}$ is a single kernel evaluation at θ for Gaussian process j .

The GPS-ABC algorithm is now run as follows (Algorithm 3). At each MH step, using Eqn 17, and for each j , M independent draws of $\mu_{\theta'}$ and μ_{θ} are sampled from their conditional predictive distribution. Note that this significantly different from the SL-ABC because there are now no default simulations to be run at each MH step; instead, the current surrogate model is used to predict both the expectation and uncertainty in simulation output. As before, Monte Carlo statistics are computed from acceptance probabilities $\alpha^{(m)}$ as follows,

$$\alpha^{(m)} = \min \left(1, \frac{\pi(\theta') \prod_j \mathcal{N}(y_j | \mu_{\theta'}^{(m)}, \sigma_j^2 + \epsilon^2) q(\theta|\theta')}{\pi(\theta) \prod_j \mathcal{N}(y_j | \mu_{\theta}^{(m)}, \sigma_j^2 + \epsilon^2) q(\theta'|\theta)} \right) \quad (19)$$

Algorithm 3 GPS-ABC MH step

inputs: $q, \theta, \pi(\mathbf{x}|\theta), S_0, \Delta S, \epsilon, \mathbf{y}, \xi$
 $\theta' \sim q(\theta'|\theta)$
repeat
 for $m = 1 : M$ **do**
 Sample $\mu_{\theta'_j}^{(m)}, \mu_{\theta_j}^{(m)}$ using Eqn 17
 Set $\alpha^{(m)}$ using Eqn 19
 end for
 Set $\tau = \text{median}(\alpha^{(m)})$
 Set $\mathcal{E}(\alpha)$ using Eqn 16
 if $\mathcal{E}(\alpha) > \xi$ **then**
 Acquire new training point.
 end if
 until $\mathcal{E}(\alpha) < \xi$
 if $\mathcal{U}(0, 1) \leq \tau$ **then**
 return θ'
 end if
return θ

The error $\mathcal{E}(\alpha)$ and acceptance threshold τ are computed from the M samples; if $\mathcal{E}(\alpha) > \xi$, then a procedure for acquiring training points (i.e. simulations) is run, with the objective of reducing uncertainty for this specific MH step. Again, as with the adaptive synthetic likelihood algorithm, computing the M samples is very cheap. The procedure is then free to select any input location to run a simulation (whereas before we were forced to run at either θ or θ'), though the new simulation should be impactful for the current MH step. This means that we can choose locations other than θ and θ' , perhaps trying to limit the number of future simulation runs required in the vicinity. Analogous to acquisition functions for Bayesian optimization [8], actively acquiring points has the implicit goals of speeding up MCMC, reducing MCMC error, and limiting simulations. We have intentionally left vague the procedure for acquiring training points; for now we run simulations at θ or θ' , even though this is an inefficient use of our surrogate. Once a new training point is selected and run, the training input-output pair is added to all J Gaussian processes and the model hyperparameters may or may not be modified (with a small number of optimization steps or by sampling).

The key advantage of GPS-ABC is that with increasing frequency, we will not have to do any expensive simulations whatsoever during a MH step because the GP surrogate is sufficiently confident about the statistics' surface in that region of parameter space.

4.1 Theoretical Aspects of GPS-ABC

Two of the main contributions of GPS-ABC are *MCMC under uncertainty* and the introduction of *memory* into the Markov chain; we consider these steps as the only way to reduce the number of expensive simulations and as such

a necessary ingredient to GPS-ABC. Nevertheless, they present major differences from typical Bayesian inference procedures.

We now address two major theoretical aspects of the GPS-ABC algorithm: the *approximate* and *adaptive* nature of GPS-ABC. Although we have postponed formal proofs for future work we have outlined their main arguments below.

GPS-ABC is *approximate* because at each MH-step there is some probability that the chain will make an error, and that this corresponds to an error in the stationary distribution of the Markov chain (i.e. it is an approximation to the stationary distribution). In [14], another approximate MCMC algorithm is presented and it provides a proof for an upper bound on the error in the stationary distribution. The main argument is that if the MH-step error is small and bounded (along with a few other mild conditions), then the error in stationary distribution is bounded as well. We feel GPS-ABC fits into this same proof framework.

GPS-ABC is also *adaptive* since the approximation to the stationary distribution changes as more training points are added to the Gaussian process (we are learning the surrogate as we run the MCMC). Two of the major requirements for a valid adaptive MCMC algorithm are *diminishing adaptation* and *ergodicity* [19]. GPS-ABC satisfies the former as the number of training points acquired over an MCMC run rapidly decreases over time. When the adaptation slows and becomes insignificant, the Markov chain resembles the algorithm in [14], which, as we stated above, provides a proof of bounded convergence to the stationary distribution (and hence ergodicity); therefore we believe that GPS-ABC satisfies the latter requirement.

5 Experiments

The main goal of our experiments is to show the correctness and computational gains of GPS-ABC. Our results indicate that correct posterior samples can be obtained by GPS-ABC with orders of magnitude fewer simulation calls than traditional ABC sampling procedures.

We perform experiments on two simulation problems: 1) a toy Bayesian inference problem (the exponential problem) and 2) inference of parameters in a chaotic ecological system (the blowfly problem). In the former, the true posterior distribution is known and therefore provides a useful test-case for determining the correctness and convergence properties of ABC algorithms. There is no ground truth in the latter problem, making inference much more difficult, but we can nevertheless assess it by the quality of raw simulation outputs and convergence to a set of chosen statistics.

Here is a brief description of the algorithms used in our experiments. We ran ϵ -tube rejection sampling (REJ); synthetic-likelihood (SL, both marginal and pseudo-marginal); and two adaptive ξ -ABC algorithms: adaptive

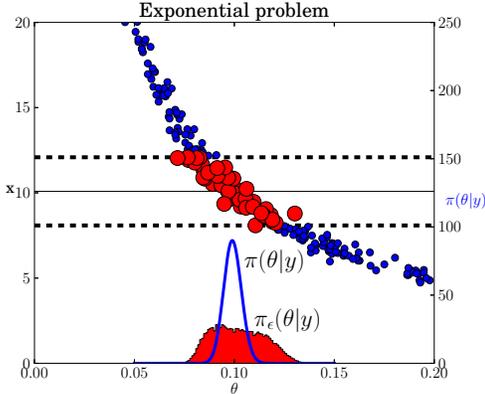

Figure 2: The exponential problem. Shown on the same y-axis are values from the simulator x and the density of the true and approximate posteriors ($\pi(\theta|y)$ and $\pi_\epsilon(\theta|y)$, respectively). The horizontal lines indicate $y \pm \epsilon$. The approximate posterior was generated from ϵ -tube rejection sampling ($\epsilon = 2$).

synthetic likelihood (ASL) and Gaussian process surrogate ABC (GPS). Rejection sampling is a procedure where θ is repeatedly drawn from the prior until all simulation statistics are within the ϵ -tube. This is repeated independently for each sample. Algorithms SL, ASL perform at least S simulations at each MH-step of a MCMC run; for marginal algorithms, this is $2S$ (the simulations at the current location are re-run), for ASL this can be higher, depending on ξ and due to randomness within the MH-step. Marginal versus pseudo-marginal results are indicated by the prefixes ‘m’ or ‘p’, respectively. Our MCMC algorithms are initialized with a single rejection sample, so initial simulation counts are affected by its ϵ value. GPS uses a small initial training set of size $S_0 = 50$. For the exponential problem, this training set was generated by rejection sampling. For the blowfly problem, a short MCMC run using SL was used to generate higher quality training points. GPS adapts its Gaussian process hyperparameters using MAP estimates found by conjugate gradient methods during initialization, and subsequently when the number of training points doubles (i.e. 100, 200, 400, etc). Finally, ASL and GPS adapt the number of simulations at each MH-step $\Delta S = 5$. Due to space constraints, some of the results are not shown in the main paper, but can be found in the supplementary material.

5.1 Inferring the parameter of an exponential distribution

In this illustrative problem we infer the rate of an exponential distribution under a gamma prior with shape α and rate β , having N observations at the true rate θ^* ; this is the *exponential example* in [27]. Let \mathbf{w} be a vector of N draws from an exponential distribution, i.e. $w_n \sim \text{Exp}(\theta)$. The posterior is a gamma distribution with shape $\alpha + N$ and rate $\beta + \sum w_n$. To use this problem with ABC, we use the exponential draws as the simulator and the mean of \mathbf{w} as the statistic y and assume that N is known. The inference

problem is therefore to sample from $p(\theta|y, \alpha, \beta, N)$.

For all runs we fixed $\alpha = \beta = 0.1$; a very broad prior over θ . Using the same random seed and $\theta^* = 0.1$, we generated $y = 10.0867$, which induces the θ -MAP value 0.09916 (not quite 10 and 0.1 due to their random draw and to a small influence from the prior). An illustration of this problem is shown in Figure 2.

Figure 3 show the results of running REJ, SL, and GPS to generate 50000 samples; this is repeated 10 times per algorithm. These three algorithms were chosen because they give roughly the same final error in distribution. In Figure 3a, the convergence to the (known) target posterior distribution (error), *per sample*, is shown. Figure 3b shows the same convergence in error, but is overlaid with the convergence *per simulation call* instead of per sample. Rejection sampling, as expected, provides the best convergence per sample (each sample is an independent sample from the approximate posterior) but computationally performs very poorly when ϵ is set to a value that gives small error in distribution.

As GPS-ABC acquires training points it is also sampling from the approximate posterior. Once the surrogate has learned the statistic surfaces in a region of parameter space, it no longer makes any simulation calls in that region. Eventually, the surrogate learns the surface for all the regions of parameter space where the posterior density is high. For this problem (with $\xi = 0.2$), this occurs after approximately 1000 simulations. As the MCMC run progresses, GPS-ABC gathers samples with decreasing amounts of computation. Figure 3c shows how the Gaussian process adaptation levels off during MCMC runs, whereas traditional ABC algorithms require a constant number of simulation calls per sample. As ξ decreases, more simulation calls are required for the GPS-ABC to model the statistics surfaces with increased precision; they all, however, have adaptation curves similar to Figure 3c.

5.2 Chaotic Ecological Systems

Adult blowfly populations exhibit dynamic behavior for which several competing population models exist. In this experiment, we use observational data and a simulation model from Wood [29], based on their improvement upon previous population dynamics theory. Population dynamics are modeled using (discretized) differential equations that can produce chaotic behavior for some parameter settings. An example blowfly replicate series is shown in Figure 4a, along with times-series generated by a sample from $\pi(\theta|y)$ using GPS-ABC.

In [29] there are several explanations of the population dynamics, corresponding to different simulations and parameters. We concentrate on the equation (1) in section 1.2.3 of the supplementary information, considered “a better al-

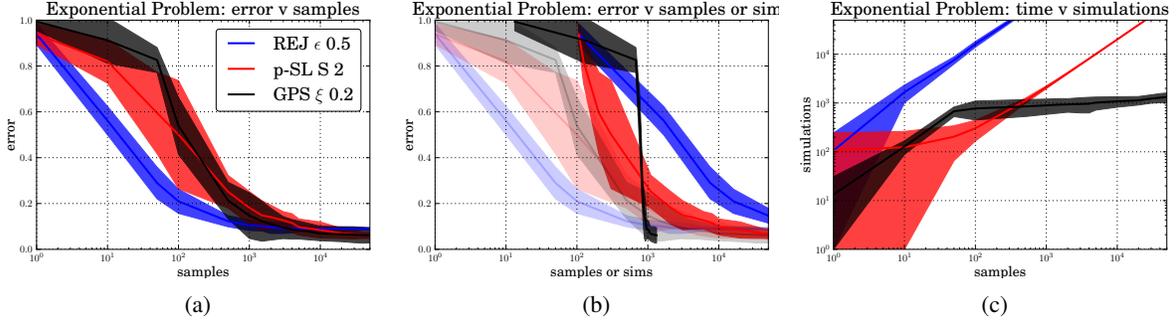

Figure 3: Convergence to target distribution for three algorithms: REJ ($\epsilon = 0.5$), p-SL ($S = 2$), and GPS ($\xi = 0.2$). The three have roughly the same final error in distribution. In (a) the convergence to the target *per sample* is shown; in (b) this convergence is overlaid with convergence *per simulation*. Around sample 1000, GPS has essentially stopped adapting, has learned the statistic surfaces, and no longer requires simulations. In (c) the growth of simulations per time step (i.e. a sample) for the sample algorithms is shown; both REJ and SL use a fixed number of simulations per iteration, whereas GPS stops adding new training points around time 1000. Note that we start the plot at the 10th sample, which requires a different number of simulations, depending on the algorithm.

ternative model” by the author. The population dynamics equation generates N_1, \dots, N_T using the following update rule:

$$N_{t+1} = PN_{t-\tau} \exp(-N_{t-\tau}/N_0)e_t + N_t \exp(-\delta\epsilon_t)$$

where $e_t \sim \mathcal{G}(1/\sigma_p^2, 1/\sigma_p^2)$ and $\epsilon_t \sim \mathcal{G}(1/\sigma_d^2, 1/\sigma_d^2)$ are sources of noise, and τ is an integer (not to be confused with the τ used as the MH acceptance threshold in our algorithms). In total, there are 6 parameters $\theta = \{\log P, \log \delta, \log N_0, \log \sigma_d, \log \sigma_p, \tau\}$. See [29] for further details about the significance of the parameters. We put Gaussian priors over all the parameters (with Gaussian proposal distributions), except for τ which has a Poisson prior (and a left/right increment proposal). Time-series generated with parameters from this prior distribution produce extremely varied results, some are chaotic, some are degenerate, etc. Modeling this simulator is *very* challenging.

As with any ABC problem the choice of statistics is important as it directly affects the quality of the results. It is also non-trivial and requires careful thought and sometimes trial and error. In total there are 10 statistics: the log of the mean of all 25% quantiles of $N/1000$ (4 statistics), the mean of the 25% quantiles of the first-order differences of $N/1000$ (4 statistics), and the maximal peaks of smoothed N , with 2 different thresholds (2 statistics). With these statistics it is possible to reproduce time-series that appear similar to the observations. Note that these statistics are different from Wood’s, but they capture similar time-series features and are sufficient to produce credible population dynamics.

The first set of experiments for the blowfly problem is shown in Figure 4b. For these experiments we compared REJ ($\epsilon = 5$), corresponding to an acceptance rate of roughly 2%, p-SL ($S = 10$), and finally GPS ($\xi = 0.3$). For SL, a small $\epsilon = 0.5$ was required to improve mixing. This helped all algorithms, but was less important for GPS, though it can be important if the Gaussian processes are not properly calibrated. Each algorithm was

run 5 times collecting 10K samples each. The GPS model for this problem consists of $J = 10$ independent Gaussian processes with $D = 6$ inputs each. The GPS was initialized with $S_0 = 50$ samples from a short SL-ABC MCMC run. In Figure 4b we show the posterior distributions for $\log P$, $\log \delta$, and $\log N_0$. Rejection sampling produces much broader posteriors than both SL and GPS, though they all share roughly the same mode. Between SL and GPS there is little difference in mode or shape, though GPS appears to have tighter confidence intervals. The real difference is the computational effort required: GPS used only 384 simulations to produce 10K, roughly 0.04 simulations per sample, whereas SL and REJ require 10 and 45 simulations for a single sample, respectively. Of course, GPS has much higher efficiency in practice, as the value 0.04 simulations per sample decreases over time and eventually reaches 0.

The second set of experiments examined the convergence properties of GPS compared to the other algorithms, focusing on the quality of the posterior predictive distributions *per sample* versus *simulation call*. For the blowfly data we do not have the ground-truth θ^* , but we do have the statistics of the observations for which we can monitor convergence. We do this by evaluating the posterior predictive distribution $p(\mathbf{y}|\mathbf{y}^*)$. Please note that we slightly change notation when discussing posterior predictive distributions by denoting \mathbf{y}^* the observed statistics, and \mathbf{y} as statistics generated by the posterior samples $p(\theta|\mathbf{y}^*)$. Pairs \mathbf{y} and θ are generated, with the exception of GPS, during the MCMC run, and are exactly the quantities we require for $p(\mathbf{y}|\mathbf{y}^*)$. Convergence will tell us the amount of computational effort required for an independent and (un)biased sample.

In Figure 4c we show the convergence in expected value of \mathbf{y} to \mathbf{y}^* per simulation. This is calculated in an online fashion by averaging statistics generated at θ (each *pos-*

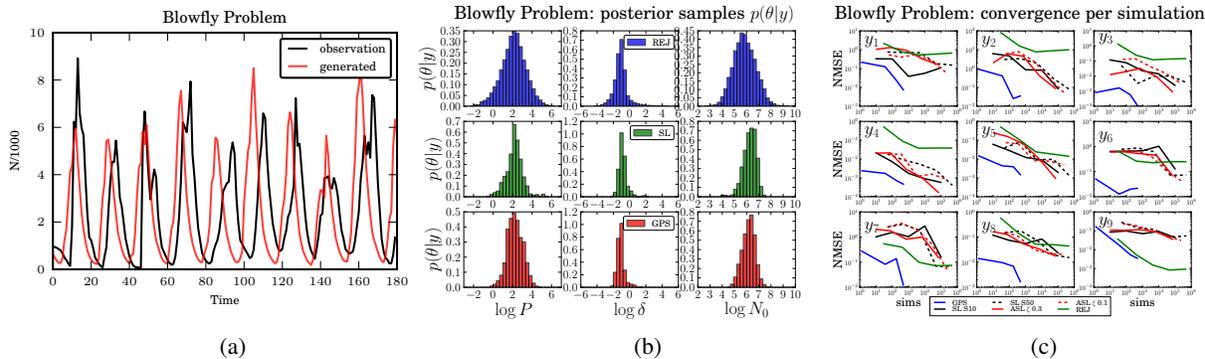

Figure 4: **(a)** The blowfly population time-series. The observations are in black lines and a generated time-series is shown in red. Note that θ is a sample from the GPS posterior ($\xi = 0.3$). See paper for description of the statistics. **(b)** Blowfly $p(\theta|y)$ for different algorithms. The top (blue) row is REJ $\epsilon = 5$, the middle (green) is pseudo-marginal SL S10, and the bottom (red) is GPS $\xi = 0.3$. Their respective simulations per sample ratios were: 45, 10, and 0.04. I.e. REJ had an acceptance rate of 2.2%, and GPS only used 384 simulations for 10K samples. Similar distributions were observed for ASL and other pseudo-marginal SL. **(c)** Convergence to y^* for different algorithms, using normalized mean-squared error. Each sub-plot shows the convergence to a single statistic as a function of simulation calls.

terior θ sample is allowed one y). We show the log-log plots of the normalized mean squared error (NMSE) versus number of simulations for the first 9 statistics. Algorithms run in this experiment were GPS ($\xi = 0.2$), p-SL ($S = 10, 50$), ASL ($\xi = 0.3, 0.1$), and REJ ($\epsilon = 5$). GPS not only converges systematically to y^* but does so with dramatically less effort. For some statistics REJ performed reasonably well, but in general exhibited significant bias. Both SL and ASL converged to similar biases, usually outperforming REJ, but in some cases was worse. Parameter settings where more computation was required for SL and ASL did result in slightly improved convergence, but the gain comes with a significantly higher computational cost. In summary, GPS is able to model the statistic surfaces, enabling it to correctly sample from the approximate posterior target distribution with higher precision and with orders of magnitude fewer simulation calls than the other algorithms.

6 Discussion and Future Work

We have presented a promising framework for performing inference in expensive, simulation-based models. Our algorithms improve current state-of-the-art ABC methods in that they require many fewer calls to the simulator, sometimes orders of magnitude fewer.

Using GPs for surrogate modeling has an appealing elegance; as nonparametric Bayesian models, they naturally incorporate both model and pseudo-data uncertainty into the MCMC algorithms. However, there are several technical issues and modeling limitations with GPs used for surrogate modeling. Heteroskedastic noise is more likely the norm than the exception for complicated simulators. The blowfly simulator is a prime example of this. Improvements to our GPs may be achieved using an input-dependent noise model [11, 13], where the noise is an additional independent Gaussian process. Another limitation

of our GP model is the output independence assumption. A more realistic assumption is a full covariance Gaussian process such as the convolution processes of [12, 7, 1]. One final limitation is GP calibration. We found that initializing the Gaussian process with rejection samples produced inferior results, as it tended to adapt its hyper-parameters optimally for those training points and had difficulty readapting. Despite these limitations, we feel that GPS-ABC deserves a place within the ABC toolbox.

Our GPS-ABC uses a random-walk proposal distribution which is inefficient for exploring the target distribution. Using GPs offers the opportunity to use other techniques to improve the mixing (and in turn computational cost). For example, in [17] a Hamiltonian Monte Carlo run on the GP surface is used to generate *independent* proposals. If applied to ABC, their algorithm would require the equivalent of a full simulation at the proposed location, whereas if we incorporated a similar technique, we would then test the GP uncertainty to determine if a simulation was required.

There has been a recent surge in interest in Bayesian optimization using Gaussian process (GP-BO) surrogates of the objective surface [8, 24]. GP-BO is often applied to problems where simulation or sometimes user feedback guides the surrogate’s construction. What is most interesting about GP-BO is its use of model uncertainty to *actively* determine the next simulation location implemented through acquisition functions. These ideas can be generalized to our GPS-ABC algorithm to further reduce simulation costs, while at the same time maintaining control of the MCMC error.

Abstract

Lifted inference approaches can considerably speed up probabilistic inference in Markov random fields (MRFs) with symmetries. Given evidence, they essentially form a lifted, i.e., reduced factor graph by grouping together indistinguishable variables and factors. Typically, however, lifted factor graphs are not amenable to off-the-shelf message passing (MP) approaches, and hence requires one to use either generic optimization tools, which would be slow for these problems, or design modified MP algorithms. Here, we demonstrate that the reliance on modified MP can be eliminated for the class of MP algorithms arising from MAP-LP relaxations of pairwise MRFs. Specifically, we show that a given MRF induces a whole family of MRFs of different sizes sharing essentially the same MAP-LP solution. In turn, we give an efficient algorithm to compute from them the smallest one that can be solved using off-the-shelf MP. This incurs no major overhead: the selected MRF is at most twice as large as the fully lifted factor graph. This has several implications for lifted inference. For instance, running MPLP results in the first convergent lifted MP approach for MAP-LP relaxations. Doing so can be faster than solving the MAP-LP using lifted linear programming. Most importantly, it suggests a novel view on lifted inference: it can be viewed as standard inference in a reparametrized model.

1 INTRODUCTION

Probabilistic logical languages [5] provide powerful formalisms for knowledge representation and inference. They allow one to compactly represent complex relational and uncertain knowledge. For instance, in the friends-and-smokers Markov logic network (MLN) [17], the weighted

formula $1.1 : fr(X, Y) \Rightarrow (sm(X) \Leftrightarrow sm(Y))$ encodes that friends in a social network tend to have similar smoking habits. Yet, performing inference in these languages is extremely costly, especially if it is done at the propositional level. Instantiating all atoms from the formulae in such a model induces a standard graphical model (potentially) with symmetries, i.e., with repeated factor structures for all grounding combinations. Recent advances in lifted probabilistic inference [16] such as [3, 15, 1, 14, 18] (see [9] for an overview that also covers exact inference approaches), have rendered many of these large, previously intractable models quickly solvable by exploiting the induced symmetries. For instance, lifted message-passing (MP) approaches such as [19, 10, 22, 8, 1] have been proven successful in several important AI applications such as link prediction, social network analysis, satisfiability and boolean model counting problems. Lifted MP approaches such as lifted Belief Propagation (BP) first automatically group together variables and factors of the graphical model into supervariables and superfactors if they have identical computation trees (i.e., the tree-structured “unrolling” of the graphical model computations rooted at the nodes). Then, they run modified MP algorithms on this lifted network. These modified MP algorithms, however, can also be considered a downside of today’s lifted MP approaches. They require more information than is actually captured by a standard factor graph. More precisely, lifted MP will typically exponentiate a message from a supervariable to a superfactor by the count of ground instances of this superfactor, which are neighbors to a ground instance of the supervariable. Since these multi-dimensional counts have to be stored in the network, the lifted factor graph becomes a multigraph (i.e., a factor graph with edge counts and self-loops), in contrast to a standard factor graph where no multiedges or loops are allowed. Hence, lifted factor graphs are not amenable to off-the-shelf MP approaches. Instead, lifted MP has its own ecosystem of lifted data structures and lifted algorithms. In this ecosystem, considerable effort is required to keep up with the state of the art in propositional inference.

In this paper we demonstrate that the reliance on modified MP can be eliminated for the class of MP algorithms aris-

ing from linear programming (LP) relaxations of MAP inference (MAP-LPs) of pairwise MRFs. MAP-LPs approximate the MAP problem as an LP with polynomially many constraints [25], which is therefore tractable, and have several nice properties. First, they yield an upper bound on the MAP value, and can thus be used within branch and bound methods. Second, they provide certificates of optimality, so that one knows if the problem has been solved exactly. Third, the LP can be solved using simple algorithms such as coordinate descent, many of which have a nice message passing structure. [12] Fourth, the LP relaxations can be progressively tightened by adding gradually constraints of a higher order. This has been shown to solve challenging MAP problems [20].

Indeed, it is already known that MAP-LP relaxations of MRFs can be lifted efficiently [13, 3, 14], and the resulting lifted LPs can be solved using any off-the-shelf LP solver¹. Unfortunately, however, the liftings employed there may not preserve the MRF structure of the underlying LP. That is, if we lift a MAP-LP, we end up with constraints that do not conform to the MAP-LP template as already observed by Bui et al. (see Section 7 in [3]). In turn, existing MP solvers for MAP-LPs such as MPLP and TRW-BP — that have been reported to often solve the MAP-LP significantly faster than generic LP solvers — will not work without modifying them. Doing so, however, takes a lot effort (if it is at all possible): it has to be done for each existing MP approach separately; there is no general methodology for doing this, and the extra coding itself is error prone. Hence this “upgrading methodology” may significantly delay the development of lifted MP approaches. Fortunately, as we demonstrate here, the theory of lifted LPs provides us with a way around these issues. The main insight is that a given MRF induces actually a whole family of MRFs of different sizes sharing essentially the same MAP-LP solution. From these, one can select the smallest one where MAP beliefs can be computed using off-the-shelf MP approaches. These beliefs then are also valid (after a simple transformation) for the original problem. Moreover, this incurs no major overhead: the selected MRF is at most twice as large than the fully lifted factor graph. In this way we eliminate the need for modified MP algorithms.

To summarize, our contributions are two-fold. **(1)** By making use of lifted linear programming, we show that LP-based lifted inference in MRFs can be formulated as ground inference on a reparametrized MRF. **(2)** We give an efficient algorithm that given a ground MRF finds the smallest reparametrized MRF and show that its size is not more than twice the size of the fully lifted model.

¹A similar approach has been proposed for exact MAP by Noesner et al. [15]. Moreover, Sarkhel et al. [18] have recently shown that MAP over MLNs can be reduced to MAP over Markov networks if the MLN has very restrictive properties. In contrast our approach is generic for MAP-LP relaxations.

This has several implications for lifted inference. For instance, using MPLP [6] results in the first convergent MP approach for MAP-LP relaxations, and using other MP approaches such as TRW-BP [24] actually spans a whole family of lifted MP approaches. This suggests a novel view on lifted probabilistic inference: *it can be viewed as standard inference in a reparametrized model.*

We proceed as follows. We start off with reviewing MAP-LP basics. Then, we touch upon equitable partitions and lifted LPs, and use them to develop the reparametrization approach. Before concluding we provide empirical illustrations, which support our theoretical results.

2 BACKGROUND

We start off by introducing MAP inference and its LP relaxation. Then we will touch upon equitable partitions and recall how they can be used in lifted linear programming.

MAP Inference in MRFs. Let $\mathbf{X} = (X_1, X_2, \dots, X_n)$ be a set of n discrete-valued random variables and let x_i represent the possible realizations of random variable X_i . Markov random fields (MRFs) compactly represent a joint distribution over \mathbf{X} by assuming that it is obtained as a product of functions defined on small subsets of variables [11]. For simplicity, we will restrict our discussion to a specific subset of MRFs, namely Ising models with arbitrary topology². In an Ising model $I = (G, \theta)$ on a graph $G = (V, E)$, all variables are binary, i.e., $\mathbf{X}_i \in \{0, 1\}$. Moreover, in an Ising model G must be a *simple* graph, i.e. G must have no self-loops or multiple edges between vertices. The model is then given by: $p(x) \propto \exp \left[\sum_{ij \in E} \theta_{ij} x_i x_j + \sum_i \theta_i x_i \right]$. In the following we will find it convenient to represent Ising models as factor graphs. The factor graph of an Ising model combines the structure and parameters of the model into a single bipartite graph. In this graph we have a variable vertex v_i for each probabilistic variable \mathbf{X}_i and a factor vertex ϕ_i for each θ_i and ϕ_{ij} for θ_{ij} . Moreover, ϕ_i is connected to v_i and ϕ_{ij} to v_i and v_j . While for ground Ising models, the factor graph does not capture any additional information, it makes the presentation of lifted structures simpler and reveals the essence of the conflict between lifting and message-passing. Hence, from now on when we refer to an Ising model $I = (G, \theta)$, by G we will mean the corresponding factor graph.

The Maximum a-posteriori (MAP) inference problem is defined as finding an assignment maximizing $p(x)$. This can equivalently be formulated as the following LP

$$\mu^* = \operatorname{argmax}_{\mu \in \mathcal{M}(G)} \sum_{ij \in E} \mu_{ij} \theta_{ij} + \sum_i \mu_i \theta_i = \theta \cdot \mu \quad (1)$$

²The shorter description of MAP-LP for Ising models makes the presentation easier. Our approach, however, can be applied to any pairwise MRF with only minor modifications.

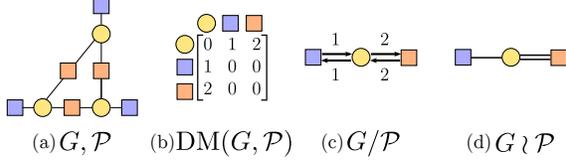

Figure 1: Lifted Structures: Example of a factor graph and its partitions and quotients. (a) A factor graph G (variables in circles, factors in squares) and its coarsest EP \mathcal{P} represented by the colors. (b) The degree DM matrix of G according to \mathcal{P} . (c) The corresponding quotient graph G/\mathcal{P} . (d) The factor quotient $G \wr \mathcal{P}$.

where the set $\mathcal{M}(G)$ is known as the marginal polytope [25]. Even though Eq. 1 is an LP, the polytope $\mathcal{M}(G)$ generally requires an exponential number of inequalities to describe [25], and is NP-complete to maximize over. Hence one typically considers tractable relaxations (outer bounds) of $\mathcal{M}(G)$. The outer bounds we consider are equivalent to the standard local consistency bounds typically considered in the literature (e.g., see [25] Eq. 8.32). However, we present them in a slightly different manner, which simplifies our presentation. Define the following set in $[0, 1]^{|V|+|E|}$:

$$L(G) = \left\{ \begin{array}{l} \boldsymbol{\mu} \geq 0, \forall \phi_{ij} \in G : \\ \alpha(ij) \equiv \mu_{ij} \leq \mu_j, \beta(ij) \equiv \mu_{ij} \leq \mu_i; \\ \gamma(ij) \equiv \mu_i + \mu_j - \mu_{ij} \leq 1 \end{array} \right\}. \quad (2)$$

The polytope $L(G)$ is sometimes referred to as the local marginal polytope [21]. The vectors with $\{0, 1\}$ coordinates in $L(G)$ are the vertices of the $\mathcal{M}(G)$. In other words $\mathcal{M}(G)$ is the convex hull of $L(G) \cap \{0, 1\}^{|V|+|E|}$. We call the relaxed inference problem over $L(G)$ MAP-LP. Note that whenever $\mathcal{M}(G)$ and $L(G)$ do not coincide, $L(G)$ (which is an outer bound on $\mathcal{M}(G)$) has fractional vertices and the resulting LP may have optima which are not valid assignments. However, all integral points in $L(G)$ correspond to valid assignments, thus if the solution $\boldsymbol{\mu}^*$ happens to be integral, then this $\boldsymbol{\mu}^*$ solves the MAP problem.

Equitable Partitions (EPs) of Graphs and Matrices.

Lifted inference approaches essentially work with reduced models by grouping together indistinguishable variables and factors. In other words, they exploit symmetries. For linear programs, Mladenov *et al.* [13, 14] have shown that such symmetries can be formally captured by equitable partitions of weighted graphs and matrices. Since these partitions also play an important part in our argument we will next review the most relevant concepts and results.³ For an illustration, we refer to Fig. 1.

³Note, however, that the definitions we present here are tailored towards bipartite structures (e.g. factor graphs with variables and factors, matrices with rows and columns) for the sake of clarity. They are not the most general ones found in literature.

Let $U = V \cup F$ be a set consisting of two kinds of objects, e.g. the variables and factors of a factor graph as in Fig. 1(a), or the row and column indices of a matrix. A partition $\mathcal{P} = \{P_1, \dots, P_p\} \cup \{Q_1, \dots, Q_q\}$ is a family of disjoint subsets of U , such that $\bigcup_{i=1}^p P_i = V$ and $\bigcup_{i=1}^q Q_i = F$. In Fig. 1 the partition is indicated by the colors of the nodes. A convenient data structure for performing algebraic operations using partitions is the incidence matrix $B \in \{0, 1\}^{|U| \times |\mathcal{P}|}$. The incidence matrix shows the assignment of the elements of U to the classes of \mathcal{P} – it has one row for every object and one column for every class. The entry in the row of object u and the column of class P_p is

$$B_{up} = 1 \text{ if } u \in P_p \text{ and } 0 \text{ if } u \notin P_p.$$

We shall also make use of the normalized transpose of B , which we denote by $\widehat{B} \in \mathbb{Q}^{|\mathcal{P}| \times |U|}$ and define as

$$\widehat{B}_{pu} = 1/|P_p| \text{ if } u \in P_p \text{ and } 0 \text{ if } u \notin P_p.$$

Algebraically, B and \widehat{B} are related as $\widehat{B} = (B^T B)^{-1} B^T$, i.e., \widehat{B} is the left pseudoinverse of B : $\widehat{B} B = I_{|\mathcal{P}|}$.

The partitions we consider will never group elements of V with elements in F . Thus, the matrix B will always be of the form $B = \begin{pmatrix} B_P & 0 \\ 0 & B_Q \end{pmatrix}$, where B_P and B_Q correspond to the partitions of V and F respectively. We shall also use the notation $B = (B_P, B_Q)$ to refer to this block diagonal matrix, and similarly $\widehat{B} = (\widehat{B}_P, \widehat{B}_Q)$.

Let $\mathbf{u} \in \mathbb{R}^{|U|}$ be a real vector composed as $\mathbf{u} = [\mathbf{c}, \mathbf{b}]^T$, $\mathbf{c} \in \mathbb{R}^{|V|}$, $\mathbf{b} \in \mathbb{R}^{|F|}$. The values of \mathbf{u} can be thought of as labels for the elements of U . We say that a partition \mathcal{P} respects \mathbf{u} if for every $x, y \in U$ that are in the same class of \mathcal{P} , we have $u_x = u_y$. Note that if \mathcal{P} respects \mathbf{u} , then $(\mathbf{c}^T B_P)_i = |P_i| c_x$ where x is any member of P_i (and similarly for B_Q, \mathbf{b}). Moreover, $(\widehat{B}_P \mathbf{c})_i = c_x$ where x is any member of P_i (and similarly for $\widehat{B}_Q, \mathbf{b}$).

We next define a special class of partitions of graphs and matrices, which play a central role in our argument. Let us first consider a bipartite graph $G = (V \cup F, E)$. Here V and F are the two sides of the graph, and E are the edges connecting them. The neighbors of a node v in this graph are denoted by $\text{nb}(v)$.

Definition 1 (Equitable partition of a bipartite graph).

An equitable partition of a bipartite graph $G = (V \cup F, E)$ given a vector $\mathbf{u} \in \mathbb{R}^{|V|+|F|}$ is a partition $\mathcal{P} = \{P_1, \dots, P_p, Q_1, \dots, Q_q\}$ of the vertex set V and F such that (a) for every pair $v, v' \in V$ in some P_m , and for every class Q_n , $|\text{nb}(v) \cap Q_n| = |\text{nb}(v') \cap Q_n|$; (b) for every pair $f, f' \in F$ in some Q_m , and for every class P_n , $|\text{nb}(f) \cap P_n| = |\text{nb}(f') \cap P_n|$. Furthermore, \mathcal{P} must respect the vector \mathbf{u} .

If we are dealing with matrices, the above definition can be extended. Essentially, we view a matrix $A \in \mathbb{R}^{m \times n}$ as a weighted graph over the set $\{\text{row}[1], \dots, \text{row}[m]\} \cup$

$\{\text{col}[1], \dots, \text{col}[n]\}$, where A_{ij} is the weight of edge between $\text{row}[i]$ and $\text{col}[j]$. More precisely:

Definition 2 (Equitable partition of a matrix). An equitable partition of a matrix $A \in \mathbb{R}^{m \times n}$ given a vector \mathbf{u} is a partition $\mathcal{P} = \{P_1, \dots, P_p, Q_1, \dots, Q_q\}$ of the sets $V = \{\text{row}[1], \dots, \text{row}[m]\}$ and $F = \{\text{col}[1], \dots, \text{col}[n]\}$ s.t. **(a)** for every pair $v, v' \in V$ in some P_m , and for every class Q_n , $\sum_{f \in Q_n} A_{vf} = \sum_{f \in Q_n} A_{v'f}$ and **(b)** for every pair $f, f' \in F$ in some Q_m , and for every class P_n , $\sum_{v \in P_n} A_{vf} = \sum_{v \in P_n} A_{vf'}$. In addition, \mathcal{P} must respect \mathbf{u} .

Note that Def. 1 is an instance of Def. 2 when we take as A the (bipartite) adjacency matrix of a graph G . An illustration of an equitable partition of a graph is given Fig. 1(a).

One notable kind of equitable partitions (EPs) are orbit partitions (OPs) – the partitions that arise under the action of the automorphism group of a graph or matrix. Their role in MAP inference has been studied in [3]. Although OP-based lifting is indeed practical in a number of cases or even the only applicable one, in particular for exact inference approaches, computing them is a GI-complete problem. Because of this we will stick to EPs which are more efficiently computable and yield more reduction (to be discussed shortly). Still, we would like to stress that our result applies to any EP, in particular to OPs.

Using an EP of a graph or a matrix, we can derive condensed representations of that graph or matrix using the partition. This is the essence of lifting: *the reduced representation is as good as the original representation for some computational task at hand, while (potentially) having a significantly smaller size.* A key insight that we exploit here is that there is a one-to-one relationship between EPs of the factor graph of an Ising model (as in Def. 1) and the EPs of its MAP-LP matrix (as in Def. 2).

One useful representation of a graph and its equitable partition is via a degree matrix, as illustrated in Fig. 1(b). The degree matrix, $\text{DM}(G, \mathcal{P})$, has $|\mathcal{P}| \times |\mathcal{P}|$ entries, where each entry represents how members of different classes interact. More precisely, $\text{DM}(G, \mathcal{P})_{ij} = |\text{nb}(u) \cap P_j|$, where u is any element of P_i . Due to the bipartiteness of G , this matrix will have the block form $\text{DM}(G, \mathcal{P}) = \begin{pmatrix} 0 & \text{DV} \\ \text{DF} & 0 \end{pmatrix}$, where DV represents the relationship of the P -classes to the Q -classes and DF vice-versa. As a shorthand, we use the notation $\text{DM} = (\text{DF}, \text{DV})$. Graphically (see Fig. 1(c)), a degree matrix can be visualized as a quotient graph G/\mathcal{P} , which is a directed multi-graph. In G/\mathcal{P} there is a node for every class of \mathcal{P} . Given two nodes u, v we have $|\text{nb}(u) \cap P_j|, u \in P_i$ many edges going from u to v . $\text{DM}(G, \mathcal{P})$ is essentially the weighted adjacency matrix of G/\mathcal{P} .

Later on, we will be interested in the interaction of the factors with variables rather than the other way around. Therefore, we introduce the factor quotient graph $G \wr \mathcal{P}$

which corresponds only to the DF-block of $\text{DM}(G, \mathcal{P})$ as shown in Fig. 1(d). That is, we draw only edges going from factor classes to variable classes, but not the other way around. Moreover, as our MRFs are pairwise, a factor class can have a degree of at most two to any variable class. We will thus not write numbers on top of the arcs, but draw double or single edges. To stay consistent with existing terminology, we call the nodes of $G \wr \mathcal{P}$ corresponding to variable classes of G “supervariables”, and factor-class nodes “superfactors”. Note that if \mathcal{P} is the OP of G , the resulting factor quotient is the “lifted graph” considered in [3].

Finally, to compute EPs one can use color-passing (also known as “color refinement” or “1-dimensional Weisfeiler-Lehman”). It is a basic algorithmic routine for graph isomorphism testing. It iteratively partitions, or colors, vertices of a graph according to an iterated degree sequence in the following fashion: initially, all vertices get their label in G as color, and then at each step two vertices that so far have the same color get different colors if for some color c they have a different number of neighbors of color c . The iteration stops if the partition remains unchanged. For matrices, a suitable extension was introduced in [7]. The resulting partition is called the *coarsest equitable partition* (CEP) of the graph, and can be computed asynchronously in quasi-linear time $O((n+m) \log n)$ (e.g., see [2]).

Lifted Linear Programming and Lifted MAP-LPs. By computing an EP of the matrix of a linear program (LP) one can derive a smaller but equivalent LP – the “lifted” LP – whose optimal solutions can easily be translated back to a solution of the original LP [13, 7]. This will be key in what follows, and is reviewed below.

Let $L = (A, \mathbf{b}, \mathbf{c})$ be a linear program, corresponding to the optimization problem $\mathbf{x}^* = \text{argmax}_{A\mathbf{x} \leq \mathbf{b}} \mathbf{c}^T \mathbf{x}$.

Theorem 3 (Lifted Linear Programs [7]⁴). Let $\mathcal{P} = \{P_1, \dots, P_p\} \cup \{Q_1, \dots, Q_q\}$ be an equitable partition with incidence matrix $B = (B_P, B_Q)$ of the rows and columns of A , which respects the vector $\mathbf{u} = [\mathbf{c}, \mathbf{b}]^T$. Then, $L' = (\widehat{B}_Q A B_P, \widehat{B}_Q \mathbf{b}, B_P^T \mathbf{c})$ is an LP with fewer variables and constraints. The following relates L and L' :

- (a)** If \mathbf{x}' is a feasible point in L' , then $B_P \mathbf{x}'$ is feasible in L . If in addition \mathbf{x}' is optimal in L' , $B_P \mathbf{x}'$ is optimal in L with the same objective value.
- (b)** if \mathbf{x} is a feasible point in L , then $\widehat{B}_P \mathbf{x}$ is feasible in L' . If in addition \mathbf{x} is optimal in L , $\widehat{B}_P \mathbf{x}$ is optimal in L' with the same objective value.

In previous works, only part **(a)** has been exploited. That is, as illustrated in Fig. 2, given any LP we construct L' using equitable partitions, solve it (often faster than the original one), and finally transfer the solution to the larger problem by virtue of **(a)** above. This “standard” way applies to MAP-LPs as follows (see [13, 7] for more details).

⁴We restrict the theorem to what is relevant for the discussion.

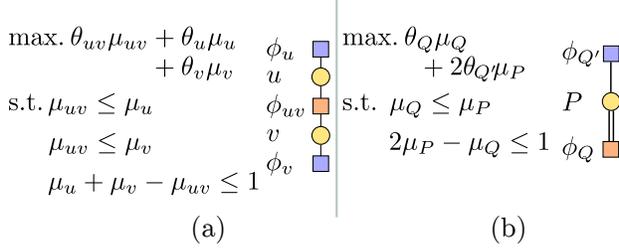

Figure 2: Illustration of lifting MAP-LPs. (a) A factor graph and the corresponding MAP-LP; (b) A factor quotient and the corresponding lifted MAP-LP. This example also illustrates that the lifted MAP-LP in (b) is not amenable to standard MP anymore, since the constraint $2\mu_P - \mu_Q \leq 1$ does not appear in standard MAP-LPs. However, note that the lifted structure is identical to the one in Fig. 1(d), yet the original factor graph in (a) above is smaller. That is, factor graphs of different sizes may share the (structurally) same lifted MAP-LP.

Given an MRF with graph G and parameter θ , which we denote by $I = (G, \theta)$, denote its standard MAP-LP relaxation by the LP defined via $(A, \mathbf{b}, \mathbf{c})$. To obtain a potentially smaller LP, we calculate the equitable partition of the LP, and its corresponding B, \hat{B} matrices. The LP defined via $(\hat{B}_Q A B_P, \hat{B}_Q \mathbf{b}, B_P^T \mathbf{c})$ is then equivalent to the original MAP-LP in the sense of Thm. 3. We refer to this LP as LMAP-LP(I).

Unfortunately, as we will show in the next section, LMAP-LP(I) is not a standard MAP-LP. In turn, it is not amenable to standard message passing based MAP-LP solvers. Fortunately, by making heavily use of part (b) of Thm. 3 as well, we will show how to produce LPs that have this special structure. This results “lifting by reparametrization”.

3 LIFTING BY REPARAMETRIZATION

To introduce the “lifting by reparametrization” approach we proceed in two steps. First, we introduce the class of all MRFs whose MAP-LPs are equivalent, in the sense that solving one such LP results in a solution to all LPs in the class. Then, we will show how to construct the smallest such equivalent MRFs for a given MRF in the class.

LP-equivalence of MRFs. We start off by discussing the structure of the lifted MAP-LP (LMAP-LP). The main purpose is to illustrate why lifting generally does not preserve the message-passing structure of the LP (see also Fig. 2). Then, as an alternative, we introduce an equivalence theorem in the spirit of Thm. 3. As illustrated in Fig. 3, instead of relating ground (original) and lifted LPs, it relates ground LPs of different sizes that have the same lifting. This is the main insight underlying our “lifting by reparametrization” approach: *instead of lifting the ground MAP-LP of an MRF at hand, we replace it by the ground*

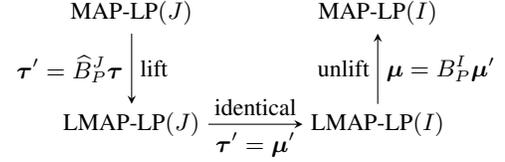

Figure 3: Commutative diagram established by Thm. 6 underlying our reparametrization approach to lifted inference.

LP of another equivalent MRF, hopefully of much smaller size. In the following we will now formally define what “equivalence” means here.

Our starting point is to note that LMAP-LP(I) only depends on I via the structure of $G \wr \mathcal{P}$. To provide the formal result, we need a few more notations. First, the graph $G \wr \mathcal{P}$ has nodes corresponding to groups of variables in the original factor graph, and nodes corresponding to groups of factors in the original factor graph. We denote those by $V(G \wr \mathcal{P})$ and $F(G \wr \mathcal{P})$ respectively. Second, $G \wr \mathcal{P}$ is a multigraph and may have multiple edges between its nodes. We define $\text{nb}(Q)$ to be the neighbors of $Q \in F(G \wr \mathcal{P})$ in $G \wr \mathcal{P}$, with repetitions. In other words, if there are two edges between $P, Q \in G \wr \mathcal{P}$, then $\text{nb}(Q)$ will contain P twice.

Proposition 4. *Let $\mathcal{P} = \{P_1, \dots, P_p\} \cup \{Q_1, \dots, Q_q\}$ be an equitable partition of the variables and factors of the MRF specified by $I = (G, \theta)$. Let $G \wr \mathcal{P}$ be the factor quotient of I . Then, LMAP-LP(I) can be written as:*

$$\mu^* = \operatorname{argmax}_{\mu' \in L'(G)} \sum_{P \in V(G \wr \mathcal{P})} \theta_P |P| \mu_P + \sum_{Q \in F(G \wr \mathcal{P})} \theta_Q |Q| \mu_Q.$$

Where θ_P, θ_Q are the parameters of I for the corresponding partition elements. The constraints $L'(G)$ are defined as the set of $\mu \geq 0$ such that:

$$\left\{ \begin{array}{l} \forall P, P' \in V(G \wr \mathcal{P}), Q \in F(G \wr \mathcal{P}) \\ \text{s.t. } P, P' \in \text{nb}(Q) : \\ \alpha'(Q) \equiv \mu_Q \leq \mu_P; \beta'(Q) \equiv \mu_Q \leq \mu_{P'}; \\ \gamma'(Q) \equiv \mu_P + \mu_{P'} - \mu_Q \leq 1 \end{array} \right\} \quad (3)$$

Proof. We omit a detailed proof of this proposition due to space restrictions. Essentially, the argument is that the reformulation of Sec. 7 in [3] holds for any equitable partition, not just the orbit partition of an MRF. In this case, the Q -classes generalize edge orbits while the P -classes generalize variable orbits. \square

This proposition tells us that we can construct $L'(G)$ by the following procedure: (1) we instantiate an LP variable μ_P for every variable class $P \in V(G \wr \mathcal{P})$ (i.e., every supervariable) (2) we instantiate an LP variable μ_Q for every factor class $Q \in F(G \wr \mathcal{P})$ (i.e. superfactor); (3) for every pair

Algorithm 1: Solving MRF I using an equivalent MRF J

Input: Ground MRF I and LP-equivalent MRF J **Output:** MAP-LP(I) solution μ

- 1 **Solve** MRF J , i.e., compute $\tau = \operatorname{argmax}_{\mu} \operatorname{MAP-LP}(J)$;
 - 2 **Lift** the solution τ to LMAP-LP(J). That is, compute $\tau' = \widehat{B}_P^J \tau$ (Thm. 3(b));
 - 3 **Recover** solution of I , i.e., compute $\mu = B_P^I \tau'$ (Thm. 3(a));
-

of classes P, Q , if some ground variable $x_i \in P$ is adjacent to some ground factor $\phi_{ij} \in Q$, we add the constraint $\mu_Q \leq \mu_P$. For every triplet P, P', Q such that there exist $x_i \in P, x_j \in P'$ adjacent to $\phi_{ij} \in Q$, we add the constraint $\mu_P + \mu_{P'} - \mu_Q \leq 1$.

Observe that the factor quotient graph $G \wr \mathcal{P}$ actually contains exactly the necessary and sufficient information to construct $L'(G)$: it gives us the number of classes and the relations between them. Hence, it would seem that $L'(G)$ is just $L(G \wr \mathcal{P})$, and we are done. Unfortunately this is not exactly the case, and we have to be a little bit more careful.

Recall our running example from Fig. 2. There can be a factor ϕ_{ij} in some Q , whose adjacent variables x_i, x_j fall into the same class, $P = P'$. In terms of constraints, the corresponding triplet P, P', Q , with $P = P'$ yields the constraint $2\mu_P - \mu_Q \leq 1$. Graphically, this situation occurs whenever $G \wr \mathcal{P}$ contains a double edge. This also happens in our running examples (see Fig. 2(b)). Unfortunately, such constraints have no analogue in MAP-LP(I)!

How can we deal with this? Assume for the moment that for any ground factor ϕ_{ij} , $\mathcal{P}(i) \neq \mathcal{P}(j)$, in other words $G \wr \mathcal{P}$ happens to be a simple graph (no edge connects at both ends to the same vertex, and there is no more than one edge between any two different vertices). Then we can compute a new weight vector $\theta' \in \mathbb{R}^q$ as $\theta'_Q = |Q|\theta_Q$, $\theta'_P = |P|\theta_P$ (cf. Eq. 3). In this case, the MRF $I' = (G \wr \mathcal{P}, \theta')$ would indeed be a smaller MRF, whose MAP-LP is identical to the LMAP-LP of I . This enables us to view lifting as reparametrization: (1) we compute $G \wr \mathcal{P}$ from G ; (2) instead of solving LMAP-LP(I), we solve MAP-LP(I') using any solver we want, including message-passing algorithms such as MPLP, TRWBP, among others; (3) because of the equivalence, we treat the solution of MAP-LP(I') as a solution of LMAP-LP(I) and unlift it using Thm. 3(a).

While our assumption does not hold in general (see e.g. Fig. 1) — and we will indeed account for it below — the procedure just outlined above is the main idea underlying “lifting by reparametrization” method. Since the LMAP-LP of I will potentially contain constraints such as $2\mu_P - \mu_Q \leq 1$, it will not be the MAP-LP of any simple graph. So instead, we will look for something

else, namely a proper (potentially much smaller) MRF J , where instead of LMAP-LP(I) = MAP-LP(J) we ask that LMAP-LP(I) = LMAP-LP(J). We call any pair of MRF where this holds LP-equivalent.

Definition 5 (LP equivalent MRFs). *Two MRFs $I = (G, \theta^I)$ and $J = (H, \theta^J)$ having simple graphs are LP-equivalent if we can find an equitable partition \mathcal{P} of G with incidence matrix $B = (B_P, B_Q)$ and an equitable partition \mathcal{P}' of H with incidence matrix $B' = (B'_P, B'_Q)$ such that $\operatorname{LMAP-LP}(I) := (\widehat{B}_Q^T A B_P, \widehat{B}_Q^T \mathbf{b}, B_P^T \mathbf{c}) = ((\widehat{B}'_Q)^T A' B'_P, (\widehat{B}'_Q)^T \mathbf{b}', (B'_P)^T \mathbf{c}') =: \operatorname{LMAP-LP}(J)$.*

Then, we apply the lifted equivalence of Thm. 3(b) and are done. As summarized in Alg. 1, we solve the smaller MAP-LP(J) using any MRF-structure-aware LP solver. We obtain an optimal solution of LMAP-LP(J) using B_P^T , as prescribed by Thm. 3(b). Due to the lifted equivalence, this solution is also a solution of LMAP-LP(I), hence we recover (or “unlift”) the solution with respect to I using B_P . In doing so, we end up with an optimal solution of MAP-LP(I). This procedure is outlined in Fig. 3. We will shortly prove its soundness.

Theorem 6. *Let I and J be two LP-equivalent MRFs of possibly different sizes. Then, (A) if τ is feasible in MAP-LP(J), $\mu = B_P \widehat{B}'_P \tau$ is feasible in MAP-LP(I). Moreover, if τ is optimal, μ is optimal as well. (B) if μ is feasible in MAP-LP(I), $\tau = B'_P \widehat{B}_P \mu$ is feasible in MAP-LP(J). Moreover, if μ is optimal, τ is optimal as well.*

Proof. We prove only (A) due to the symmetry of the statement. Let τ be feasible in MAP-LP(J). By Thm. 3(b), $\tau' = B'_P \tau$ is feasible in LMAP-LP(J). Due to LP-equivalence, $\operatorname{LMAP-LP}(J) = \operatorname{LMAP-LP}(I)$, τ' is also a solution to LMAP-LP(I). Now, we unlift τ' with respect to LMAP-LP(I). Due to Thm. 3(b), $\mu = B_P (\widehat{B}'_P) \tau'$ is feasible in MAP-LP(I). Moreover, if τ is optimal in MAP-LP(J), Thm. 3 tells us that optimality will hold throughout the entire chain of LPs. \square

To summarize our argument so far, Thm. 6 provides us with a way to exploit the MAP-LP equivalence between MRFs of different sizes. What is still missing is a way to efficiently construct such smaller LP-equivalent MRFs as input to Alg. 1. We will now address this issue.

Finding equivalent MRFs. So far we discussed the equivalence of MRFs of different sizes in terms of their (lifted) MAP-LPs. Making use of our result, however, requires efficient algorithm to find LP-equivalent MRFs of considerably smaller size. Given an MRF I and its EP, Alg. 2 finds the smallest LP-equivalent MRF I' in linear time. Next to illustrating Alg. 2 and proving that it is sound, we will also show that the size of I' is at most $2|G \wr \mathcal{P}|$.

Let $I = (G, \theta)$ be an MRF and \mathcal{P} be an EP of its variables and factors. We will introduce the algorithm in two

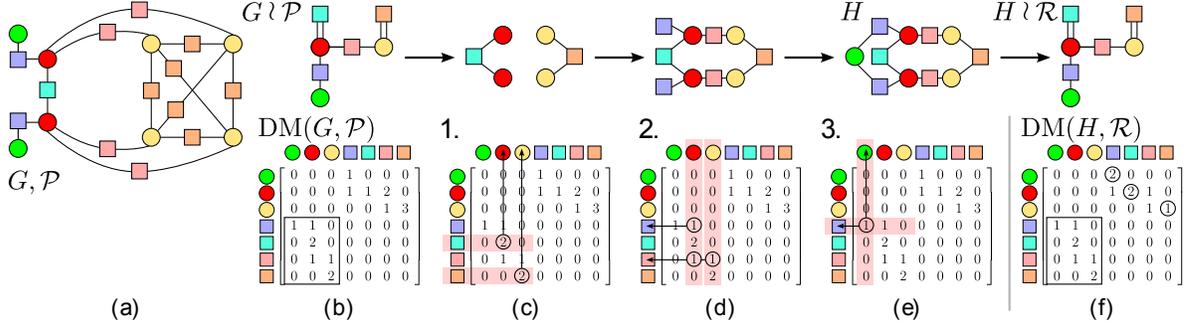

Figure 4: Illustration of “lifted inference by reparametrization” as summarized in Alg. 2 and used as input to Alg. 1. (a) input: a graph G and its coarsest equitable partition \mathcal{P} ; (b) the factor quotient $G \wr \mathcal{P}$ and the corresponding degree matrix; (c) **Step (A)**: representing all degree 2 factors and the corresponding degree 2 variables. (d) **Step (B)**: instantiating degree 1 factors adjacent to degree 2 variables; (e) **Step (C)**: instantiating the remaining classes. After this step we terminate and output the result H ; (f) soundness: $H \wr \mathcal{R}$ is identical to $G \wr \mathcal{P}$. Observe that the upper-right corner of $DM(G, \mathcal{P})$ is different from that of $DM(H, \mathcal{R})$. (Best viewed in color.)

steps: first, we discuss how to obtain a simple graph G' which gives the structure of an LP-equivalent MRF, i.e. $L'(G) = L'(G')$. Then we show how to find weights θ' for this graph, such that the MRF $I' = (G', \theta')$ is LP-equivalent to I . Finally, we will show correctness and minimality of our approach.

Recall that in Eq. 3 the lifted Ising polytope of LMAP-LP(I) is fully defined by the factor quotient $G \wr \mathcal{P}$. Hence, a necessary and sufficient condition for LP-equivalence (regarding the constraints of the LP, we will deal with the objective shortly) in MRFs is that the corresponding graphs exhibit the same factor quotients for some equitable partitions. Thus, the problem of finding an LP-equivalent structure boils down to finding G' such that $G \wr \mathcal{P} = G' \wr \mathcal{P}'$ for some partition \mathcal{P}' . Moreover, to maximize the compression, we want \mathcal{P} to be the coarsest EP of G (resulting in the smallest possible $G \wr \mathcal{P}$) and that G' is the smallest possible LP-equivalent MRF. Let us now see how to find G' . As a running example, we will use the factor graph in Fig 4(a).

Suppose $G \wr \mathcal{P}$ is given, e.g. computed using color-refinement. For our running example, $G \wr \mathcal{P}$ is shown in Fig. 4(b). Let us divide the superfactors and supervariables of $G \wr \mathcal{P}$ into classes based on their connectivity. A superfactor connected to a supervariable via a double edge is called a **(2)-superfactor**. In Fig. 4(b), these are the cyan and orange superfactors. Correspondingly, we call a variable connected to a superfactor via a double edge a **(2)-supervariable** (red and yellow in Fig. 4(b)). Next, a superfactor connected to at least one (2)-supervariable via a *single* edge is called a **(1, 2)-superfactor** (violet and pink in Fig. 4(b)). Finally, all other superfactors and supervariables are **(1)-superfactors** and **(1)-supervariables** respectively (e.g. the green supervariable).

We then compute G' in the following way as also illustrated in Fig. 4(c)-(e). We start with an empty graph. Then, **Step**

(A) as illustrated in Fig. 4(c) consists of adding for every (2)-superfactor in $G \wr \mathcal{P}$ exactly one representative factor to G' . Furthermore, for every (2)-supervariable, we add two representatives in G' and connect them to the corresponding (2)-superfactor representatives whenever the supernodes they represent are connected in $G \wr \mathcal{P}$. In **Step (B)**, see Fig. 4(d), for every (1, 2)-superfactor, we instantiate two representatives. Moreover, for every (2)-supervariable (all of them are already represented in G'), we match the two (1, 2)-superfactor representatives to the two (2)-supervariable representatives whenever the represented supernodes are connected in $G \wr \mathcal{P}$. Finally, **Step (C)** as shown in Fig. 4(e) introduces one representative for every other supernode and connects it to other representatives based on $G \wr \mathcal{P}$. If it happens that the represented supernode is connected to a (2)-supervariable or (1, 2)-superfactor in $G \wr \mathcal{P}$, we connect the representative to both representatives of the corresponding neighbor.

This is summarized in Alg. 2 and provably computes a minimal structure of an LP-equivalent MRF. Finally, we must compute a parameter vector for I' to facilitate LP-equivalence. Suppose \mathcal{P}' is the EP of G' induced by Alg. 2 (the partition which groups nodes in G' together if they represent the same supernode of $G \wr \mathcal{P}$). Let Q be any factor class in \mathcal{P} and Q' be the corresponding class in \mathcal{P}' . We then compute the weight $\theta_{Q'}$ of the factors $\phi' \in Q'$ of I' as

$$\theta_{Q'} = (|Q|/|Q'|)\theta_Q, \quad (4)$$

where θ_Q is the weight associated with the class Q in \mathcal{P} (recall Prop. 4). We now argue that the resulting Ising model $I' = (G', \theta')$ is LP-equivalent to $I = (G, \theta)$.

Theorem 7 (Soundness). $I' = (G', \theta')$ as computed above is LP-equivalent to $I = (G, \theta)$.

Proof. Following Def. 5 we must show that given I and its EP \mathcal{P} , there is a partition \mathcal{P}' of I' such that the lifted

Algorithm 2: Computing the smallest LP-equivalent MRF.

Input: Fully lifted factor $G \wr \mathcal{P}$ of G **Output:** G' such that $\exists \mathcal{P}' : G' \wr \mathcal{P}' = G \wr \mathcal{P}$.

```
1 Initialize  $G' \leftarrow \emptyset$ , i.e., the empty graph;
   /* Step (A) Treat double edges */
2 for every (2)-superfactor  $Q$  in  $G \wr \mathcal{P}$  with neighboring
   (2)-supervariable  $P$  do
3     Add a factor  $q$  representing  $Q$  to  $G'$ ;
4     Add two variables  $p, p'$  representing  $P$  in  $G'$  and
     connect them to the factor  $q$ ;
5 end
   /* Step (B) To preserve degrees, treat now single
   edges in  $G'$  incident to double edges */
6 for every (1,2)-superfactor  $Q$  in  $G \wr \mathcal{P}$  do
7     Add two factors  $q, q'$  representing  $Q$  to  $G'$ ;
8     Connect  $q$  to  $p$  and  $q'$  to  $p'$  where  $p, p'$  are the
     representatives of a (2)-supervariable  $P$  in  $G \wr \mathcal{P}$ 
     that is neighboring  $Q$ ;
9 end
   /* Step (C) Add remaining nodes and edges to  $G'$  */
10 for all supervariables  $P$  and superfactor  $Q$  in
     $G \wr \mathcal{P}$  not represented in  $G'$  so far do
11     Add a single variable  $p$  resp. factor  $q$  to  $G'$ ;
12     Connect  $p$  to all representatives of superfactor  $Q$ 
     neighboring to  $P$  in  $G \wr \mathcal{P}$ ;
13 end
```

LPs are equal. We take the partition \mathcal{P}' to be the one induced by Alg. 2. \mathcal{P}' is equitable on G' by construction: we can go through Alg. 2 to verify that every two nodes in G' representing the same supernode of $G \wr \mathcal{P}$ are connected to the same number of representatives of every other supernode of $G \wr \mathcal{P}$ (we omit this due to space restrictions). Now, to show that LMAP-LP(I) has the same constraints as LMAP-LP(I'), we need $G \wr \mathcal{P} = G' \wr \mathcal{P}'$. To see that this holds, observe that Alg. 2 connects p to q in G' if only if P is connected to Q in $G \wr \mathcal{P}$: if Q is a (2)-superfactor, P is a (2)-supervariable – q will be connected to p in **Step (A)**. If P is a (2)-supervariable and Q is (1, 2)-superfactor, p and q will be connected in **Step (B)**. If Q is (1, 2)- of a (1)-superfactor and P is a (1)-supervariable, p and q will be connected in **Step (C)**. There are no other possible combinations. Hence, as P' consists of all representatives of P and Q' consists of all representatives of Q , P' and Q' are connected in $G' \wr \mathcal{P}'$ iff P is connected to Q . Moreover, representatives of (2)-superfactors are the only ones connected to two representatives of the same supervariable in G' , hence Q' is connected to P' via a double edge in $G' \wr \mathcal{P}'$ if and only if Q is connected to P via a double edge in $G \wr \mathcal{P}$.

Next, we argue that the objectives of the lifted LPs are the same. Using the parameters calculated with Eq. 4, the objective of LMAP-LP(I') is $\sum_{Q' \in \mathcal{P}'} |Q'| \theta_{Q' \mu_{Q'}} = \sum_{Q' \in \mathcal{P}'} |Q'| (|Q|/|Q'|) \theta_{Q \mu_{Q'}} = \sum_{Q' \in \mathcal{P}'} |Q| \theta_{Q \mu_{Q'}} =$

$\sum_{Q \in \mathcal{P}} |Q| \theta_{Q \mu_Q}$. Observe that the final term is exactly the objective of LMAP-LP(I) as given by Prop. 4. We conclude LMAP-LP(I) = LMAP-LP(I'). \square

We have thus shown that Alg. 2 and Eq. 4 together produce an LP-equivalent MRF. We will now show that this MRF is the smallest LP-equivalent MRF to the original.

Theorem 8 (Minimality). *Let $I = (G, \theta)$ be an Ising model and an $I' = (G', \theta')$ be computed as above. Then there is no other LP-Equivalent MRF with less factors or less vertices than G' . Moreover, $|V(G')| \leq 2|V(G \wr \mathcal{P})|$ and G' and $|E(G')| \leq 2|E(G \wr \mathcal{P})|$, i.e., the size of I' is at most twice the size of the fully lifted model.*

Proof. Let H be any graph with the same factor quotient as G . Then, let Q be a (2)-superfactor in $G \wr \mathcal{P}$ adjacent to some (2)-supervariable P . Due to equivalence, Q' is a (2)-superfactor in $H \wr \mathcal{P}'$ as well and P' is a (2)-supervariable. Hence, the class $P' \in \mathcal{P}'$ must have at least two ground variables from H . Next, let Q be a (1, 2)-factor in $G \wr \mathcal{P}$ adjacent to a (2)-supervariable. Analogously, Q' is a (1, 2)-factor in $H \wr \mathcal{P}'$ and P' is a (2)-supervariable. As we have established P' must have at least two ground elements in H . Since P' is connected to Q' via a single edge, the same holds on the ground level: any $p \in P'$ is connected to $q \in Q'$ via a single edge. This means that there are at least as many $q \in Q'$ as there are $p \in P'$, that is, at least two. All other supernodes must have at least one representative. These conditions are necessary for any LP-equivalent H .

Now, let G' be computed from Alg. 2 and \mathcal{P}' be the corresponding partition. To see why G' is minimal, observe that G' has *exactly* two representatives of any (2)-supervariable in $G \wr \mathcal{P}$ (step 1) and *exactly* two representatives of any (1, 2)-superfactor (step 2). All other supernodes have *exactly* one representative (steps 1 and 3). Therefore, G' meets the conditions with equality and is thus minimal. Finally, since we represent any supernode of $G \wr \mathcal{P}$ by at most 2 nodes in G' , G' can have at most twice as many factors and variables as $G \wr \mathcal{P}$. \square

Since Alg. 2 makes only one pass over the lifted factor graph, the overall time to compute the LP-equivalent MRF (which is then input to Alg. 1) is dominated by color-refinement, which is quasi-linear in the size of G .

4 EMPIRICAL ILLUSTRATION

The empirical illustration of our theoretical results investigates two questions. **(Q1)** Is reparametrization comparable to lifted MAP-LPs in terms of time and quality when using LP solvers? **(Q2)** If so, can lifted MPLP and TRW by reparametrization pay-off when solving MAP-LPs? And finally, **(Q3)** how does reparametrization behave in the presence of approximate evidence?

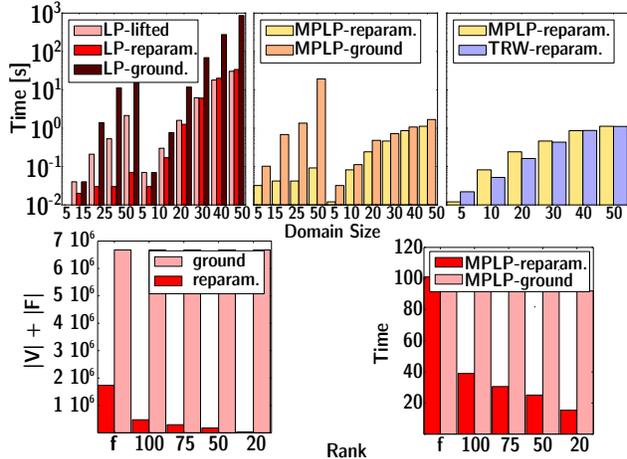

Figure 5: Experimental illustration (for ease of comparison the first three plots have the same scales). From top to bottom, from left to right: (a) Comparison (domain size vs. end-to-end running time) of solving LPs using GLPK (ground, fully lifted, and reparametrization). The first block of domain sizes (5, 15, 25, 50) are from the friends-smoker MLN; the second block (5, 10, . . . , 50) is on the CORA MLN. (b) Performance of MPLP (ground vs. reparametrization) on the same MLNs (same block structure). (c) Comparison (domain size vs. end-to-end running time) of TRW and MPLP by reparametrization on CORA. (d,e) Model sizes for exact evidence (“f”) and approximations of ranks 100 to 20 and running times.

To this aim we implemented the reparametrization approach on a single Linux machine (4×3.4 GHz cores, 32 GB main memory) using Python and C/C++. For evaluation we considered three sets of MRFs. One was generated from grounding a modified version of a Markov Logic Network (MLN) used for entity resolution on the CORA dataset. Five different MRFs were generated by grounding the model for 5, 10, 20, 30, 40 and 50 entities, having 960, 4081, 13933, 27850, 4699 and 76274 factors respectively. The second set was generated from a pairwise version of the friends-smokers MLN [4] for 5, 15, 25 and 50 people, having 190, 1620, 4450 and 17650 factors. The third set considers a simple $\text{fr}(X, Y) \Rightarrow (\text{sm}(X) \Leftrightarrow \text{sm}(Y))$ rule (converted to a pairwise MLN) where we used the `link_common` observations from the “Cornell” dataset as evidence for `fr`. Then we computed different low-rank approximations of the evidence using [23].

In all cases, there were only few additional factors due to treating double edges. What is more interesting are the running times and overall performances. Fig. 5(a) shows the end-to-end running time for solving the corresponding ground, (fully) lifted, and reparametrized LPs using GLPK. As one can see, reparametrization is competitive to lifted linear programming (LLP) in time. Actually, it can even save time since it runs directly on the factor graph and

not on the LP matrix — which is larger than the factor graph — for discovering symmetries. Moreover, in all cases the same objective was achieved, that is, reparametrization does not sacrifice quality. In turn, question (Q1) can clearly be answered affirmatively. Fig. 5(b) summarizes the performance of MPLP on the reparametrized models. As one can see, MPLP can be significantly faster than LLP for solving MAP-LPs without sacrificing the objective; it was always identical to the LP solutions. To illustrate that one may also run other LP-based message-passing solvers, Figs. 5(c) summarizes the performance of TRW on CORA. As one can see, lifting TRW by reparametrization is possible and differences in time are likely due to initialization, stopping criterion, etc. In any case, question (Q2) can clearly be answered affirmatively. All results so far show that lifted LP-based MP solvers can be significantly faster than generic LP solvers. Figs. 5(d,e) summarize the results for low-rank evidence approximation. As one can see in (d), significant reduction in model size can be achieved even at rank 100, which in turn can lead to faster MPLP running times (e). For each low-rank model, the ground and the reparametrized MPLP achieved the same objective. Plot (e), however, omits the time for performing BMF. It can be too costly to first run BMF canceling the benefits of lifted LP-based inference (in contrast to exact inference as in [23]). Nevertheless, w.r.t. (Q3) these results illustrate that evidence approximation can result in major speed-ups.

5 CONCLUSIONS

In this paper, we proved that lifted MAP-LP inference in MRFs with symmetries can be reduced to MAP-LP inference in standard models of reduced size. In turn, we can use any off-the-shelf MAP-LP inference algorithm — in particular approaches based on message-passing — for lifted inference. This incurs no major overhead: for given evidence, the reduced MRF is at most twice as large than the corresponding fully lifted MRF. By plugging in different existing MAP-LP inference algorithms, our approach yields a family of lifted MAP-LP inference algorithms. We illustrated this empirically for MPLP and tree-reweighted BP. In fact, running MPLP yields the first provably convergent lifted MP approach for MAP-LP relaxations. More importantly, our result suggests a novel view on lifted inference: *lifted inference can be viewed as standard inference in a reparametrized model*. Exploring this view for marginal inference as well as for branch-and-bound MAP inference approaches are the most attractive avenue for future work.

Abstract

Gaussian processes (GP) are a powerful tool for nonparametric regression; unfortunately, calculating the posterior variance in a standard GP model requires time $O(n^2)$ in the size of the training set. Previous work by Shen et al. (2006) used a k -d tree structure to approximate the posterior mean in certain GP models. We extend this approach to achieve efficient approximation of the posterior covariance using a tree clustering on pairs of training points, and demonstrate significant improvements in performance with negligible loss of accuracy.

1 INTRODUCTION

Complex Bayesian models often tie together many smaller components, each of which must provide its output in terms of probabilities rather than discrete predictions. Gaussian process (GP) regression (Rasmussen and Williams, 2006) is a natural fit for such systems, but its applications have been limited by computational concerns: training a GP model on n points requires $O(n^3)$ time, while computing the posterior distribution at a test point requires $O(n)$ and $O(n^2)$ operations for the mean and variance respectively.

This paper focuses on the fast evaluation of GP posterior probabilities in a running inference system, for which a model has already been trained. Fast runtime performance is a common requirement for real-world systems; for example, a speech recognition system might be trained once in the cloud, then run many times on a smartphone under a tight computational budget. Our particular work is motivated by an application to nuclear test monitoring: after training on historical seismic events, we want to identify and localize new events in realtime by processing signals from a worldwide sensor network. In this application, as with many others, probabilities from a GP are computed in the inner loop of a message-passing or MCMC

inference algorithm; this computation must be efficient if inference is to be feasible.

Previous work has explored the use of space-partitioning tree structures for efficient computation of GP posterior means in models where the covariance kernel has a short lengthscale or compact support (Shen et al., 2006). We extend this in several ways. First, we describe the *product tree* data structure, along with an algorithm that uses this structure to efficiently compute posterior covariances. This provides what is to our knowledge the first account of GP regression in which the major test-time operations (posterior mean and covariance) run in time sublinear in the training set size, given a suitably sparse kernel matrix. We give a novel cutoff rule, applicable to both mean and covariance calculations, that guarantees provably bounded error. We also extend the class of models to which tree-based methods can be efficiently applied, by showing how to include a low-rank global component modeled either by an explicit parametric representation or by an approximate GP with inducing points (Snelson and Ghahramani, 2006). Finally, we evaluate this work empirically, with results demonstrating significant speedups on synthetic and real-world data, and in the process identify a simple method that often provides competitive performance to the more complex product tree.

2 BACKGROUND

2.1 GP REGRESSION MODEL

We assume as training input a set of labeled points $\{(\mathbf{x}_i, y_i) | i = 1, \dots, n\}$, where we suppose that

$$y_i = f(\mathbf{x}_i) + \epsilon_i \quad (1)$$

for some unknown function $f(\cdot)$ and i.i.d. Gaussian observation noise $\epsilon_i \sim \mathcal{N}(0, \sigma_n^2)$. Treating the estimation of $f(\cdot)$ as a Bayesian inference problem, we consider a Gaussian process prior distribution $f(\cdot) \sim GP(0, k)$, parameterized by a positive-definite *covariance* or *kernel* function $k(x, x')$. Given a set X^* containing m test points, we de-

rive a Gaussian posterior distribution $f(X^*) \sim \mathcal{N}(\mu^*, \Sigma^*)$, where

$$\mu^* = K^{*T} K_y^{-1} \mathbf{y} \quad (2)$$

$$\Sigma^* = K^{**} - K^{*T} K_y^{-1} K^* \quad (3)$$

and $K_y = k(X, X) + \sigma_n^2 I$ is the covariance matrix of training set observations, $K^* = k(X, X^*)$ denotes the $n \times m$ matrix containing the kernel evaluated at each pair of training and test points, and similarly $K^{**} = k(X^*, X^*)$ gives the kernel evaluations at each pair of test points. Details of the derivations, along with general background on GP regression, can be found in Rasmussen and Williams (2006).

In this work, we make the additional assumption that the input points \mathbf{x}_i and test points \mathbf{x}_p^* lie in some metric space (\mathcal{M}, d) , and that the kernel is a monotonically decreasing function of the distance metric. Many common kernels fit into this framework, including squared-exponential, rational quadratic, piecewise-polynomial and Matérn kernel families; anisotropic kernels can be represented through choice of an appropriate metric.

2.2 RELATED WORK

Tree structures such as k -d trees (Friedman et al., 1977) form a hierarchical, multiresolution partitioning of a dataset, and are commonly used in machine learning for efficient nearest-neighbor queries. They have also been adapted to speed up nonparametric regression (Moore et al., 1997; Shen et al., 2006); the general approach is to view the regression computation of interest as a sum over some quantity associated with each training point, weighted by the kernel evaluation against a test point. If there are sets of training points having similar weight – for example, if the kernel is very wide, if the points are very close to each other, or if the points are all far enough from the query to have effectively zero weight – then the weighted sum over the set of points can be approximated by an unweighted sum (which does not depend on the query and may be precomputed) times an estimate of the typical weight for the group, saving the effort of examining each point individually. This is implemented as a recursion over a tree structure augmented at each node with the unweighted sum over all descendants, so that recursion can be cut off with an approximation whenever the weight function is shown to be suitably uniform over the current region.

This tree recursion can be thought of as an approximate matrix-vector multiplication (MVM) operation; a related method, the Improved Fast Gauss Transform (Morariu et al., 2008), implements fast MVM for the special case of the SE kernel. It is possible to accelerate GP training by combining MVM methods with a conjugate gradient solver, but models thus trained do not allow for the computation of predictive variances. One argument against MVM techniques (and, by extension, the approach of this paper)

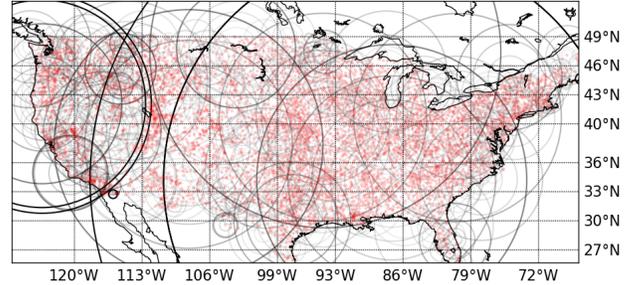

Figure 1: Cover tree decomposition of USA precipitation measurement stations (see Section 5.3).

is that their efficiency requires shorter lengthscales than are common in machine learning applications (Murray, 2009); however, we have found them quite effective on datasets which do have genuinely sparse covariance structure (e.g., geospatial data), or in which the longer-scale variation can be represented by a low-rank component.

Another related approach is the use of local approximations, in which different GPs are trained in different regions of the input space. There is some evidence that these can provide accurate predictions which are very fast to evaluate (Chalupka et al., 2013); however, they face boundary discontinuities and inaccurate uncertainty estimates if the data do not naturally form independent clusters.

2.3 k -d VERSUS COVER TREES

Although related work (Moore et al., 1997; Shen et al., 2006) has generally used k -d trees as the multiresolution structure, this paper instead uses cover trees (Beygelzimer et al., 2006) to allow for non-Euclidean metrics. A cover tree on n points can be constructed in $O(n \log n)$ time, and the construction and query times scale only with the *intrinsic* dimensionality of the data, allowing for efficient nearest-neighbor queries in higher-dimensional spaces (Beygelzimer et al., 2006). Figure 1 shows a cover-tree decomposition of one of our test datasets.

We do not depend specifically on the cover tree algorithm; any similar tree construction algorithm could be used, provided (a) there is a one-to-one correspondence between the leaves of the tree and the training points $x_i \in X$, and (b) each non-leaf node \mathbf{n} is associated with some point $x_{\mathbf{n}} \in \mathcal{M}$, such that all descendants of \mathbf{n} are contained within a ball of radius $r_{\mathbf{n}}$ centered at $x_{\mathbf{n}}$. For example, a ball tree (Uhlmann, 1991), or a tree created through agglomerative clustering on the training points, could also satisfy these criteria.

Figure 2: Recursive algorithm to computing GP covariance entries using a product tree. Abusing notation, we use \mathbf{n} to represent both a tree node and the pair of points $\mathbf{n} = (\mathbf{n}_1, \mathbf{n}_2)$ associated with that node.

3 EFFICIENT COVARIANCE USING PRODUCT TREES

We now consider efficient calculation of the GP covariance (3). The primary challenge is the multiplication $K^{*T}K_y^{-1}K^*$. For simplicity of exposition, we will focus on computing the (i, j) th entry of the resulting matrix, i.e., on the multiplication $\mathbf{k}_i^{*T}K_y^{-1}\mathbf{k}_j^*$ where \mathbf{k}_i^* denotes the vector of kernel evaluations between the training set and the i th test point, or equivalently the i th column of K^* . Note that a naïve implementation of this multiplication requires $O(n^2)$ time.

We might be tempted to apply the vector multiplication primitive of Shen et al. (2006) separately for each row of K_y^{-1} to compute $K_y^{-1}\mathbf{k}_j^*$, and then once more to multiply the resulting vector by \mathbf{k}_i^* . Unfortunately, this requires n vector multiplications and thus scales (at least) linearly in the size of the training set. Instead, we note that we can rewrite $\mathbf{k}_i^{*T}K_y^{-1}\mathbf{k}_j^*$ as a weighted sum of the entries of K_y^{-1} , where the weight of the (p, q) th entry is given by $k(\mathbf{x}_i^*, \mathbf{x}_p)k(\mathbf{x}_j^*, \mathbf{x}_q)$:

$$\mathbf{k}_i^{*T}K_y^{-1}\mathbf{k}_j^* = \sum_{p=1}^n \sum_{q=1}^n (K_y^{-1})_{pq} k(\mathbf{x}_i^*, \mathbf{x}_p) k(\mathbf{x}_j^*, \mathbf{x}_q). \quad (4)$$

Our goal is to compute this weighted sum efficiently using a tree structure, similar to Shen et al. (2006), except that instead of clustering points with similar weights, we now want to cluster *pairs* of points having similar weights.

To do this, we consider the *product space* $\mathcal{M} \times \mathcal{M}$ consisting of all pairs of points from \mathcal{M} , and define a *product*

metric δ on this space. The details of the product metric will depend on the choice of kernel function (section 3.2). For the moment, we will assume an SE kernel, of the form $k_{SE}(d) = \exp(-d^2)$, for which a natural choice is the 2-product metric:

$$\delta((\mathbf{x}_a, \mathbf{x}_b), (\mathbf{x}_c, \mathbf{x}_d)) = \sqrt{d(\mathbf{x}_a, \mathbf{x}_c)^2 + d(\mathbf{x}_b, \mathbf{x}_d)^2},$$

which has the fortunate property

$$k_{SE}(d(\mathbf{x}_a, \mathbf{x}_b))k_{SE}(d(\mathbf{x}_c, \mathbf{x}_d)) = k_{SE}(\delta((\mathbf{x}_a, \mathbf{x}_b), (\mathbf{x}_c, \mathbf{x}_d))),$$

i.e., the property that evaluating the SE kernel in the product space (the right hand side) gives us the correct weight for our weighted sum (4) (the left hand side). Note that this property is convenient but not necessary; Section 3.2 describes how to choose a product metric for several common kernels.

Now we can run any metric tree construction algorithm (e.g., a cover tree) using the product metric to build a *product tree* on all *pairs* of training points. At each leaf node \mathbf{L} , representing a pair of training points, we store the entry $(K_y^{-1})_{\mathbf{L}}$ corresponding to those two training points, and at each higher-level node \mathbf{n} we cache the unweighted sum $S_{\mathbf{n}}^{\text{UW}}$ of these entries over all of its descendant leaf nodes, as well as the sum of absolute values $S_{\mathbf{n}}^{\text{Abs}}$ (these cached sums will be used to determine when to cut off recursive calculations):

$$S_{\mathbf{n}}^{\text{UW}} = \sum_{\mathbf{L} \in \text{leaves}(\mathbf{n})} (K_y^{-1})_{\mathbf{L}} \quad (5)$$

$$S_{\mathbf{n}}^{\text{Abs}} = \sum_{\mathbf{L} \in \text{leaves}(\mathbf{n})} |(K_y^{-1})_{\mathbf{L}}|. \quad (6)$$

Given a product tree augmented in this way, the weighted-sum calculation (4) is approximated by the WEIGHTEDMETRICSUM algorithm of Figure 2. It proceeds by a recursive descent down the tree, where at each non-leaf node \mathbf{n} it computes upper and lower bounds on the weight of any descendant, and applies a cutoff rule (Section 3.1) to determine whether to continue the descent. Whenever the descent is halted, we approximate the contribution from leaves below \mathbf{n} by $\frac{1}{2}(w_{\max} + w_{\min}) \cdot S_{\mathbf{n}}^{\text{UW}}$, i.e., by the average weight times the unweighted sum. Otherwise, the computation continues recursively over \mathbf{n} 's children.

3.1 CUTOFF RULE

The decision of when to cut off the tree recursion is crucial to correctness and performance. Many cutoff rules are possible. For predictive mean calculation, Moore et al. (1997) and Shen et al. (2006) maintain an accumulated lower bound on the total overall weight, and cut off whenever the difference between the upper and lower weight bounds at the current node is a small fraction of the lower bound on the overall weight. By contrast, we introduce a

rule (8) which takes into account the weights as well as the entries of K_y^{-1} being summed over (since we expect this matrix to be approximately sparse, some entries will contribute much more to the sum than others), and which provides a provable guarantee on approximation error not available in the earlier work. First, at each node \mathbf{n} we compute an error bound

$$\epsilon_{\mathbf{n}} = \frac{1}{2}(w_{\max} - w_{\min})S_{\mathbf{n}}^{\text{Abs}}, \quad (7)$$

which we justify by the following lemma:

Lemma 1. *The error introduced in approximating the subtree at \mathbf{n} by $\frac{1}{2}(w_{\max} + w_{\min})S_{\mathbf{n}}^{\text{UW}}$ is bounded by $\epsilon_{\mathbf{n}}$.*

Proof. Let $S_{\mathbf{n}}^+$ and $S_{\mathbf{n}}^-$ denote the sum of positive and negative leaf entries under \mathbf{n} , respectively, so $S_{\mathbf{n}}^{\text{UW}} = (S_{\mathbf{n}}^+ + S_{\mathbf{n}}^-)$ and $S_{\mathbf{n}}^{\text{Abs}} = (S_{\mathbf{n}}^+ - S_{\mathbf{n}}^-)$. The worst case for the approximation is if the true sum gives weight w_{\max} to $S_{\mathbf{n}}^+$ and w_{\min} to $S_{\mathbf{n}}^-$ (or vice versa), yielding an approximation error of

$$\left| (w_{\max}S_{\mathbf{n}}^+ + w_{\min}S_{\mathbf{n}}^-) - \frac{w_{\max} + w_{\min}}{2}S_{\mathbf{n}}^{\text{UW}} \right| = \epsilon_{\mathbf{n}}.$$

□

Intuitively, we see that $\epsilon_{\mathbf{n}}$ is small whenever the leaves below \mathbf{n} have nearly uniform weights, or when the total mass of K_y^{-1} entries under \mathbf{n} is small. This motivates our cutoff rule

$$\epsilon_{\mathbf{n}} \leq \kappa_{\mathbf{n}}/(n - \kappa) \cdot (\epsilon_{\text{abs}} - \epsilon), \quad (8)$$

in which ϵ_{abs} is a user-specified bound on the absolute error of the overall computation, $\kappa_{\mathbf{n}}$ denotes the number of leaves below \mathbf{n} , n and κ denote respectively the total number of leaves in the tree and the leaves included thus far in the partially computed sum, and $\epsilon = \sum_{\mathbf{n} \in C} \epsilon_{\mathbf{n}}$, where C is the set of all intermediate nodes whose leaf sums we have previously approximated, is a running upper bound on the total error accumulated thus far in the sum. Intuitively, $(\epsilon_{\text{abs}} - \epsilon)$ gives the “error budget” remaining out of an initial budget of ϵ_{abs} ; each cutoff is allowed to use a fraction of this budget proportional to the number of leaves being approximated. We show the following correctness result:

Theorem 1. *Let \mathbf{T} be a product tree constructed on K_y^{-1} , where $\hat{\Sigma}_{ij}^* = K_{ij}^{**} - \text{WEIGHTEDMETRICSUM}(\mathbf{T}, (\mathbf{x}_i^*, \mathbf{x}_j^*), \epsilon_{\text{abs}})$ denotes the approximation returned by the tree recursion to the true posterior covariance Σ_{ij}^* . Then $|\Sigma_{i,j}^* - \hat{\Sigma}_{i,j}^*| \leq \epsilon_{\text{abs}}$.*

Proof. By our cutoff rule (8), we proceed with the approximation at \mathbf{n} only if $\epsilon' := \epsilon_{\mathbf{n}} + \epsilon \leq \epsilon_{\text{abs}}$, i.e. only if the new error being introduced (bounded by Lemma 1), plus the error already accumulated, is still bounded by ϵ_{abs} .¹ Thus at

¹We have ignored the factor $\kappa_{\mathbf{n}}/(n - \kappa)$ here since it is always ≤ 1 ; this factor is included to help “pace” the computation and is not necessary for correctness.

every step we maintain the invariant $\epsilon \leq \epsilon_{\text{abs}}$, which establishes the result. □

Remark. *Although Theorem 1 bounds absolute error, we can also apply it to bound relative error in the case of computing a predictive variance that includes a noise component. Since the noise variance σ_n^2 is a lower bound on the predictive variance Σ_{ii}^* , setting $\epsilon_{\text{abs}} = \epsilon_{\text{rel}} \cdot \sigma_n^2$ is sufficient to ensure that the approximation error is smaller than $\epsilon_{\text{rel}} \cdot \Sigma_{ii}^*$.*

Note that this cutoff rule and correctness proof can be easily back-ported into the WEIGHTEDSUM algorithm of Shen et al. (2006), providing a bounded error guarantee for tree-based calculations of GP posterior means as well as covariances.

3.2 OTHER KERNEL FUNCTIONS

As noted above, the SE kernel has the lucky property that, if we choose product metric $\delta = \sqrt{d_1^2 + d_2^2}$, then the product of two SE kernels is equal to the kernel of the product metric δ :

$$k_{SE}(d_1)k_{SE}(d_2) = \exp(-d_1^2 - d_2^2) = k_{SE}(\delta).$$

In general, however, we are not so lucky: it is not the case that every kernel we might wish to use has a corresponding product metric such that a product of kernels can be expressed in terms of the product metric. In such cases, we may resort to upper and lower bounds in place of computing the exact kernel value. Note that such bounds are all we require to evaluate the error bound (7), and that when we reach a leaf node representing a specific pair of points we can always evaluate the exact product of kernels directly at that node.

For example, consider the kernel $k_{CS,0}(d) = (1 - d)_+^j$ (taking $j = \lfloor \frac{D}{2} \rfloor + 1$, where D is the input dimension); this is a simple example of a more general class of piecewise-polynomial compactly supported kernels (Rasmussen and Williams, 2006) whose computational advantages are especially relevant to tree-based algorithms. Considering the product of two such kernels,

$$k_{CS,0}(d_1)k_{CS,0}(d_2) = (1 - (d_1 + d_2) + \Delta)_+^j$$

where $\Delta = d_1d_2$ if $(d_1 < 1, d_2 < 1)$ else 0

we notice that this is almost equivalent to $k_{CS,0}(\delta)$ for the choice of $\delta = d_1 + d_2$, but with an additional pairwise term Δ . We bound this term by noting that it is maximized when $d_1 = d_2 = \delta/2$ (for $\delta < 2$) and minimized whenever either $d_1 = 0$ or $d_2 = 0$, so we have $(\delta/2)^2 \geq \Delta \geq 0$. This yields the bounds $k_{\text{lower}}^{\text{prod}}$ and $k_{\text{upper}}^{\text{prod}}$ as shown in Table 1. Bounds for other common kernels are obtained analogously in Table 1.

3.3 OPTIMIZATIONS

A naïve product tree on n points will have n^2 leaves, but we can reduce this and achieve substantial speedups by

Kernel	$k(d)$	$k(d_1)k(d_2)$	$\delta(d_1, d_2)$	$k_{\text{lower}}^{\text{prod}}(\delta)$	$k_{\text{upper}}^{\text{prod}}(\delta)$
SE	$\exp(-d^2)$	$\exp(-d_1^2 - d_2^2)$	$\sqrt{d_1^2 + d_2^2}$	$\exp(-(\delta)^2)$	$\exp(-(\delta)^2)$
γ -exponential	$\exp(-d^\gamma)$	$\exp(-d_1^\gamma - d_2^\gamma)$	$(d_1^\gamma + d_2^\gamma)^{1/\gamma}$	$\exp(-(\delta)^\gamma)$	$\exp(-(\delta)^\gamma)$
Piecewise polynomial CS $D, q=0, j = \lfloor \frac{D}{2} \rfloor + 1$	$(1-d)_+^j$	$(1 - (d_1 + d_2) + \Delta)_+^j$ where $\Delta = d_1 d_2$ if $(d_1 < 1, d_2 < 1)$ else 0	$d_1 + d_2$	$(1-\delta)_+^j$	$\left(1 - \delta + \frac{(\delta)^2}{4}\right)_+^j$
Rational Quadratic	$\left(1 + \frac{d^2}{2\alpha}\right)^{-\alpha}$	$\left(1 + \frac{d_1^2 + d_2^2}{2\alpha} + \frac{d_1^2 d_2^2}{4\alpha^2}\right)^{-\alpha}$	$\sqrt{d_1^2 + d_2^2}$	$\left(1 + \frac{(\delta)^2}{2\alpha} + \frac{(\delta)^4}{16\alpha^2}\right)^{-\alpha}$	$\left(1 + \frac{(\delta)^2}{2\alpha}\right)^{-\alpha}$
Matérn ($\nu = 3/2$)	$(1 + \sqrt{3}d) \cdot \exp(-\sqrt{3}d)$	$(1 + \sqrt{3}(d_1 + d_2) + 3d_1 d_2) \cdot \exp(-\sqrt{3}(d_1 + d_2))$	$d_1 + d_2$	$(1 + \sqrt{3}\delta) \cdot \exp(-\sqrt{3}\delta)$	$(1 + \sqrt{3}\delta + 3(\delta/2)^2) \cdot \exp(-\sqrt{3}\delta)$

Table 1: Bounds for products of common kernel functions, all from from Rasmussen and Williams (2006).

exploiting the structure of K_y^{-1} and of the product space $\mathcal{M} \times \mathcal{M}$:

Sparsity. If K_y is sparse, as with compactly supported kernel functions, or can be well-approximated as sparse, as when using standard kernels with short lengthscales, then it can be shown that K_y^{-1} may also be approximated as sparse (Bickel and Lindner, 2012, sections 2 and 4.1). When this is the case, the tree need include only those pairs $(\mathbf{x}_p, \mathbf{x}_q)$ for which $(K_y^{-1})_{pq}$ is non-negligible.

Symmetry. Since K_y^{-1} is a symmetric matrix, it is redundant to include leaves for both $(\mathbf{x}_p, \mathbf{x}_q)$ and $(\mathbf{x}_q, \mathbf{x}_p)$ in our tree. Instead, we can build separate trees to compute the diagonal and upper-triangular components of the sum, then reuse the upper-triangle result for the lower triangle.

Factorization of product distances. In general, computing the product distance δ will usually involve two calls to the underlying distance metric d ; these can often be reused. For example, when calculating both $\delta((\mathbf{x}_a, \mathbf{x}_b), (\mathbf{x}_c, \mathbf{x}_d))$ and $\delta((\mathbf{x}_a, \mathbf{x}_e), (\mathbf{x}_c, \mathbf{x}_d))$, we can reuse the value of $d(\mathbf{x}_a, \mathbf{x}_c)$ for both computations. This reduces the total number of calls to the distance function during tree construction from a worst-case n^4 (for all pairs of pairs of training points) to a maximum of n^2 , and in general much fewer if other optimizations such as sparsity are implemented as well.

Leaf binning at short distances. If all leaves below a node \mathbf{n} are within a kernel lengthscale of \mathbf{n} , we cut off the tree at \mathbf{n} and just compute the exact weighted sum over those leaves, avoiding the tree recursion.

4 MIXED LOCAL/GLOBAL GP REPRESENTATIONS

In this section, we extend the GP model (1) to include both a local and a global component $g(\mathbf{x}_i)$, i.e.,

$$y_i = h(\mathbf{x}_i) + \epsilon_i = f(\mathbf{x}_i) + g(\mathbf{x}_i) + \epsilon_i, \quad (9)$$

where f is modeled by a short-lengthscale/compactly-supported GP, and g is a global component of constant rank (i.e., not directly dependent on n). We will show how to

efficiently calculate posteriors from such models using a product tree.

Formally, we assume a GP of the form

$$h(X) \sim \mathcal{N}(\phi(X)^T \mathbf{b}, k_f(X) + \phi(X)^T B \phi(X)) \quad (10)$$

where $k_f(X)$ is a sparse matrix, B is an $m \times m$ matrix and \mathbf{b} an m -dimensional vector, and $\phi(X)$ computes an $n \times m$ feature representation where $m \ll n$. This ‘‘sparse+low rank’’ formulation includes a wide range of models capturing global and local structure. For example, we can express the ‘‘explicit basis functions’’ model from section 2.7 of Rasmussen and Williams (2006) by letting $\phi(X)$ denote the basis functions $H(X)$ and letting \mathbf{b}, B denote the mean and covariance of a Gaussian prior on their weights. Similarly, the CS+FIC model given by Vanhatalo and Vehtari (2008) may be represented² by taking $\phi(X) = K_{u,n}$, $B = K_{u,u}^{-1}$, $\mathbf{b} = \mathbf{0}$, and letting $k_f(X)$ absorb the diagonal term Λ . Other approximate GP models for global variation (e.g., Quiñonero-Candela and Rasmussen, 2005; Snelson and Ghahramani, 2007; Rahimi and Recht, 2007; Vedaldi and Zisserman, 2010) can also be expressed in this form.

Given any model in the form of Eqn. (10), the posterior distribution $h(X^*) \sim \mathcal{N}(\mu'_*, \Sigma'_*)$ can be derived (Rasmussen and Williams, 2006) as

$$\mu'_* = \phi^{*T} \bar{\beta} + K^{*T} K_y^{-1} (\mathbf{y} - \phi^* \bar{\beta}) \quad (11)$$

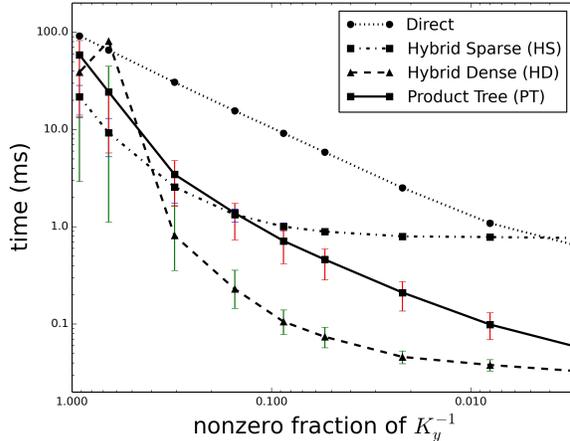

$$\Sigma'_* = K^{**} - K^{*T} K_y^{-1} K^* + R^T (B^{-1} + \phi K_y^{-1} \phi^T) R \quad (12)$$

where we let $\phi = \phi(X)$ and $\phi^* = \phi(X^*)$, and we have $\bar{\beta} = (B^{-1} + \phi K_y^{-1} \phi^T)^{-1} (\phi K_y^{-1} \mathbf{y} + B^{-1} \mathbf{b})$ and $R = \phi^* - \phi(X) K_y^{-1} K^*$. Section 2.7 of Rasmussen and Williams (2006) gives further details.

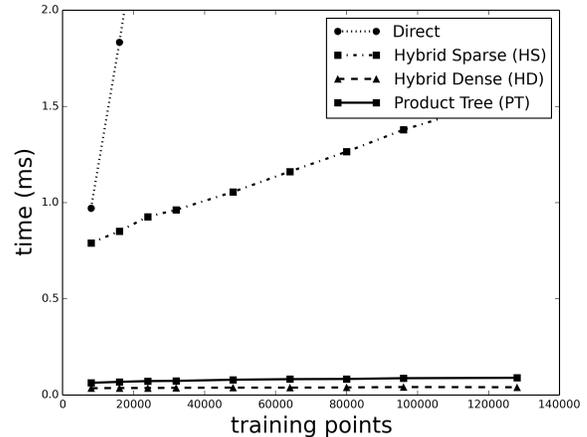

4.1 EFFICIENT OPERATIONS IN SPARSE+LOW RANK MODELS

Calculating the posterior given by (11, 12) is a straightforward extension of the standard case. The predictive

²Here the right side of each expression follows the notation of Vanhatalo and Vehtari.

(a) As a function of input density for a fixed-size (5000 points) training set, with error bars at the 10th to 90th percentiles.

(b) As a function of training set size with constant density $v = 5$.

Figure 3: Mean times to compute posterior variance on 2D synthetic data using a piecewise-polynomial $CS_{2,2}$ kernel.

mean (11) can be accommodated within the framework of Shen et al. (2006) using a tree representation of the vector $K_y^{-1}(\mathbf{y} - \phi^{*T}\bar{\beta})$, then adding in the easily evaluated parametric component $\phi^{*T}\bar{\beta}$. In the covariance (12) we can use a product tree to approximate $K^{*T}K_y^{-1}K^*$ as described above; of the remaining terms, $\bar{\beta}$ and $B^{-1} + \phi K_y^{-1}\phi^T$ can be precomputed at training time, and ϕ^* and K^{**} don't depend on the training set. This leaves $\phi K_y^{-1}K^*$ as the one remaining challenge; we note that this quantity can be computed efficiently using m applications per test point of the vector multiplication primitive from Shen et al. (2006), reusing the same tree structure to multiply each column of K^* by each row of ϕK_y^{-1} . Thus, the full posterior distribution at a test point can be calculated efficiently with no explicit dependence on n (i.e., with no direct access to the training points except through space-partitioning tree structures).

5 EVALUATION

We compare the use of a product tree (PT) for predictive variance calculation with several alternatives:

Direct: sparse matrix multiplication, using a sparse representation of K_y^{-1} and dense representation of \mathbf{k}_i^* .

Hybrid Sparse (HS): sparse matrix multiplication, using a sparse representation of \mathbf{k}_i^* constructed by querying a cover tree for all training points within distance r of the query point \mathbf{x}_i^* , where r is chosen such that $k(r')$ is negligible for $r' > r$, and then filling in only those entries of \mathbf{k}_i^* determined to be non-negligible. Since all our experiments involve kernels with compact support, we simply set r equal to the kernel lengthscale.

Hybrid Dense (HD):³ dense matrix multiplication, using only those entries of K_y^{-1} that correspond to training points within distance r of the query point. These training points are identified using a cover tree, as above, and entries of K_y^{-1} are retrieved from a hash table.

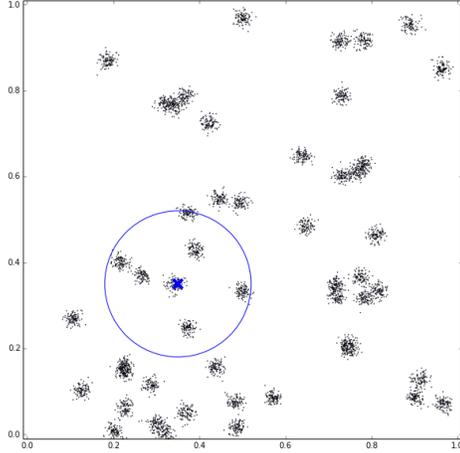

We do not show a comparison to the naïve dense matrix approach, since this is generally slower by orders of magnitude on the datasets we consider.

Our product tree implementation is a Python extension written in C++, based on the cover tree implementation of Beygelzimer et al. (2006) and implementing the optimizations from Section 3.3. In all experiments we set the approximation parameter ϵ_{rel} to ensure an approximation error of less than 0.1% of the exact variance. All sparse matrix multiplications are in CSR format using SciPy's sparse routines; we impose a sparsity threshold of 10^{-8} such that any entry less than the threshold is set to zero. Code to reproduce all experiments, along with the datasets, is included in the supplementary materials.

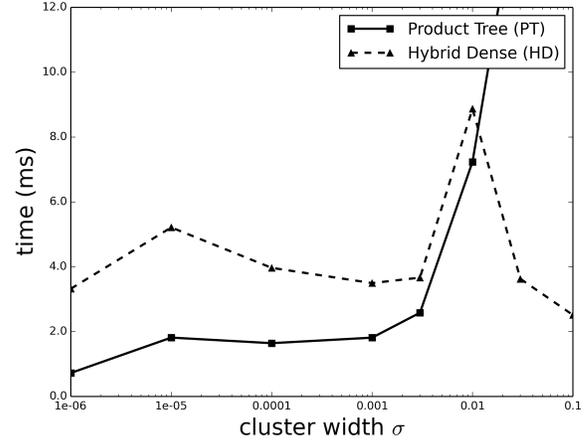

5.1 SYNTHETIC DATA

Figures 3a and 3b compare our methods on a simple two-dimensional synthetic data set, consisting of points sampled uniformly at random from the unit square. We train a GP on n such points and then measure the mean time per point to compute the predictive variance at 1000 random test points. The GP uses a piecewise-polynomial $CS_{2,2}$ kernel with observation noise $\sigma_n^2 = 1.0$ and lengthscale $\ell = \sqrt{v\pi/n}$, where v is a parameter indicating the average number of training points within a one-lengthscale ball of

³We are grateful to Iain Murray for suggesting this approach for comparison.

(a) Clumpy data with $\sigma = 0.01$, with a ball of covariance lengthscale $\frac{1}{\sqrt{10\pi}}$ overlaid.

(b) Mean times to compute posterior variance on data of varying clumpiness, using a piecewise-polynomial $CS_{2,2}$ kernel.

Figure 4: HD versus PT on clumpy data.

a random query point.

We see from Figure 3a that the hybrid dense method performs best when the kernel lengthscale is extremely short, followed by the product tree; in the most extreme cases these methods outperform the alternatives by an order of magnitude. However, performance degrades as the kernel lengthscale increases.

Figure 3b examines the scaling behavior of the algorithms in a relatively sparse setting, $v = 5$, chosen to allow the tractable inversion of large kernel matrices. Here we see that the direct calculation scales quite steeply (though linearly: the runtime at $n = 160000$ is approximately 15ms) with training size due to the need to explicitly compute all n entries of \mathbf{k}_i^* . The hybrid sparse calculation avoids this bottleneck and is significantly more efficient, but its scaling is ultimately also linear with n , an inherent limitation of sparse matrix multiplication (Bank and Douglas, 1993) since it does not have access to the geometry of the data. By contrast, in this sparse setting the hybrid dense and product tree approaches remain efficient even for very large datasets, with a small constant-factor advantage for the hybrid dense method.

5.2 CLUMPINESS

The strong performance in the previous experiments of the hybrid dense method, relative to the product tree, is due to the uniformity of the training data. With no natural clusters, the only available optimization is to discard faraway points. The product tree would be expected to perform better when the data are ‘clumpy’, allowing it to merge kernel evaluations from nearby points. This is explored in Figure 4b, which compares the two methods on a synthetic dataset of 5000 points, sampled from a mixture of 50 Gaus-

sians each with covariance $\sigma^2\mathcal{I}$ for varying clumpiness σ . As expected, the product tree is fastest when the data are tightly clustered and many points can be merged. Figure 4a shows an example of a dataset at $\sigma=0.01$, the approximate ‘crossover’ point at which the lower constant factor of the hybrid dense method begins to outweigh the advantages of the product tree.

5.3 REAL DATA

We evaluate the performance of our methods on the following datasets, shown in Table 2:

seismic: 20000 travel-time residuals between observed P-wave travel times to the seismic array in Alice Springs, Australia, and the times predicted by a one-dimensional IASPEI91 model (Kennett and Engdahl, 1991), indexed by latitude/longitude and depth of the source event.

snow: 20000 observations of water content of California snow pack recorded daily at 128 stations from November 1, 2011 to June 1, 2012, indexed by date, latitude/longitude and elevation. Collected from <http://cdec.water.ca.gov/queryCSV.html>.

precip: shown in Figure 1, total annual precipitation recorded in 1995 by each of 5775 stations in the continental US, indexed by latitude, longitude, and elevation (Vanhatalo and Vehtari, 2008).

tco: Total column ozone as recorded over the Earth’s surface by the NIMBUS-7/TOMS satellite on October 1, 1998 (Park et al., 2011). Our experiments use a random sample of 20000 from the full 48331 measurements.

housing: Data from the 1990 California census, as used by Shen et al. (2006). We predict the median income of each block group as a function of median age and median house

value.

Table 3 compares, for each dataset, the performance of an SE kernel to that of a piecewise-polynomial, compactly-supported kernel $CS_{D,2}$ with a hand-selected number of FIC inducing points capturing global variation. The goal here is to show that the CS+FIC models, which are well-suited for fast tree-based calculations at test time, are a reasonable modeling choice even for purely predictive reasons. Model quality is measured by the Standardized Mean Squared Error (SMSE), i.e., the squared error divided by the squared error of the trivial predictor that just predicts the mean of the training set, and Mean Standardized Log Loss (MSLL), obtained by averaging $-\log p(y_i^* | x_i^*, X, \mathbf{y})$ over the test set and subtracting the same score for a trivial model which always predicts the mean and variance of the training set. Hyperparameters for each model were obtained by maximizing the marginal likelihood over a random subset of 5000 training points using a truncated Newton method; a prior was used to encourage short lengthscales for the CS components of the CS+FIC models. Note that, for each of the datasets considered in this paper, the CS+FIC model provides better posterior probability estimates (lower MSLL) than an SE model.⁴

In Table 4 we show, for each method and dataset, the mean and standard deviation of posterior variance computation time evaluated over the test set. Here the **HS**, **HD**, and **PT** methods use the tree-optimized FIC calculations from Section 4.1, while the **Direct** and **HS_N** methods use a naive FIC calculation; the latter is included explicitly for comparison with the tree-optimized version. Interestingly, the hybrid dense calculation is quickest in every case, sometimes tied by the product tree, suggesting that these real datasets do not possess the degree of clumpiness necessary for the product tree to dominate (Table 5 directly compares the number of terms used by the two method, showing that the product tree succeeds in merging a significant number of points only on the housing dataset). Both the product tree and the hybrid dense method are generally faster than the hybrid sparse method, with the exception of the US precipitation data in which the relative fullness of the inverse

⁴The SE model may still be superior in many cases, of course. For example, we experimented with the well-known SARCOS inverse kinematics dataset but were unable to find a CS+FIC model that was competitive with the SE baseline.

	d	n_{train}	n_{test}	t_{build}
seismic	3	16000	4000	4.9s
snow	4	15000	5000	4.2s
precip	3	5000	775	23.0s
tco	2	15000	5000	2.2s
housing	2	18000	2000	3.3s

Table 2: Datasets, with product tree construction times.

	model	K_y^{-1} %	SMSE	MSLL
seismic	CS+FIC (20)	0.6%	0.82	-0.20
	SE	33.9%	0.84	-0.11
snow	CS+FIC (20)	0.8%	0.0030	-2.91
	SE	36.3%	0.0097	-2.31
precip	CS+FIC (20)	45.3%	0.129	-1.17
	SE	50.2%	0.125	-1.06
tco	CS+FIC (90)	0.4%	0.041	-1.63
	SE	34.6%	0.054	-1.45
housing	CS+FIC (20)	0.5%	0.83	-0.18
	SE	100%	0.80	-0.086

Table 3: Predictive performance of compactly-supported and squared-exponential kernels on the test datasets. Smaller is better for both SMSE and MSLL.

kernel matrix for that model (Table 3) greatly increases the size of the product tree. Comparing **HS** to **HS_N**, we see that the tree-optimized FIC calculation provides significant speedups on all datasets except for the precipitation data, with an especially significant speedup for the **tco** data which uses 90 inducing points.

6 CONCLUSION AND FUTURE WORK

This paper introduces the *product tree*, a method for efficient adaptive calculation of GP covariances using a multi-resolution clustering of pairs of training points. We empirically evaluate the performance of several such methods and find that a simple heuristic that discards faraway training points (the hybrid dense method described above) may yield the best performance on many real datasets. This follows Murray (2009), who found that tree-based methods are often unable to effectively merge points, though we do identify a regime of clustered data in which the product tree has an advantage. Other contributions of this paper include a cutoff rule with provable error bounds, applicable to both mean and covariance calculations on trees, and a description of efficient calculation in GP models incorporating both sparse and low-rank components, showing how such models can model global-scale variation while maintaining the efficiency of short-lengthscale GPs.

A limitation of all of the approaches considered in this paper is the need to invert the kernel matrix during training; this can be difficult for large problems. One avenue for future work could be an iterative factorization of K_y analogous to the CG training performed by MVM methods (Shen et al., 2006; Gray, 2004; Morariu et al., 2008).

Although our work has been focused primarily on low-dimensional applications, the use of cover trees instead of k -d trees ought to enable an extension to higher dimensions. We are not aware of previous work applying tree-based regression algorithms to high-dimensional data, but

	Direct (ms)	HS _N (ms)	HS (ms)	HD (ms)	PT (ms)

as high-dimensional covariance matrices are often sparse, this may be a natural fit. For high-dimensional data that do not lie on a low-dimensional manifold, other nearest-neighbor techniques such as locality-sensitive hashing (Andoni and Indyk, 2008) may have superior properties to tree structures; the adaptation of such techniques to GP regression is an interesting open problem.

Abstract

Communication costs, resulting from synchronization requirements during learning, can greatly slow down many parallel machine learning algorithms. In this paper, we present a parallel Markov chain Monte Carlo (MCMC) algorithm in which subsets of data are processed independently, with very little communication. First, we arbitrarily partition data onto multiple machines. Then, on each machine, any classical MCMC method (e.g., Gibbs sampling) may be used to draw samples from a posterior distribution given the data subset. Finally, the samples from each machine are combined to form samples from the full posterior. This embarrassingly parallel algorithm allows each machine to act independently on a subset of the data (without communication) until the final combination stage. We prove that our algorithm generates asymptotically exact samples and empirically demonstrate its ability to parallelize burn-in and sampling in several models.

1 Introduction

Markov chain Monte Carlo (MCMC) methods are popular tools for performing approximate Bayesian inference via posterior sampling. One major benefit of these techniques is that they guarantee asymptotically exact recovery of the posterior distribution as the number of posterior samples grows. However, MCMC methods may take a prohibitively long time, since for N data points, most methods must perform $O(N)$ operations to draw a sample. Furthermore, MCMC methods might require a large number of “burn-in” steps before beginning to generate representative samples. Further complicating matters is the issue that, for many big data applications, it is necessary to store and process

data on multiple machines, and so MCMC must be adapted to run in these data-distributed settings.

Researchers currently tackle these problems independently, in two primary ways. To speed up sampling, multiple independent chains of MCMC can be run in parallel [20, 11, 13]; however, each chain is still run on the entire dataset, and there is no speed-up of the burn-in process (as each chain must still complete the full burn-in before generating samples). To run MCMC when data is partitioned among multiple machines, each machine can perform computation that involves a subset of the data and exchange information at each iteration to draw a sample [10, 14, 18]; however, this requires a significant amount of communication between machines, which can greatly increase computation time when machines wait for external information [1, 7].

We aim to develop a procedure to tackle both problems simultaneously, to allow for quicker burn-in and sampling in settings where data are partitioned among machines. To accomplish this, we propose the following: on each machine, run MCMC on only a subset of the data (independently, without communication between machines), and then combine the samples from each machine to algorithmically construct samples from the full-data posterior distribution. We’d like our procedure to satisfy the following four criteria:

1. Each machine only has access to a portion of the data.
2. Each machine performs MCMC independently, without communicating (i.e. “embarrassingly parallel”).
3. Each machine can use any type of MCMC to generate samples.
4. The combination procedure yields provably asymptotically exact samples from the full-data posterior.

The third criterion allows existing MCMC algorithms or software packages to be run directly on subsets of the data—the combination procedure then acts as a post-processing step to transform the samples to the correct distribution. Note that this procedure is particularly

suitable for use in a MapReduce [4] framework. Also note that, unlike current strategies, this procedure does not involve multiple “duplicate” chains (as each chain uses a different portion of the data and samples from a different posterior distribution), nor does it involve parallelizing a single chain (as there are multiple chains operating independently). We will show how this allows our method to, in fact, parallelize and greatly reduce the time required for burn-in.

In this paper we will (1) introduce and define the *subposterior* density—a modified posterior given a subset of the data—which will be used heavily, (2) present methods for the embarrassingly parallel MCMC and combination procedure, (3) prove theoretical guarantees about the samples generated from our algorithm, (4) describe the current scope of the presented method (i.e. where and when it can be applied), and (5) show empirical results demonstrating that we can achieve speed-ups for burn-in and sampling while meeting the above four criteria.

2 Embarrassingly Parallel MCMC

The basic idea behind our method is to partition a set of N i.i.d. data points $x^N = \{x_1, \dots, x_N\}$ into M subsets, sample from the *subposterior*—the posterior given a data subset with an underweighted prior—in parallel, and then combine the resulting samples to form samples from the full-data posterior $p(\theta|x^N)$, where $\theta \in \mathbb{R}^d$ and $p(\theta|x^N) \propto p(\theta)p(x^N|\theta) = p(\theta)\prod_{i=1}^N p(x_i|\theta)$.

More formally, given data x^N partitioned into M subsets $\{x^{n_1}, \dots, x^{n_M}\}$, the procedure is:

1. For $m = 1, \dots, M$ (in parallel):
Sample from the subposterior p_m , where

$$p_m(\theta) \propto p(\theta)^{\frac{1}{M}} p(x^{n_m}|\theta). \quad (1)$$

2. Combine the subposterior samples to produce samples from an estimate of the subposterior density product $p_1 \cdots p_M$, which is proportional to the full-data posterior, i.e. $p_1 \cdots p_M(\theta) \propto p(\theta|x^N)$.

We want to emphasize that we do not need to iterate over these steps and the combination stage (step 3) is the only step that requires communication between machines. Also note that sampling from each subposterior (step 2) can typically be done in the same way as one would sample from the full-data posterior. For example, when using the Metropolis-Hastings algorithm, one would compute the likelihood ratio as $\frac{p(\theta^*)^{\frac{1}{M}} p(x^{n_m}|\theta^*)}{p(\theta)^{\frac{1}{M}} p(x^{n_m}|\theta)}$

instead of $\frac{p(\theta^*)p(x^N|\theta^*)}{p(\theta)p(x^N|\theta)}$, where θ^* is the proposed move. In the next section, we show how the combination stage (step 3) is carried out to generate samples from the full-data posterior using the subposterior samples.

3 Combining Subposterior Samples

Our general idea is to combine the subposterior samples in such a way that we are implicitly sampling from an estimate of the subposterior density product function $\widehat{p_1 \cdots p_M}(\theta)$. If our density product estimator is consistent, then we can show that we are drawing asymptotically exact samples from the full posterior. Further, by studying the estimator error rate, we can explicitly analyze how quickly the distribution from which we are drawing samples is converging to the true posterior (and thus compare different combination algorithms).

In the following three sections we present procedures that yield samples from different estimates of the density product. Our first example is based on a simple parametric estimator motivated by the Bernstein-von Mises theorem [12]; this procedure generates approximate (asymptotically biased) samples from the full posterior. Our second example is based on a nonparametric estimator, and produces asymptotically exact samples from the full posterior. Our third example is based on a semiparametric estimator, which combines beneficial aspects from the previous two estimators while also generating asymptotically exact samples.

3.1 Approximate posterior sampling with a parametric estimator

The first method for forming samples from the full posterior given subposterior samples involves using an approximation based on the Bernstein-von Mises (Bayesian central limit) theorem, an important result in Bayesian asymptotic theory. Assuming that a unique, true data-generating model exists and is denoted θ_0 , this theorem states that the posterior tends to a normal distribution concentrated around θ_0 as the number of observations grows. In particular, under suitable regularity conditions, the posterior $P(\theta|x^N)$ is well approximated by $\mathcal{N}_d(\theta_0, F_N^{-1})$ (where F_N is the fisher information of the data) when N is large [12]. Since we aim to perform posterior sampling when the number of observations is large, a normal parametric form often serves as a good posterior approximation. A similar approximation was used in [2] in order to facilitate fast, approximately correct sampling. We therefore estimate each subposterior density with $\widehat{p}_m(\theta) = \mathcal{N}_d(\theta|\widehat{\mu}_m, \widehat{\Sigma}_m)$ where $\widehat{\mu}_m$ and $\widehat{\Sigma}_m$ are the sample mean and covariance, respectively, of the subposterior samples. The product of the M subposterior densities will be proportional to a Gaussian pdf, and our estimate of the density product function $p_1 \cdots p_M(\theta) \propto p(\theta|x^N)$ is

$$\widehat{p_1 \cdots p_M}(\theta) = \widehat{p}_1 \cdots \widehat{p}_M(\theta) \propto \mathcal{N}_d\left(\theta|\widehat{\mu}_M, \widehat{\Sigma}_M\right),$$

where the parameters of this distribution are

$$\widehat{\Sigma}_M = \left(\sum_{m=1}^M \widehat{\Sigma}_m^{-1} \right)^{-1} \quad (2)$$

$$\widehat{\mu}_M = \widehat{\Sigma}_M \left(\sum_{m=1}^M \widehat{\Sigma}_m^{-1} \widehat{\mu}_m \right). \quad (3)$$

These parameters can be computed quickly and, if desired, online (as new subposterior samples arrive).

3.2 Asymptotically exact posterior sampling with nonparametric density product estimation

In the previous method we made a parametric assumption based on the Bernstein-von Mises theorem, which allows us to generate approximate samples from the full posterior. Although this parametric estimate has quick convergence, it generates asymptotically biased samples, especially in cases where the posterior is particularly non-Gaussian. In this section, we develop a procedure that implicitly samples from the product of nonparametric density estimates, which allows us to produce asymptotically exact samples from the full posterior. By constructing a consistent density product estimator from which we can generate samples, we ensure that the distribution from which we are sampling converges to the full posterior.

Given T samples¹ $\{\theta_{t_m}^m\}_{t_m=1}^T$ from a subposterior p_m , we can write the kernel density estimator $\widehat{p}_m(\theta)$ as,

$$\begin{aligned} \widehat{p}_m(\theta) &= \frac{1}{T} \sum_{t_m=1}^T \frac{1}{h^d} K \left(\frac{\|\theta - \theta_{t_m}^m\|}{h} \right) \\ &= \frac{1}{T} \sum_{t_m=1}^T \mathcal{N}_d(\theta | \theta_{t_m}^m, h^2 I_d), \end{aligned}$$

where we have used a Gaussian kernel with bandwidth parameter h . After we have obtained the kernel density estimator $\widehat{p}_m(\theta)$ for M subposteriors, we define our nonparametric density product estimator for the full posterior as

$$\begin{aligned} \widehat{p_1 \cdots p_M}(\theta) &= \widehat{p}_1 \cdots \widehat{p}_M(\theta) \\ &= \frac{1}{T^M} \prod_{m=1}^M \sum_{t_m=1}^T \mathcal{N}_d(\theta | \theta_{t_m}^m, h^2 I_d) \\ &\propto \sum_{t_1=1}^T \cdots \sum_{t_M=1}^T w_t \cdot \mathcal{N}_d \left(\theta \mid \bar{\theta}_t, \frac{h^2}{M} I_d \right). \quad (4) \end{aligned}$$

¹For ease of description, we assume each machine generates the same number of samples, T . In practice, they do not have to be the same.

This estimate is the probability density function (pdf) of a mixture of T^M Gaussians with *unnormalized* mixture weights w_t . Here, we use $t \cdot = \{t_1, \dots, t_M\}$ to denote the set of indices for the M samples $\{\theta_{t_1}^1, \dots, \theta_{t_M}^M\}$ (each from a separate machine) associated with a given mixture component, and we define

$$\bar{\theta}_t = \frac{1}{M} \sum_{m=1}^M \theta_{t_m}^m \quad (5)$$

$$w_t = \prod_{m=1}^M \mathcal{N}_d(\theta_{t_m}^m | \bar{\theta}_t, h^2 I_d). \quad (6)$$

Although there are T^M possible mixture components, we can efficiently generate samples from this mixture by first sampling a mixture component (based on its unnormalized component weight w_t) and then sampling from this (Gaussian) component. In order to sample mixture components, we use an independent Metropolis within Gibbs (IMG) sampler. This is a form of MCMC, where at each step in the Markov chain, a single dimension of the current state is proposed (i.e. sampled) independently of its current value (while keeping the other dimensions fixed) and then is accepted or rejected. In our case, at each step, a new mixture component is proposed by redrawing one of the M current sample indices $t_m \in t \cdot$ associated with the component uniformly and then accepting or rejecting the resulting proposed component based on its mixture weight. We give the IMG algorithm for combining subposterior samples in Algorithm 1.²

In certain situations, Algorithm 1 may have a low acceptance rate and therefore may mix slowly. One way to remedy this is to perform the IMG combination algorithm multiple times, by first applying it to groups of $\tilde{M} < M$ subposteriors and then applying the algorithm again to the output samples from each initial application. For example, one could begin by applying the algorithm to all $\frac{M}{2}$ pairs (leaving one subposterior alone if M is odd), then repeating this process—forming pairs and applying the combination algorithm to pairs only—until there is only one set of samples remaining, which are samples from the density product estimate.

3.3 Asymptotically exact posterior sampling with semiparametric density product estimation

Our first example made use of a parametric estimator, which has quick convergence, but may be asymptotically biased, while our second example made use of

²Again for simplicity, we assume that we generate T samples to represent the full posterior, where T is the number of subposterior samples from each machine.

Algorithm 1 Asymptotically Exact Sampling via Non-parametric Density Product Estimation

Input: Subposterior samples: $\{\theta_{t_1}^1\}_{t_1=1}^T \sim p_1(\theta), \dots, \{\theta_{t_M}^M\}_{t_M=1}^T \sim p_M(\theta)$

Output: Posterior samples (asymptotically, as $T \rightarrow \infty$): $\{\theta_i\}_{i=1}^T \sim p_1 \cdots p_M(\theta) \propto p(\theta|x^N)$

- 1: Draw $t \cdot = \{t_1, \dots, t_M\} \stackrel{\text{iid}}{\sim} \text{Unif}(\{1, \dots, T\})$
 - 2: **for** $i = 1$ **to** T **do**
 - 3: Set $c \leftarrow i^{-1/(4+d)}$
 - 4: **for** $m = 1$ **to** M **do**
 - 5: Set $c_m \leftarrow c$
 - 6: Draw $c_m \sim \text{Unif}(\{1, \dots, T\})$
 - 7: Draw $u \sim \text{Unif}([0, 1])$
 - 8: **if** $u < w_{c_m}/w_t$ **then**
 - 9: Set $t \leftarrow c_m$
 - 10: **end if**
 - 11: **end for**
 - 12: Draw $\theta_i \sim \mathcal{N}_d(\bar{\theta}_t, \frac{h^2}{M} I_d)$
 - 13: **end for**
-

a nonparametric estimator, which is asymptotically exact, but may converge slowly when the number of dimensions is large. In this example, we implicitly sample from a semiparametric density product estimate, which allows us to leverage the fact that the full posterior has a near-Gaussian form when the number of observations is large, while still providing an asymptotically unbiased estimate of the posterior density, as the number of subposterior samples $T \rightarrow \infty$.

We make use of a semiparametric density estimator for p_m that consists of the product of a parametric estimator $\hat{f}_m(\theta)$ (in our case $\mathcal{N}_d(\theta|\hat{\mu}_m, \hat{\Sigma}_m)$ as above) and a nonparametric estimator $\hat{r}(\theta)$ of the correction function $r(\theta) = p_m(\theta)/\hat{f}_m(\theta)$ [6]. This estimator gives a near-Gaussian estimate when the number of samples is small, and converges to the true density as the number of samples grows. Given T samples $\{\theta_{t_m}^m\}_{t_m=1}^T$ from a subposterior p_m , we can write the estimator as

$$\begin{aligned} \hat{p}_m(\theta) &= \hat{f}_m(\theta) \hat{r}(\theta) \\ &= \frac{1}{T} \sum_{t_m=1}^T \frac{1}{h^d} K\left(\frac{\|\theta - \theta_{t_m}^m\|}{h}\right) \frac{\hat{f}_m(\theta)}{\hat{f}_m(\theta_{t_m}^m)} \\ &= \frac{1}{T} \sum_{t_m=1}^T \frac{\mathcal{N}_d(\theta|\theta_{t_m}^m, h^2 I_d) \mathcal{N}_d(\theta|\hat{\mu}_m, \hat{\Sigma}_m)}{\mathcal{N}_d(\theta_{t_m}^m|\hat{\mu}_m, \hat{\Sigma}_m)}, \end{aligned}$$

where we have used a Gaussian kernel with bandwidth parameter h for the nonparametric component of this estimator. Therefore, we define our semiparametric

density product estimator to be

$$\begin{aligned} \widehat{p_1 \cdots p_M}(\theta) &= \hat{p}_1 \cdots \hat{p}_M(\theta) \\ &= \frac{1}{T^M} \prod_{m=1}^M \sum_{t_m=1}^T \frac{\mathcal{N}_d(\theta|\theta_{t_m}^m, h I_d) \mathcal{N}_d(\theta|\hat{\mu}_m, \hat{\Sigma}_m)}{h^d \mathcal{N}_d(\theta_{t_m}^m|\hat{\mu}_m, \hat{\Sigma}_m)} \\ &\propto \sum_{t_1=1}^T \cdots \sum_{t_M=1}^T W_t \cdot \mathcal{N}_d(\theta|\mu_t, \Sigma_t). \end{aligned}$$

This estimate is proportional to the pdf of a mixture of T^M Gaussians with unnormalized mixture weights,

$$W_t = \frac{w_t \cdot \mathcal{N}_d(\bar{\theta}_t|\hat{\mu}_M, \hat{\Sigma}_M + \frac{h}{M} I_d)}{\prod_{m=1}^M \mathcal{N}_d(\theta_{t_m}^m|\hat{\mu}_m, \hat{\Sigma}_m)},$$

where $\bar{\theta}_t$ and w_t are given in Eqs. 5 and 6. We can write the parameters of a given mixture component $\mathcal{N}_d(\theta|\mu_t, \Sigma_t)$ as

$$\begin{aligned} \Sigma_t &= \left(\frac{M}{h} I_d + \hat{\Sigma}_M^{-1}\right)^{-1}, \\ \mu_t &= \Sigma_t \cdot \left(\frac{M}{h} I_d \bar{\theta}_t + \hat{\Sigma}_M^{-1} \hat{\mu}_M\right), \end{aligned}$$

where $\hat{\mu}_M$ and $\hat{\Sigma}_M$ are given by Eq. 2 and 3. We can sample from this semiparametric estimate using the IMG procedure outlined in Algorithm 1, replacing the component weights w_t with W_t and the component parameters $\bar{\theta}_t$ and $\frac{h}{M} I_d$ with μ_t and Σ_t .

We also have a second semiparametric procedure that may give higher acceptance rates in the IMG algorithm. We follow the above semiparametric procedure, where each component is a normal distribution with parameters μ_t and Σ_t , but we use the nonparametric component weights w_t instead of W_t . This procedure is also asymptotically exact, since the semiparametric component parameters μ_t and Σ_t approach the nonparametric component parameters $\bar{\theta}_t$ and $\frac{h}{M} I_d$ as $h \rightarrow 0$, and thus this procedure tends to the nonparametric procedure given in Algorithm 1.

4 Method Complexity

Given M data subsets, to produce T samples in d dimensions with the nonparametric or semiparametric asymptotically exact procedures (Algorithm 1) requires $O(dTM^2)$ operations. The variation on this algorithm that performs this procedure $M-1$ times on pairs of subposteriors (to increase the acceptance rate; detailed in Section 3.2) instead requires only $O(dTM)$ operations.

We have presented our method as a two step procedure, where first parallel MCMC is run to completion, and

then the combination algorithm is applied to the M sets of samples. We can instead perform an online version of our algorithm: as each machine generates a sample, it immediately sends it to a master machine, which combines the incoming samples³ and performs the accept or reject step (Algorithm 1, lines 3-12). This allows the parallel MCMC phase and the combination phase to be performed in parallel, and does not require transferring large volumes of data, as only a single sample is ever transferred at a time.

The total communication required by our method is transferring $O(dTM)$ scalars (T samples from each of M machines), and as stated above, this can be done online as MCMC is being carried out. Further, the communication is unidirectional, and each machine does not pause and wait for any information from other machines during the parallel sampling procedure.

5 Theoretical Results

Our second and third procedures aim to draw asymptotically exact samples by sampling from (fully or partially) nonparametric estimates of the density product. We prove the asymptotic correctness of our estimators, and bound their rate of convergence. This will ensure that we are generating asymptotically correct samples from the full posterior as the number of samples T from each subposterior grows.

5.1 Density product estimate convergence and risk analysis

To prove (mean-square) consistency of our estimator, we give a bound on the mean-squared error (MSE), and show that it tends to zero as we increase the number of samples drawn from each subposterior. To prove this, we first bound the bias and variance of the estimator. The following proofs make use of similar bounds on the bias and variance of the nonparametric and semiparametric density estimators, and therefore the theory applies to both the nonparametric and semiparametric density product estimators.

Throughout this analysis, we assume that we have T samples $\{\theta_{tm}^n\}_{t,m=1}^T \subset \mathcal{X} \subset \mathbb{R}^d$ from each subposterior ($m = 1, \dots, M$), and that $h \in \mathbb{R}_+$ denotes the bandwidth of the nonparametric density product estimator (which is annealed to zero as $T \rightarrow \infty$ in Algorithm 1). Let Hölder class $\Sigma(\beta, L)$ on \mathcal{X} be defined as the set of all $\ell = \lfloor \beta \rfloor$ times differentiable functions $f : \mathcal{X} \rightarrow \mathbb{R}$ whose derivative $f^{(\ell)}$ satisfies

$$|f^{(\ell)}(\theta) - f^{(\ell)}(\theta')| \leq L |\theta - \theta'|^{\beta - \ell} \quad \text{for all } \theta, \theta' \in \mathcal{X}.$$

³For the semiparametric method, this will involve an online update of mean and variance Gaussian parameters.

We also define the class of densities $\mathcal{P}(\beta, L)$ to be

$$\mathcal{P}(\beta, L) = \left\{ p \in \Sigma(\beta, L) \mid p \geq 0, \int p(\theta) d\theta = 1 \right\}.$$

We also assume that all subposterior densities p_m are bounded, i.e. that there exists some $b > 0$ such that $p_m(\theta) \leq b$ for all $\theta \in \mathbb{R}^d$ and $m \in \{1, \dots, M\}$.

First, we bound the bias of our estimator. This shows that the bias tends to zero as the bandwidth shrinks.

Lemma 5.1. *The bias of the estimator $p_1 \widehat{\cdots} p_M(\theta)$ satisfies*

$$\sup_{p_1, \dots, p_M \in \mathcal{P}(\beta, L)} |\mathbb{E}[p_1 \widehat{\cdots} p_M(\theta)] - p_1 \cdots p_M(\theta)| \leq \sum_{m=1}^M c_m h^{m\beta}$$

for some $c_1, \dots, c_M > 0$.

Proof. For all $p_1, \dots, p_M \in \mathcal{P}(\beta, L)$,

$$\begin{aligned} |\mathbb{E}[p_1 \widehat{\cdots} p_M] - p_1 \cdots p_M| &= |\mathbb{E}[\widehat{p}_1 \cdots \widehat{p}_M] - p_1 \cdots p_M| \\ &= |\mathbb{E}[\widehat{p}_1] \cdots \mathbb{E}[\widehat{p}_M] - p_1 \cdots p_M| \\ &\leq |(p_1 + \tilde{c}_1 h^\beta) \cdots (p_M + \tilde{c}_M h^\beta) - p_1 \cdots p_M| \\ &\leq |c_1 h^\beta + \dots + c_M h^{M\beta}| \\ &\leq |c_1 h^\beta| + \dots + |c_M h^{M\beta}| \\ &= \sum_{m=1}^M c_m h^{m\beta} \end{aligned}$$

where we have used the fact that $|\mathbb{E}[\widehat{p}_m] - p| \leq \tilde{c}_m h^\beta$ for some $\tilde{c}_m > 0$. \square

Next, we bound the variance of our estimator. This shows that the variance tends to zero as the number of samples grows large and the bandwidth shrinks.

Lemma 5.2. *The variance of the estimator $p_1 \widehat{\cdots} p_M(\theta)$ satisfies*

$$\sup_{p_1, \dots, p_M \in \mathcal{P}(\beta, L)} \mathbb{V}[p_1 \widehat{\cdots} p_M(\theta)] \leq \sum_{m=1}^M \binom{M}{m} \frac{c_m}{T^m h^{dm}}$$

for some $c_1, \dots, c_M > 0$ and $0 < h \leq 1$.

Proof. For all $p_1, \dots, p_M \in \mathcal{P}(\beta, L)$,

$$\begin{aligned} \mathbb{V}[p_1 \widehat{\cdots} p_M] &= \mathbb{E}[\widehat{p}_1^2] \cdots \mathbb{E}[\widehat{p}_M^2] - \mathbb{E}[\widehat{p}_1]^2 \cdots \mathbb{E}[\widehat{p}_M]^2 \\ &= \left(\prod_{m=1}^M \mathbb{V}[\widehat{p}_m] + \mathbb{E}[\widehat{p}_m]^2 \right) - \left(\prod_{m=1}^M \mathbb{E}[\widehat{p}_m]^2 \right) \\ &\leq \sum_{m=0}^{M-1} \binom{M}{m} \frac{\tilde{c}^m c^{M-m}}{T^{M-m} h^{d(M-m)}} \\ &\leq \sum_{m=1}^M \binom{M}{m} \frac{c_m}{T^m h^{dm}} \end{aligned}$$

where we have used the facts that $\mathbb{V}[\widehat{p}_m] \leq \frac{c}{Th^d}$ for some $c > 0$ and $\mathbb{E}[\widehat{p}_m]^2 \leq \tilde{c}$ for some $\tilde{c} > 0$. \square

Finally, we use the bias and variance bounds to bound the MSE, which shows that our estimator is consistent.

Theorem 5.3. *If $h \asymp T^{-1/(2\beta+d)}$, the mean-squared error of the estimator $\widehat{p_1 \cdots p_M}(\theta)$ satisfies*

$$\begin{aligned} \sup_{p_1, \dots, p_M \in \mathcal{P}(\beta, L)} \mathbb{E} \left[\int (\widehat{p_1 \cdots p_M}(\theta) - p_1 \cdots p_M(\theta))^2 d\theta \right] \\ \leq \frac{c}{T^{2\beta/(2\beta+d)}} \end{aligned}$$

for some $c > 0$ and $0 < h \leq 1$.

Proof. For all $p_1, \dots, p_M \in \mathcal{P}(\beta, L)$, using the fact that the mean-squared error is equal to the variance plus the bias squared, we have that

$$\begin{aligned} \mathbb{E} \left[\int (\widehat{p_1 \cdots p_M}(\theta) - p_1 \cdots p_M(\theta))^2 d\theta \right] \\ \leq \left(\sum_{m=1}^M c_m h^{m\beta} \right)^2 + \sum_{m=1}^M \binom{M}{m} \frac{\tilde{c}_m}{T^m h^{dm}} \\ \leq k T^{-2\beta/(2\beta+d)} + \frac{\tilde{k}}{T^{1-d(2\beta+d)}} \quad (\text{for some } k, \tilde{k} > 0) \\ \leq \frac{c}{T^{2\beta/(2\beta+d)}} \end{aligned}$$

for some $c_1, \dots, c_M > 0$ and $\tilde{c}_1, \dots, \tilde{c}_M > 0$. \square

6 Method Scope

The theoretical results and algorithms in this paper hold for posterior distributions over finite-dimensional real spaces. These include generalized linear models (e.g. linear, logistic, or Poisson regression), mixture models with known weights, hierarchical models, and (more generally) finite-dimensional graphical models with unconstrained variables. This also includes both unimodal and multimodal posterior densities (such as in Section 8.2). However, the methods and theory presented here do not yet extend to cases such as infinite dimensional models (e.g. nonparametric Bayesian models [5]) nor to distributions over the simplex (e.g. topics in latent Dirichlet allocation [3]). In the future, we hope to extend this work to these domains.

7 Related Work

In [19, 2, 16], the authors develop a way to sample approximately from a posterior distribution when only a small randomized mini-batch of data is used at each step. In [9], the authors used a hypothesis test to decide whether to accept or reject proposals using a small set of data (adaptively) as opposed to the exact

Metropolis-Hastings rule. This reduces the amount of time required to compute the acceptance ratio. Since all of these algorithms are still sequential, they can be directly used in our algorithm to generate subposterior samples to further speed up the entire sampling process.

Several parallel MCMC algorithms have been designed for specific models, such as for topic models [18, 14] and nonparametric mixture models [21]. These approaches still require synchronization to be correct (or approximately correct), while ours aims for more general model settings and does not need synchronization until the final combination stage.

Consensus Monte Carlo [17] is perhaps the most relevant work to ours. In this algorithm, data is also partitioned into different machines and MCMC is performed independently on each machine. Thus, it roughly has the same time complexity as our algorithm. However, the prior is not explicitly reweighted during sampling as we do in Eq 1, and final samples for the full posterior are generated by averaging subposterior samples. Furthermore, this algorithm has few theoretical guarantees. We find that this algorithm can be viewed as a relaxation of our nonparametric, asymptotically exact sampling procedure, where samples are generated from an evenly weighted mixture (instead of each component having weight w_t .) and where each sample is set to θ_t instead of being drawn from $\mathcal{N}(\theta_t, \frac{h}{M} I_d)$. This algorithm is one of our experimental baselines.

8 Empirical Study

In the following sections, we demonstrate empirically that our method allows for quicker, MCMC-based estimation of a posterior distribution, and that our consistent-estimator-based procedures yield asymptotically exact results. We show our method on a few Bayesian models using both synthetic and real data. In each experiment, we compare the following strategies for parallel, communication-free sampling:⁴

- **Single chain full-data posterior samples (regularChain)**—Typical, single-chain MCMC for sampling from the full-data posterior.
- **Parametric subposterior density product estimate (parametric)**—For M sets of subposterior samples, the combination yielding samples from the parametric density product estimate.
- **Nonparametric subposterior density product estimate (nonparametric)**—For M sets of subposterior samples, the combination yielding samples from the nonparametric density product estimate.

⁴We did not directly compare with the algorithms that require synchronization since the setup of these experiments can be rather different. We plan to explore these comparisons in the extended version of this paper.

- **Semiparametric subposterior density product estimate** (`semiparametric`)—For M sets of subposterior samples, the combination yielding samples from the semiparametric density product estimate.
- **Subposterior sample average** (`subpostAvg`)—For M sets of subposterior samples, the average of M samples consisting of one sample taken from each subposterior.
- **Subposterior sample pooling** (`subpostPool`)—For M sets of subposterior samples, the union of all sets of samples.
- **Duplicate chains full-data posterior sample pooling** (`duplicateChainsPool`)—For M sets of samples from the full-data posterior, the union of all sets of samples.

To assess the performance of our sampling and combination strategies, we ran a single chain of MCMC on the full data for 500,000 iterations, removed the first half as burn-in, and considered the remaining samples the “groundtruth” samples for the true posterior density. We then needed a general method to compare the distance between two densities given samples from each, which holds for general densities (including multimodal densities, where it is ineffective to compare moments such as the mean and variance⁵). Following work in density-based regression [15], we use an estimate of the L_2 distance, $d_2(p, \hat{p})$, between the groundtruth posterior density p and a proposed posterior density \hat{p} , where $d_2(p, \hat{p}) = \|p - \hat{p}\|_2 = (\int (p(\theta) - \hat{p}(\theta))^2 d\theta)^{1/2}$.

In the following experiments involving timing, to compute the posterior L_2 error at each time point, we collected all samples generated before a given number of seconds, and added the time taken to transfer the samples and combine them using one of the proposed methods. In all experiments and methods, we followed a fixed rule of removing the first $\frac{1}{6}$ samples for burn-in (which, in the case of combination procedures, was applied to each set of subposterior samples before the combination was performed).

Experiments were conducted with a standard cluster system. We obtained subposterior samples by submitting batch jobs to each worker since these jobs are all independent. We then saved the results to the disk of each worker and transferred them to the same machine which performed the final combination.

8.1 Generalized Linear Models

Generalized linear models are widely used for many regression and classification problems. Here we conduct experiments, using logistic regression as a test case, on

⁵In these cases, dissimilar densities might have similar low-order moments. See Section 8.2 for an example.

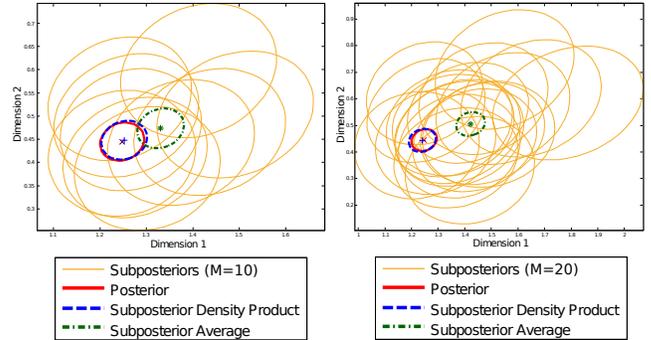

Figure 1: Bayesian logistic regression posterior ovals. We show the posterior 90% probability mass ovals for the first 2-dimensional marginal of the posterior, the M subposteriors, the subposterior density product (via the `parametric` procedure), and the subposterior average (via the `subpostAvg` procedure). We show $M=10$ subsets (left) and $M=20$ subsets (right). The subposterior density product generates samples that are consistent with the true posterior, while the `subpostAvg` produces biased results, which grow in error as M increases.

both synthetic and real data to demonstrate the speed of our parallel MCMC algorithm compared with typical MCMC strategies.

8.1.1 Synthetic data

Our synthetic dataset contains 50,000 observations in 50 dimensions. To generate the data, we drew each element of the model parameter β and data matrix X from a standard normal distribution, and then drew each outcome as $y_i \sim \text{Bernoulli}(\text{logit}^{-1}(X_i\beta))$ (where X_i denotes the i^{th} row of X)⁶. We use Stan, an automated Hamiltonian Monte Carlo (HMC) software package,⁷ to perform sampling for both the true posterior (for groundtruth and comparison methods) and for the subposteriors on each machine. One advantage of Stan is that it is implemented with C++ and uses the No-U-Turn sampler for HMC, which does not require any user-provided parameters [8].

In Figure 1, we illustrate results for logistic regression, showing the subposterior densities, the subposterior density product, the subposterior sample average, and the true posterior density, for the number of subsets M set to 10 (left) and 20 (right). Samples generated by our approach (where we draw samples from the subposterior density product via the `parametric` procedure) overlap with the true posterior much better than those generated via the `subpostAvg` (subposterior sample average) procedure—averaging of samples appears to create systematic biases. Further, the error in

⁶Note that we did not explicitly include the intercept term in our logistic regression model.

⁷<http://mc-stan.org>

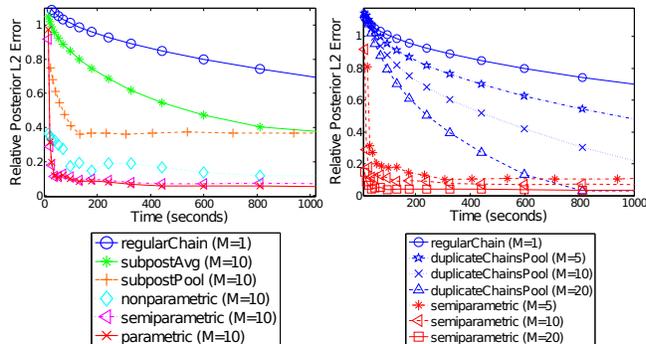

Figure 2: Posterior L_2 error vs time for logistic regression. Left: the three combination strategies proposed in this paper (**parametric**, **nonparametric**, and **semiparametric**) reduce the posterior error much more quickly than a single full-data Markov chain; the **subpostAvg** and **subpostPool** procedures yield biased results. Right: we compare with multiple full-data Markov chains (**duplicateChainsPool**); our method yields faster convergence to the posterior even though only a fraction of the data is being used by each chain.

averaging appears to increase as M grows. In Figure 2 (left) we show the posterior error vs time. A regular full-data chain takes much longer to converge to low error compared with our combination methods, and simple averaging and pooling of subposterior samples gives biased solutions.

We next compare our combination methods with multiple independent “duplicate” chains each run on the full dataset. Even though our methods only require a fraction of the data storage on each machine, we are still able to achieve a significant speed-up over the full-data chains. This is primarily because the duplicate chains cannot parallelize burn-in (i.e. each chain must still take some n steps before generating reasonable samples, and the time taken to reach these n steps does not decrease as more machines are added). However, in our method, each subposterior sampler can take each step more quickly, effectively allowing us to decrease the time needed for burn-in as we increase M . We show this empirically in Figure 2 (right), where we plot the posterior error vs time, and compare with full duplicate chains as M is increased.

Using a Matlab implementation of our combination algorithms, all (batch) combination procedures take under twenty seconds to complete on a 2.5GHz Intel Core i5 with 16GB memory.

8.1.2 Real-world data

Here, we use the *covtype* (predicting forest cover types)⁸ dataset, containing 581,012 observations in 54 dimen-

⁸<http://www.csie.ntu.edu.tw/~cjlin/libsvmtools/datasets>

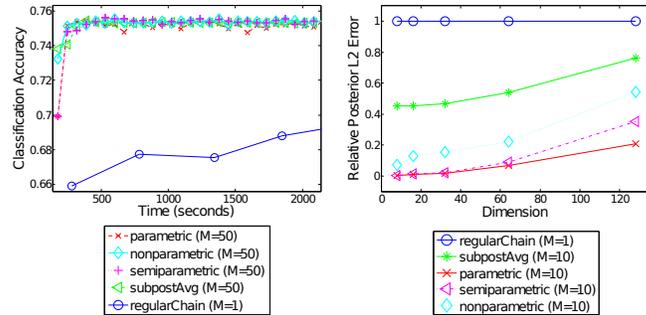

Figure 3: Left: Bayesian logistic regression classification accuracy vs time for the task of predicting forest cover type. Right: Posterior error vs dimension on synthetic data at 1000 seconds, normalized so that **regularChain** error is fixed at 1.

sions. A single chain of HMC running on this entire dataset takes an average of 15.76 minutes per sample; hence, it is infeasible to generate groundtruth samples for this dataset. Instead we show classification accuracy vs time. For a given set of samples, we perform classification using a sample estimate of the posterior predictive distribution for a new label y with associated datapoint x , i.e.

$$P(y|x, y^N, x^N) = \int P(y|x, \beta, y^N, x^N)P(\beta|x^N, y^N) \\ \approx \frac{1}{S} \sum_{s=1}^S P(y|x, \beta_s)$$

where x^N and y^N denote the N observations, and $P(y|x, \beta_s) = \text{Bernoulli}(\text{logit}^{-1}(x^\top \beta_s))$. Figure 3 (left) shows the results for this task, where we use $M=50$ splits. The parallel methods achieve a higher accuracy much faster than the single-chain MCMC algorithm.

8.1.3 Scalability with dimension

We investigate how the errors of our methods scale with dimensionality, to compare the different estimators implicit in the combination procedures. In Figure 3 (right) we show the relative posterior error (taken at 1000 seconds) vs dimension, for the synthetic data with $M=10$ splits. The errors at each dimension are normalized so that the **regularChain** error is equal to 1. Here, the **parametric** (asymptotically biased) procedure scales best with dimension, and the **semiparametric** (asymptotically exact) procedure is a close second. These results also demonstrate that, although the **nonparametric** method can be viewed as implicitly sampling from a nonparametric density estimate (which is usually restricted to low-dimensional densities), the performance of our method does not suffer greatly when we perform parallel MCMC on posterior distributions in much higher-dimensional spaces.

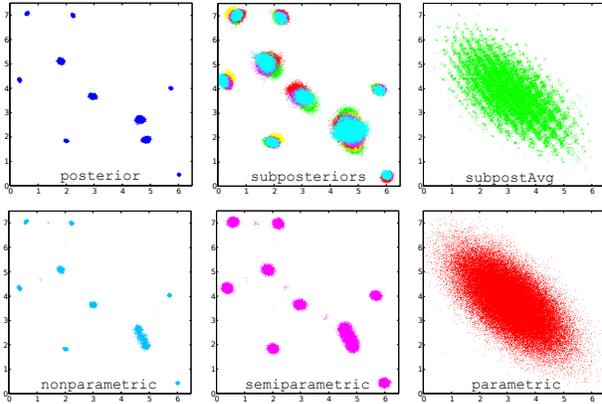

Figure 4: Gaussian mixture model posterior samples. We show 100,000 samples from a single 2-d marginal (corresponding to the posterior over a single mean parameter) of the full-data posterior (top left), all subposteriors (top middle—each one is given a unique color), the subposterior average via the `subpostAvg` procedure (top right), and the subposterior density product via the `nonparametric` procedure (bottom left), `semiparametric` procedure (bottom middle), and `parametric` procedure (bottom right).

8.2 Gaussian mixture models

In this experiment, we aim to show correct posterior sampling in cases where the full-data posterior, as well as the subposteriors, are multimodal. We will see that the combination procedures that are asymptotically biased suffer greatly in these scenarios. To demonstrate this, we perform sampling in a Gaussian mixture model. We generate 50,000 samples from a ten component mixture of 2-d Gaussians. The resulting posterior is multimodal; this can be seen by the fact that the component labels can be arbitrarily permuted and achieve the same posterior value. For example, we find after sampling that the posterior distribution over each component mean has ten modes. To sample from this multimodal posterior, we used the Metropolis-Hastings algorithm, where the component labels were permuted before each step (note that this permutation results in a move between two points in the posterior distribution with equal probability).

In Figure 4 we show results for $M=10$ splits, showing samples from the true posterior, overlaid samples from all five subposteriors, results from averaging the subposterior samples, and the results after applying our three subposterior combination procedures. This figure shows the 2-d marginal of the posterior corresponding to the posterior over a single mean component. The `subpostAvg` and `parametric` procedures both give biased results, and cannot capture the multimodality of the posterior. We show the posterior error vs time in Figure 5 (left), and see that our asymptotically exact

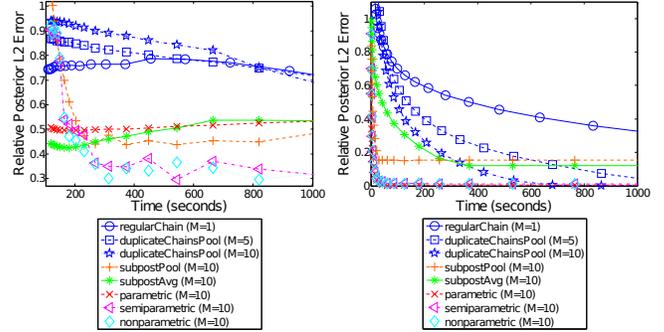

Figure 5: Left: Gaussian mixture model posterior error vs time results. Right: Poisson-gamma hierarchical model posterior error vs time results.

methods yield quick convergence to low posterior error.

8.3 Hierarchical models

We show results on a hierarchical Poisson-gamma model of the following form

$$\begin{aligned}
 a &\sim \text{Exponential}(\lambda) & b &\sim \text{Gamma}(\alpha, \beta) \\
 q_i &\sim \text{Gamma}(a, b) & x_i &\sim \text{Poisson}(q_i t_i) \quad i = 1, \dots, N
 \end{aligned}$$

for $N=50,000$ observations. We draw $\{x_i\}_{i=1}^N$ from the above generative process (after fixing values for a, b, λ , and $\{t_i\}_{i=1}^N$), and use $M=10$ splits. We again perform MCMC using the Stan software package.

In Figure 5 (right) we show the posterior error vs time, and see that our combination methods complete burn-in and converge to a low posterior error very quickly relative to the `subpostAvg` and `subpostPool` procedures and full-data chains.

9 Discussion and Future Work

In this paper, we present an embarrassingly parallel MCMC algorithm and provide theoretical guarantees about the samples it yields. Experimental results demonstrate our method’s potential to speed up burn-in and perform faster asymptotically correct sampling. Further, it can be used in settings where data are partitioned onto multiple machines that have little intercommunication—this is ideal for use in a MapReduce setting. Currently, our algorithm works primarily when the posterior samples are real, unconstrained values and we plan to extend our algorithm to more general settings in future work.

Abstract

Out of the many potential factors that determine which links form in a document citation network, two in particular are of high importance: first, a document may be cited based on its subject matter—this can be modeled by analyzing document content; second, a document may be cited based on which other documents have previously cited it—this can be modeled by analyzing citation structure. Both factors are important for users to make informed decisions and choose appropriate citations as the network grows. In this paper, we present a novel model that integrates the merits of content and citation analyses into a single probabilistic framework. We demonstrate our model on three real-world citation networks. Compared with existing baselines, our model can be used to effectively explore a citation network and provide meaningful explanations for links while still maintaining competitive citation prediction performance.

1 Introduction

Many large citation networks—Wikipedia, arXiv, and PubMed¹, to name a few—continue to quickly grow in size, and the structure of these networks continues to increase in complexity. To effectively explore large-scale and complex data like these and extract useful information, users rely more and more on various types of guidance for help. An important type of guidance comes from the citations (or links) in the network. Citations serve as paths that users can easily follow, and do not require users to specify certain keywords in advance. In scientific research, for example, researchers

often find potentially interesting articles by following citations made in other articles. In Wikipedia, users often find explanations of certain terms by following the links made by other Wikipedia users. Thus, generating relevant citations is important for many users who may frequently rely on these networks to explore data and find useful information.

We believe that, among many, two important factors largely determine how a document citation network is formed: the documents' contents and the existing citation structure. Take as an example a citation network of computer science articles. A research paper about “support vector machines (SVMs)”, for instance, might be cited by several other articles that develop related methods, based on the subject matter alone. This type of information can be well captured by analyzing the content of the documents. However, the existing citation structure is also important. If this SVM paper included great results on a computer vision dataset, for example, it might be cited by many vision papers that are *not* particularly similar in content. Though different in content, this SVM paper could be very important to users in a different topic area, and should be considered by these users when choosing citations. This type of information cannot be easily captured by analyzing document content, but can be discovered by analyzing the existing citation structure among documents while studying the contents of the papers that generated these citations.

Given these observations, we present a probabilistic model to accurately model citation networks by integrating content and citation/link information into a single framework. We name our approach a *latent random offset* (LRO) model. The basic idea is as follows: we first represent the content of each document using a latent vector representation (i.e. “topics”) that summarizes the document content. Then, each latent representation is augmented in an additive manner with a random offset vector; this vector models information from the citation structure that is not well captured

Sistine Chapel (Simple English Wikipedia)

Text: "The Sistine Chapel is a large chapel in the Vatican Palace, the place in Italy where the Pope lives. The Chapel was built between 1473 and 1481 by Giovanni dei Dolci for Pope Sistus IV...The Sistine Chapel is famous for its fresco paintings by the Renaissance painter Michelangelo..."

In-Links (Citing Documents): (1) Raphael, (2) Ten Commandments, (3) Chapel, (4) Apostolic Palace, (5) St. Peter's Basilica

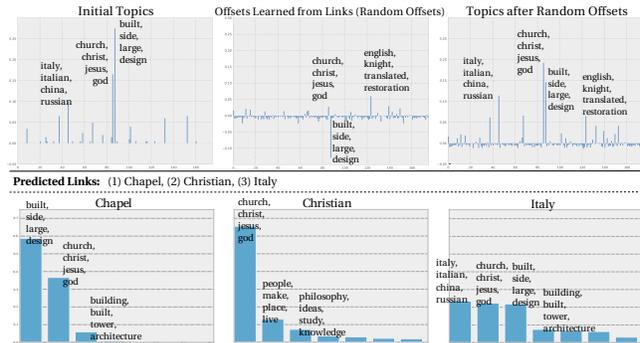

Figure 1: Analysis of content, latent offsets, and predicted links for the *Sistine Chapel* document in the Simple English Wikipedia dataset. The first row shows an example passage from the document. The next row shows the names of the documents that cite *Sistine Chapel*. The next row shows the initial latent topics (first column), the latent offsets learned from links (second column), and the latent topics after applying the offsets (third column). The final row shows interpretable link predictions; for each predicted link, we show the relative weight that each latent topic contributed to the prediction.

by document content. The final augmented representation is then used to model how this document is cited by other documents. To motivate this representation, we present sample outputs from running LRO on the Simple English Wikipedia.

Examples from Simple English Wikipedia.

The first graph in the top row of Figure 1 shows, for the *Sistine Chapel* article in the Simple English Wikipedia, the latent vector representation, which is concentrated around three topics: **countries** (*italy, italian, china, russian*), **Christianity** (*church, christ, jesu, god*), and **architecture** (*built, side, large, design*). Here we've listed the top four words in each topic (in parens). The incoming links to the *Sistine Chapel* article are also shown; these citing documents determine the random offsets for *Sistine Chapel*. The random offsets can be thought of as "corrections" to the latent vector representation, based on the content of citing documents—for example, the two largest positive offsets are **Christianity** (*church, christ, jesu, god*) and **Anglicanism** (*english, knight, translated, restoration*), meaning that the citing documents strongly exhibit these two topics (compared to the *Sistine Chapel* article). On the other hand, there is a large negative offset on **architecture** (*built, side, large, design*), indicating that the citing documents do not exhibit this topic as

much as *Sistine Chapel*.

Notably, the topic **Anglicanism** (containing words related to Christianity in England) is found in the random offsets for *Sistine Chapel*, but is absent from its latent vector representation. This is because the Sistine Chapel is in the Vatican City, and thus its article does not emphasize content relating to England or Anglicanism (even though they are all related to Christianity). However, documents that link to *Sistine Chapel*, such as *Chapel*, talk about the Anglican Church in England. This is an example where pertinent information is found in the citation structure, but not in the document content. By capturing this citation information, the LRO model provides insights into the context surrounding a document.

Following this idea, we can add the latent vector and random offsets together to obtain the "augmented representation" of a document (i.e. the "topics after random offsets" graph in Figure 1), which takes into account not just its content, but the content of its citing documents as well. Link predictions in the LRO model are based upon the intuition that a document i cites document j only if both documents have similar representations. This intuition is captured in the bottom row of graphs in Figure 1, which explains three out-links predicted by the LRO model for the *Sistine Chapel* document. For each predicted link, we show the topics that contributed most to the prediction, and not surprisingly, the most important topics for each link also feature strongly in the augmented representation for the *Sistine Chapel*. Knowing which topics contributed to the prediction of links not only helps users interpret existing links within a document corpus, but also gives users an explanation for every new link predicted by the LRO model—for instance, a user might invoke LRO to recommend citations for an academic paper, and such "link explanations" give the user a quick overview of why each recommendation is relevant.

We note that of the three predicted out-links for *Sistine Chapel*, two of them (*Chapel, Italy*) are actual out-links in *Sistine Chapel*, while the third, *Christian*, is obviously relevant but not found in the document. This motivates another application of LRO: predicting relevant but missing links in document corpora; in this case, we are completing the references for a Wikipedia article. Another application context is academic paper writing: LRO can be used to recommend important (but otherwise overlooked) citations for a newly-written academic paper.

The rest of this paper is organized as follows: we begin by formalizing latent random offset modeling, and then show how we can use it to model citation networks. We then develop a fast learning algorithm

with linear complexity in the size of the number of citations, and empirically evaluate our approach using three real-world citation networks. Compared with several baselines, our model not only improves citation prediction performance, but also provides meaningful explanations for citations within the networks. By studying latent random offset representations, we show these explanations can be used to effectively interpret why our model predicts links for given documents and to explore citation networks.

2 Latent Random Offset Models

We introduce the general framework of latent random offsets for citation network modeling. Suppose our citation network consists of D documents (i.e. nodes), $\mathcal{D} = \{x_1, x_2, \dots, x_D\}$. We use $y_{ij} = 1$ or 0 to indicate whether document i cites document j or not. Note that y_{ij} is *directed*, meaning y_{ij} is not necessarily the same as y_{ji} .

Each document x_j is usually a high-dimensional vector in \mathbb{R}^V , where V is the vocabulary size, so it is desirable to represent x_j using a low-dimensional vector θ_j . In other words, the mapping

$$\theta_j = \theta_j(x_j) \tag{1}$$

serves as a summarization of the original document content x_j , and these summarizations can be used to measure the content similarities of different documents.

However, in real citation networks, a document can be cited by others for reasons outside of its content information. For example, a target document might provide an influential idea that can be used in many different fields and thus be cited by a diverse set of documents. This information is encoded not in the document content but in the citation network structure. We choose to model this phenomenon by allowing a random offset vector ϵ_j to augment the low-dimensional vector θ_j , which gives the augmented representation

$$v_j = \theta_j + \epsilon_j. \tag{2}$$

The offset vector ϵ_j is used to capture the network structure information that is *not* contained in the document’s content. One important property of this augmented representation is that the random offset ϵ_j is aligned in the same space as θ_j . If the dimension of θ_j has some semantic explanations, then ϵ_j can be understood as modifications of those explanations.

Finally we consider using a function f to model the citation from document i to document j , such that

$$f(\theta_i, \theta_j + \epsilon_j) \approx y_{ij} \quad (\text{for all } i, j)$$

where y_{ij} is the citation indicator from document i to document j . Notice the asymmetric structure here for document i and j —we do not consider the offset vector ϵ_i for document i in our function f . In real citation networks, when a new document joins the citation network by citing some other documents, this new document is effectively “not in” the network. It will be most likely to cite other documents based only on their content and their citations, as no network information exists for this new document. One advantage of this formulation is that we can make citation predictions for a brand new document by only using its content information.

In the next two sections, we first describe how we create the low-dimensional document content representation θ_j and how we use the latent random offset model for citation network modeling.

2.1 Probabilistic topic models for document content representation

There are many potential ways to create the low-dimensional document content representation described in Eq. 1. Here we choose to use probabilistic topic models. Topic models [5] are used to discover a set of “topics” (or themes) from a large collection of documents. These topics are distributions over terms, which are biased to be associated under a single theme. One notable property of these models is that they often provide an interpretable low-dimensional representation of the documents [10]. They have been used for tasks like corpus exploration [8], information retrieval [23] and recommendation [22].

Here we describe the simplest topic model, latent Dirichlet allocation (LDA) [7] and use it to create the low-dimensional document content representations. Assume there are K topics, β_k , $k = 1, \dots, K$ and each β_k is a distribution over a fixed vocabulary. For each document j , the generative process is as follows,

1. Draw topic proportions $\theta_j \sim \text{Dirichlet}(\alpha)$
2. For each word x_{jn} in document j ,
 - (a) Draw topic assignment $z_{jn} \sim \text{Mult}(\theta_j)$
 - (b) Draw word $x_{jn} \sim \text{Mult}(\beta_{z_{jn}})$

This process describes how the words of a document are generated from a mixture of topics that are shared by the corpus. The topic proportions θ_j are document-specific and we use these topic proportions as our low-dimensional document content representation.

Given a document collection, the only observations are the words in the documents. The topics, topic proportions for each document, and topic assignments for each word, are all latent variables that have to be

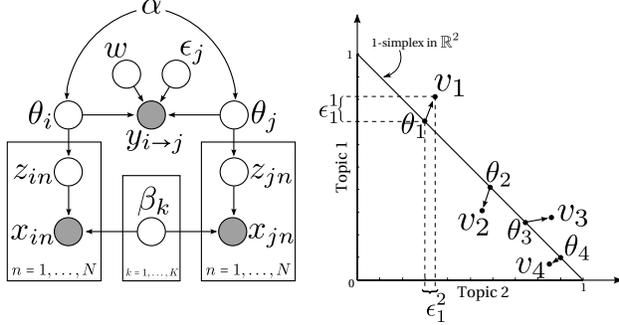

Figure 2: Left: The LRO graphical model. Only two documents (i and j) and one citation (from i to j) are shown. The augmented latent representation for document j is $v_j = \theta_j + \epsilon_j$. Right: An illustration of the random offsets. We show each document’s content vector θ_j (which lies on the simplex), its offsets ϵ_j due to link structure (the superscript indicates the dimension for ϵ_j), and the resulting augmented latent representation v_j .

determined from the data. LDA has been extensively studied in the literature and many efficient algorithms have been proposed to fit the LDA model variables [7, 12, 21]. For example, standard learning algorithms like variational EM or Gibbs sampling can be used to estimate these quantities [7]. These methods give us the estimated document content representations θ_j in terms of an approximate posterior distribution or point estimates.

2.2 Modeling citations via random offsets

Having described how we represent the documents in a low dimensional space, we now consider how to create the augmented representations introduced in Eq. 2. We model our latent random offset vector ϵ_j with a multivariate Gaussian distribution

$$\epsilon_j \sim \mathcal{N}(0, \lambda^{-1} I_K).$$

where λ is a scalar precision parameter for the latent random offsets.

Using the general idea of latent random offset modeling shown in Eq. 2 and probabilistic topic models described in Section 2.1, our *latent random offset model* (LRO) for citation network modeling has the following generative process (Figure 2 shows the graphical model). Assuming K topics, $\beta_{1:K}$,

1. For each document j ,
 - (a) Draw topic proportions $\theta_j \sim \text{Dirichlet}(\alpha)$
 - (b) Draw latent random offset $\epsilon_j \sim \mathcal{N}(0, \lambda^{-1} I_K)$ and set the document augmented representation as $v_j = \theta_j + \epsilon_j$

- (c) For each word x_{jn} ,
 - i. Draw topic assignment $z_{jn} \sim \text{Mult}(\theta)$
 - ii. Draw word $x_{jn} \sim \text{Mult}(\beta_{z_{jn}})$

2. For each *directed* pair of documents (i, j), draw the citation indicator

$$y_{ij} \sim \mathcal{N}(y | w\theta_i^\top v_j, \tau_{ij}^{-1}).$$

where $w \in \mathbb{R}_+$ is a global scaling parameter to account for potential inefficiencies of the topic proportions θ_i , which are constrained to the simplex.² We chose a Gaussian response to model the citations, in similar fashion to [22]. Notation τ_{ij}^{-1} is the precision parameter for the Gaussian distribution. Here, we choose to stray from a formal generative process and also treat the y_{ij} as parameters, such that τ_{ij} satisfies

$$\tau_{ij} = \begin{cases} \tau_1 & \text{if } y_{ij} = 1 \\ \tau_0 & \text{if } y_{ij} = 0. \end{cases}$$

In this formulation, τ_1 specifies the precision if a link exists from document i to j , while τ_0 is for the case where the link does not exist. We set τ_0 to be much smaller (i.e. higher noise) than τ_1 — this is similar to the assumption made in [22], which models the fact that $y_{ij} = 0$ could either mean it is not appropriate for document i to cite document j , or simply that document i should cite document j but has inadvertently neglected to cite it. This also enables a fast learning algorithm with complexity linear in the number of citations (See Section 3 for details).

The expectation of the citation can be computed as

$$\mathbb{E}[y_{ij}] = w\theta_i^\top v_j = w(\theta_i^\top \theta_j) + w(\theta_i^\top \epsilon_j).$$

This reveals how likely it is for a citation from document i to document j to occur under our model. If the documents have similar content or document j has certain large positive offsets, it is more likely to be cited by document i .

For a document j , our latent representation θ_j is over a simplex. In Figure 2 (right), we show how the random offsets ϵ_j produce the augmented representation v_j .

2.3 Citation prediction

In a system for citation prediction, it is more realistic to suggest citations than to make hard decisions for the users. This is common in many recommender systems [13, 22]. For a particular document i , we rank the potential citations according to the score

$$S_{ij} = w\theta_i^\top v_j,$$

²Our experiments show that optimizing the global scaling parameter w is important for obtaining good results.

for all other documents j , and suggest citations based on this score (excluding document i and all pre-existing citations).

3 Learning Algorithm

We use maximum a posteriori (MAP) estimation to learn the latent parameters of the LRO, where we perform a coordinate ascent procedure to carry out the optimization. Maximization of the posterior is equivalent to maximizing the complete log likelihood of $v_{1:D}$, $\theta_{1:D}$ and $\beta_{1:K}$, which we can write as

$$\mathcal{L} = -\frac{\lambda}{2} \sum_j (v_j - \theta_j)^\top (v_j - \theta_j) - \sum_{i \neq j} \frac{\tau_{ij}}{2} (y_{ij} - w\theta_i^\top v_j)^2 + \sum_j \sum_n \log \left(\sum_k \theta_{jk} \beta_{k,x_{jn}} \right).$$

where we have omitted a constant and set $\alpha = 1$.

First, given topics $\beta_{1:K}$ and augmented representations $v_{1:D}$, for all documents, we describe how to learn the topic proportions θ_j . We first define $\phi_{jnk} = q(z_{jn} = k)$. Then we separate the items that contain θ_j and apply Jensen's inequality,

$$\begin{aligned} \mathcal{L}(\theta_j) &\geq -\frac{\lambda}{2} \sum_j (v_j - \theta_j)^\top (v_j - \theta_j) \\ &\quad + \sum_n \sum_k \phi_{jnk} (\log \theta_{jk} \beta_{k,x_{jn}} - \log \phi_{jnk}) \\ &= \mathcal{L}(\theta_j, \phi_j). \end{aligned}$$

where $\phi_j = (\phi_{jnk})_{n=1, k=1}^{D \times K}$. The optimal ϕ_{jnk} then satisfies

$$\phi_{jnk} \propto \theta_{jk} \beta_{k,x_{jn}}.$$

The $\mathcal{L}(\theta_j, \phi_j)$ gives the *tight* lower bound of $\mathcal{L}(\theta_j)$. We cannot optimize θ_j analytically, but we can use the projection gradient [3] method for optimization.³

Second, given this ϕ , we can optimize the topics $\beta_{1:K}$ with

$$\beta_{kx} \propto \sum_j \sum_n \phi_{jnk} 1[x_{jn} = x].$$

This is the same M-step update for topics as in LDA [7].

Next, we would like to optimize the augmented representations $v_{1:D}$. We can write the component of the log likelihood with terms containing v_j as

$$\begin{aligned} \mathcal{L}(v_j) &= -\frac{\lambda}{2} (v_j - \theta_j)^\top (v_j - \theta_j) \\ &\quad - \sum_{i, i \neq j} \frac{\tau_{ij}}{2} (y_{ij} - w\theta_i^\top v_j)^2. \end{aligned}$$

³On our data, we found that simply fixing θ_j as the estimate from the LDA model gives comparable performance and saves computation.

To maximize this quantity, we take the gradient of $\mathcal{L}(v_j)$ with respect to v_j and set it to 0, which gives an update for v_j

$$\begin{aligned} v_j^* &\leftarrow \left(\lambda I_K + w^2 \left((\tau_1 - \tau_0) \sum_{i \in \{i: i \rightarrow j\}} \theta_i \theta_j^\top + \tau_0 \sum_{i, i \neq j} \theta_i \theta_j^\top \right) \right)^{-1} \\ &\quad \times \left(\theta_j + w\tau_1 \sum_{i \in \{i: i \rightarrow j\}} \theta_i \right) \end{aligned} \quad (3)$$

where $\{i : i \rightarrow j\}$ denotes the set of documents that cite document j . For the second line of Eq. 3, we can see that the augmented representation v_j is affected by two main parts: the first is the content from document j (topic proportions θ_j) and the second is the content from other documents who cite document j (topic proportions θ_i , where $i \in \{i : i \rightarrow j\}$).

Next, we want to optimize the global scaling variable w . Isolating the terms in the complete log likelihood that contain w gives

$$\mathcal{L}(w) = -\sum_{i \neq j} \frac{\tau_{ij}}{2} (y_{ij} - w\theta_i^\top v_j)^2.$$

In a similar manner as the previous step, to maximize this quantity we take the gradient of $\mathcal{L}(w)$ with respect to w and set it to 0, which gives its update⁴

$$\begin{aligned} w^* &\leftarrow \left(\sum_j \left((\tau_1 - \tau_0) \sum_{i \in \{i: i \rightarrow j\}} (\theta_i^\top v_j)^2 + \tau_0 \sum_{i, i \neq j} (\theta_i^\top v_j)^2 \right) \right)^{-1} \\ &\quad \times \left(\tau_1 \sum_j \sum_{i \in \{i: i \rightarrow j\}} \theta_i^\top v_j \right). \end{aligned} \quad (4)$$

Empirically, we found that an optimal trade-off between computation time and performance involves performing LDA [7] initially to learn the latent representations θ_j , and then performing coordinate ascent to learn the augmented representations v_j and global parameter w . We detail this procedure in Algorithm 1.

Computational efficiency. We now show that our learning algorithm (Algorithm 1) has runtime complexity linear in the number of documents and citations.

First, estimating the topic proportions θ_j , $j = 1, \dots, D$ has the same complexity as the standard learning algorithm for LDA, which is linear in the number of documents.

Second, the augmented representations v_j , $j = 1, \dots, D$ and global scaling parameter w can be estimated in linear time, via a caching strategy — this is similar to the method adopted by [13, 22]. We now describe this strategy.

⁴In theory, this update could lead to a negative value. However, in our experiments, we did not see this happen.

Algorithm 1 MAP Parameter Learning

Input: A citation network of documents $\{x_j\}_{j=1}^D$ with directed links y_{ij} for $i, j \in \{1, \dots, D\}$, and stopping criteria δ

Output: Latent content representations θ_j , link-offset representations v_j , and global scale parameter w

- 1: Run LDA [7] on $\{x_j\}_{j=1}^D$ to learn $\theta_{1:D}$
 - 2: Initialize $v_{1:D} = \theta_{1:D}$ and $\text{eps} = \infty$
 - 3: **while** $\text{eps} > \delta$ **do**
 - 4: Update $w \leftarrow w^*$ ▷ Equation 4
 - 5: **for** $j = 1$ **to** D **do**
 - 6: Update $v_j \leftarrow v_j^*$ ▷ Equation 3
 - 7: **end for**
 - 8: Set $\text{eps} \leftarrow \|v_{1:D} - \tilde{v}_{1:D}\|$
 - 9: **end while**
-

For the augmented representation v_j (Eq. 3), we cache $\theta_0 = \sum_i \theta_i$. This allows us to update v_j (Eq. 3) using the identity

$$\sum_{i, i \neq j} \theta_i = \theta_0 - \theta_j.$$

Every time we update a θ_j , we also update the cache θ_0 , and this takes constant time w.r.t. the number of documents and citations.

For the global scaling parameter w (Eq. 4), we can compute

$$\begin{aligned} \sum_{i, i \neq j} (\theta_i^\top v_j)^2 &= \sum_{i, i \neq j} v_j^\top \theta_i \theta_i^\top v_j \\ &= v_j^\top (\sum_{i, i \neq j} \theta_i \theta_i^\top) v_j \\ &= v_j^\top (\sum_i \theta_i \theta_i^\top) v_j - v_j^\top \theta_j \theta_j^\top v_j \end{aligned}$$

in $O(K^2)$ time (constant in the number of docs and citations) by simply caching $\Theta_0 = \sum_i \theta_i \theta_i^\top$. This cache variable also requires $O(K^2)$ time to update whenever we modify some θ_j .

The remaining sums in Eqs 3,4 touch every citation exactly once, therefore a single update sweep over all v_j and w only requires constant work per edge (treating K as constant). We have therefore shown that Algorithm 1 is linear in the number of documents and citations. Moreover, we have attained linear scalability without resorting to treating missing citations as hidden data. This gives our LRO a data advantage over methods that hide missing citations, such as the RTM [9].

4 Related Work

Our proposed work focuses on two aspects of citation network modeling: 1) network understanding/exploration and 2) citation prediction. We therefore divide the related work section into these two categories.

Network understanding/exploration.

Network exploration is a broad empirical task concerned with, amongst other things, understanding the overall structure of the network [19], understanding the context of individual nodes [2], and discovering anomalous nodes or edges [20]. In addition to methods that operate on purely graph data, there are techniques that leverage both the graph as well as textual content, such as relational topic models (RTM) [9], Link-PLSA-LDA [17], and TopicFlow [18]. The idea behind such hybrid methods is that text and graph data are often orthogonal, providing complementary insights [11].

Our LRO model incorporates network information by modeling per-document random offsets that capture topical information from connected neighbors. These random offsets represent relevant topics that would otherwise not be found in the documents through content analysis. The Simple English Wikipedia analysis from the introduction provides a good example: the *Sistine Chapel* article’s random offsets (the top row of Figure 1) contain the topic **Anglicanism** (which is also related to Christianity), even though the article text’s latent topic representation makes no mention of it. In this manner, the LRO model helps us understand the context of network nodes (a.k.a. documents), and helps us to detect anomalous nodes (such as documents whose random offsets diverge greatly from their latent topic vectors).

Citation prediction.

The citation prediction task can be approached by considering text features, network features, or a combination of both. In the text-only setting, approaches based on common text features (e.g., TF-IDF scores [4]) and latent space models (e.g., topic models [5]) can be used to measure similarities between two documents, allowing for ranking and prediction. However, text-only approaches cannot account for citation behavior due to the network structure.

In the network-only setting without document content, there are a number of commonly-used measures of node similarity, such as the Jaccard Coefficient, the Katz measure [14] and the Adamic/Adar measure [1]. Latent space models such as matrix factorization (MF) methods [15] can be used here. However, when test documents are out-of-sample with respect to the network (when we consider newly-written papers with no preexisting citations), these measures are inapplicable.

Finally, there are methods that combine both document content and network structure to predict citations. One such method is the relational topic models (RTM) [9], in which link outcomes depend on a reweighted inner product between latent positions (under the LDA model). The weights are learned for each latent dimension (topic), but are not specific to any document,

and thus only capture network behavior due to topic-level interactions. In contrast, our random offsets are learned on a per-document basis, capturing interaction patterns specific to each document, which in turn yields better predictive performance as shown in our empirical study. In [16], in addition to the document content, author information is also considered to model the citation structure. In [17], citations were treated as a parallel document (of citations) as to the document content of words. Neither of these methods use per-document offsets to model citation structure.

5 Empirical Study

We will empirically demonstrate the use of our model for modeling citation networks. We will first show quantitative results for citation prediction then present qualitative results using our model to explore citation networks.

Datasets. We use three citation network datasets,

1. The ACL Anthology paper citation network (*ACL*) contains 16,589 documents and 94,973 citations over multiple decades.
2. The arXiv high energy physics citation network (*arXiv*) contains 34,546 arXiv/hep-th articles and 421,578 citations from January 1993 through April 2003.
3. The Simple English Wikipedia citation network (*Wikipedia*) contains 27,443 articles, and 238,957 citations corresponding to user-curated hyperlinks between articles.

5.1 Citation prediction

For citation prediction, we compare against the RTM [9], matrix factorization (MF) [15], LDA-based predictions [7], and three common baseline algorithms. A detailed description is given below.

The first task is predicting held-out citations. Here we used a five-fold cross validation: for each document that has cited more than 5 documents, we held out 20% of the documents into test set and the rest into the training set.

The second task is predicting citations for new documents. To simulate this scenario, we train our model using all the citations before a certain year and predict the citations of the new documents published in that year. This task is important for a real citation prediction system, where user may input some text without existing citations. For this experiment, we excluded MF from the comparisons, because it cannot perform this task.

Evaluation metric. Our goal is to make citation predictions, where it is more realistic to provide a rank list of citation predictions than to make hard decisions for the users. For a given set of M predicted citations, we use a performance metric, Recall@ M ,

$$\text{Recall@}M = \frac{\text{number of citations in the predicted set}}{\text{total number of citations}}$$

which can be viewed as the proportion of “true” citations successfully predicted by a given method, when the method is allowed to provide M guesses.

Comparison methods. We compare our model with a number of competing strategies, starting with the RTM [9]. In order to make predictions using the RTM, we learn a latent representation for each document and predict citations using a similarity function between these representations (detailed in [9]). The second comparison is an LDA-based prediction strategy, in which document predictions are determined by the similarity between the latent document representation vectors θ_j . The similarity is computed using inverse of the Hellinger distance [6]

$$S_{ij} = H(\theta_i, \theta_j)^{-1} = \sqrt{2} \|\sqrt{\theta_i} - \sqrt{\theta_j}\|^{-1}.$$

Third, we compare with matrix factorization (MF), but only on the first task. (MF cannot make the citation predictions for a brand new document.) Finally, we compare with three simple baseline methods on both tasks. The first is that of Adamic/Adar [1], described in Section 4. The second is based on term frequency-inverse document frequency (TF-IDF) scores, where citations are predicted based on similarities in the documents’ scores [4]. The third baseline is called “in-degree”, where each document is given a score proportional to the number of times it is cited; in this case, the same set of predictions are given for every test document. Hyperparameters are set via cross validation.

Task one: predicting held-out citations. Given the document contents and the remaining links, the task is to predict the held out citations for each document. We show results for our model and six comparison methods on the ACL dataset in Figure 3. Our model (LRO) achieves a significantly higher recall over all ranges of the number of predictions, and we observed similar results for the other two datasets.

We also wanted to determine how our method performs across different datasets. To make the results comparable, we normalized the number of predictions M by setting it to a fraction of the total number of documents in each respective dataset. The results are shown in Figure 4: LRO performs well on all three datasets, though we note that ACL has a much better score than

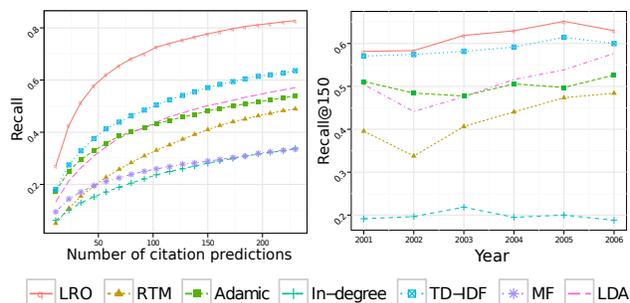

Figure 3: Left: Citation prediction performance on the ACL dataset for task one (predicting held-out citations). Right: Citation prediction performance on task two (predicting citations for new documents) on subsets of the ACL dataset for 7 years. In both cases, the LRO yields the highest recall over all ranges.

the other two. We attribute this to the fact that ACL contains only refereed academic papers, and is therefore more structured than either arXiv (which is unrefereed) or Simple English Wikipedia (whose articles are not always subject to editorial attention).

Task two: predicting citations for new documents. The second task is to predict citations for documents with no prior citation information, corresponding to scenarios in which one needs to suggest citations for newly written documents. This task is often referred to as the “cold start problem” in recommender systems.

We simulate the process of introducing newly written papers into a citation network by dividing them according to publication year. Specifically, from the ACL citation network dataset, we select the citations and documents that existed before the year Y as training data, for Y ranging from 2001 to 2006. After training on this subset, the task is then to predict the citations occurring in year Y for the new documents written in year Y .

For this task, we compared our model against the same comparison methods used in the previous task, except for matrix factorization, which cannot make citation predictions for new documents. Figure 3 (right) shows the results. We fix the number of citation predictions $M = 150$ (other M values have similar trends). Again, our model achieves the best performance over a majority of the M values in all six years, and increases its lead over the comparison methods in later years, after a larger portion of the citation network has formed and can be used as training data.

Hyperparameter sensitivity. We also study how different hyperparameters affect performance, including the number of topics K , precision parameters τ_0 and τ_1 , and latent random offset precision parameter λ

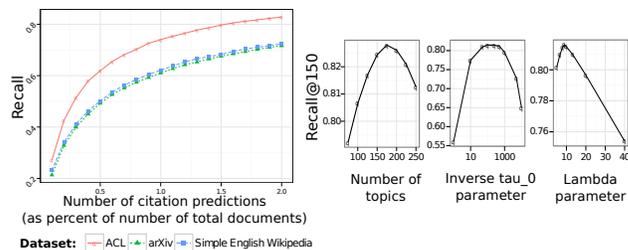

Figure 4: Left: citation prediction performance of our LRO model on three real-world datasets. The ACL dataset has a better score than the other two datasets. See main text for details. Right: citation prediction performance for a range of hyperparameter settings, including the number of topics K , the non-link variance parameter τ_0 , and the latent random offset variance parameter λ .

(Figure 4, right). Again, we fix $M = 150$. First, we varied the number of topics from 75 to 250, and found an optimal value of approximately 175 topics. Next, in order to find the optimal balance between parameters τ_0 and τ_1 , we fixed $\tau_1 = 1$ and varied τ_0 from $1/10000$ to 1 , finding an optimal value of approximately $\tau_0 = 1/100$. Finally, we varied the parameter λ from 5 to 40, and found an optimal value at approximately $\lambda = 9$.

5.2 Exploring citation networks

The latent random offsets can yield useful information that allows for analysis and exploration of documents in the citation network. Our model provides, for each document, a content representation vector θ_j , which captures the topics associated with the content of the document, and a latent offset vector ϵ_j , which captures topics not necessarily contained within the document but expressed by others who cited the document. Highly positive latent offsets may capture the topics where a given document has been influential within the context of the citation network; alternatively, negative offsets can represent topics that are expressed highly in a document, but that have not proven to be influential within the context of the network.

Given a document, we can therefore explore its contents by examining the learned set of topics, and we can explore its role in the citation network (and see the topics of documents that it has influenced) by examining the latent offsets. In Figures 1 and 5 we show the latent topic representations of document contents, the learned random offsets, and the final augmented representations (the sum of topic representations and random offsets), for a document in each of the Simple English Wikipedia and ACL datasets. The augmented representations provide information on both the content and context of a document: they incorporate information contained in the document as well as in other

documents that cite it.

For highly cited documents, we have a great deal of information from the citing documents (i.e. the in-links), and this information can be used to more strongly offset the latent topic representations. Intuitively, the content is like a prior belief about a document’s latent representation, and as more sources start citing the document, this outside information further offsets the latent topic representations. Additionally, the offsets do not only “add” more information to the latent representation from the citing documents. In Figure 5 (top row), the offsets acted primarily to reduce the weights of many of the largest topics in the content representation, and only added weight to two topics. Here, the offsets served to dampen many of the content topics that did not appear to be relevant to the citing documents, and for this reason, the augmented representation is more sparse than the initial content representation.

Interpreting predictions. In addition to maintaining competitive prediction performance, our model allows for interpretable link prediction: for each predicted link we can use our latent representations to give users an understanding of why the link was returned. In particular, we can find the contribution that each topic provides to the final prediction score in order to determine the “reasons” (in terms of the latent topics) why a given document was predicted. We illustrate this in Figures 1 and 5 (bottom row of graphs). In Figure 1, for the *Sistine Chapel* document, *Chapel* is cited largely due to three topics (architecture, Christianity, and buildings), *Christian* is cited primarily due to a single topic (Christianity), and *Italy* is mainly cited due to six lower-weighted topics (countries, Christianity, architecture, buildings, music, and populace). Since *Italy* is a highly cited document and its augmented latent representation emphasizes a large number of topics (many of those expressed by its in-links), it was predicted due to a slight similarity in a number of topics as opposed to a strong similarity in just a few.

In Figure 5 we show three predictions for the document *Automatic Recognition of Chinese Unknown Words Based on Roles Tagging*. We can see that each of the predicted documents was due to a different aspect of this paper: the document *Automatic Rule Induction For Unknown-Word Guessing* was chosen primarily due to the **unknown-word** topic (related to the paper’s goal of recognizing unknown words), the document *Word Identification for Mandarin Chinese Sentences* was chosen primarily due to the **China** topic (related to the paper’s language domain area), and the document *A Knowledge-Free Method For Capitalized Word Disambiguation* was chosen primarily due to the **pronoun** topic (related to the paper’s use of names, locations,

and roles).

Automatic Recognition Of Chinese Unknown Words Based On Roles Tagging (ACL)

Text: “This paper ... is based on the idea of ‘roles tagging’, to the complicated problems of Chinese unknown words recognition ... an unknown word is identified according to its component tokens and context tokens. In order to capture the functions of tokens, we use the concept of roles...We have got excellent precision and recalling rates, especially for person names and transliterations...”

In-Links (Citing Documents): (1) A...word segmentation system for Chinese, (2) Chinese lexical analysis..., (3) HHMM-based Chinese lexical analyzer..., (4) Chinese word segmentation...of characters, (5) Chinese unknown...character-based tagging...

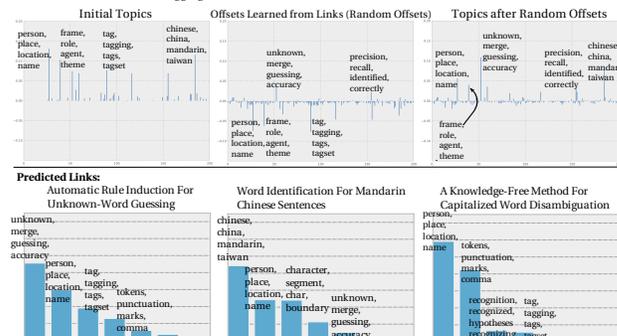

Figure 5: Interpreting citation predictions for the document *Automatic Recognition Of Chinese Unknown Words Based On Roles Tagging* in the ACL dataset. For each predicted link, we show the relative weight that each latent topic (denoted by the top four words) contributed to the prediction. These provide reasons why each predicted link was chosen, in terms of the topics.

6 Conclusion

In this paper, we proposed a probabilistic approach for citation network modeling that integrates the merits of both content and link analyses. Our empirical results showed improved performance compared with several popular approaches for citation prediction. Furthermore, our approach can suggest citations for brand new documents without prior citations—an essential ability for building a real citation recommendation system.

Qualitatively, our approach provides meaningful explanations for how predictions are made, through the latent random offsets. These explanations provide additional information that can be useful for making informed decisions. For example, in a citation recommendation system, we can inform users whether a citation is suggested more due to content similarities or due to the existing network structure, and we can show the relative amounts that individual topics contributed to the prediction. In future work, we would like to conduct user studies to quantify how this additional information helps users find more relevant citations in a more efficient way.

Abstract

We introduce the collaborative multi-output Gaussian process (GP) model for learning dependent tasks with very large datasets. The model fosters task correlations by mixing sparse processes and sharing multiple sets of inducing points. This facilitates the application of variational inference and the derivation of an evidence lower bound that decomposes across inputs and outputs. We learn all the parameters of the model in a single stochastic optimization framework that scales to a large number of observations per output and a large number of outputs. We demonstrate our approach on a toy problem, two medium-sized datasets and a large dataset. The model achieves superior performance compared to single output learning and previous multi-output GP models, confirming the benefits of correlating sparsity structure of the outputs via the inducing points.

1 INTRODUCTION

Gaussian process models (GPs, Rasmussen and Williams, 2006) are a popular choice in Bayesian regression due to their ability to capture complex dependencies and non-linearities in data. In particular, when having multiple outputs or tasks they have proved effective in modeling the dependencies between the tasks, outperforming competitive baselines and single output learners (Bonilla et al., 2008; Teh et al., 2005; Alvarez and Lawrence, 2009; Wilson et al., 2012). However, the prohibitive cost of performing exact inference in GP models severely hinders their application to large scale multi-output problems. For example, naïve inference in a fully coupled Gaussian process model over P outputs and N data points can have

a complexity of $\mathcal{O}(N^3P^3)$ and $\mathcal{O}(N^2P^2)$ in time and memory, respectively.

A motivating example of a large scale multi-output application is the tracking of movements of a robot arm using 2 or more joint torques. If one of the robot motors malfunctions and fails to record a torque, data collected from the other motors may be used to infer the missing torque values. However, taking 100 measurements per second already results in a total of over 40,000 data points per torque in just 7 minutes. Clearly this problem is well beyond the capabilities of conventional multiple output GPs. Building multi-output GP models that can learn correlated tasks at the scale of these types of problems is thus the main focus of this paper.

In the single output setting previous attempts to scale up GP inference resort to approximate inference. Most approximation methods can be understood within a single probabilistic framework that uses a set of *inducing points* in order to obtain an approximate process (or a low-rank approximate covariance) over which inference can be performed more efficiently (Quiñonero-Candela and Rasmussen, 2005). These models have been referred to in the literature as sparse models. Nevertheless, straightforward application of such approximate techniques will yield a computational cost of at least $\mathcal{O}(PNM^2)$ in time and $\mathcal{O}(PNM)$ in memory, where M is the number of inducing points. This high complexity still prevents us from applying GP models to large scale multi-output problems.

In this work we approach the challenge of building scalable multi-output Gaussian process models based on the following observations. Firstly, inducing variables are the key catalyst for achieving sparsity and dealing with large scale problems in Gaussian process models. In particular, they capture the *sufficient statistics* of a dataset allowing the construction of sparse processes that can approximate arbitrarily well the exact GP model (Titsias, 2009). Secondly, the use of global latent variables (such as the inducing points) allows us

to induce dependencies in a highly correlated model efficiently. This observation is exploited in Hensman et al. (2013) for single output GP regression models where, by explicitly representing a distribution over the inducing variables, stochastic variational inference can be used to work with millions of data points. Finally, the key to multi-output and multi-task learning is to model dependencies between the outputs based on realistic assumptions of what can be shared across the tasks. It turns out that sharing “sparsity structure” can not only be a reasonable assumption but also a crucial component when modeling dependencies between different related tasks.

Based on these observations, we propose the collaborative multi-output Gaussian Process (COGP) model where latent processes are mixed to generate dependent outputs. Each process is sparse and characterized by its own set of inducing points. The sparsity structure enabling output correlations is thus created via the shared inducing sets. To learn this structure, we maintain an explicit representation of the posterior over the inducing points which in turn allows inference to be carried out efficiently. In particular, we obtain a variational lower bound of the model evidence that decomposes across inputs and outputs. This decomposition makes possible the application of stochastic variational inference, thus allowing the model to handle a large number of observations per output and a large number of outputs. Furthermore, learning of all the parameters in the model, including kernel hyperparameters and inducing inputs, can be done in a single stochastic optimization framework.

We analyze our multi-out model on a toy problem where the inducing variables are shown to be conducive to the sharing of information between two related tasks. Additionally, we evaluate our model on two moderate-sized datasets in which we show that it can outperform previous non-scalable multi-output approaches as well as single output baselines. Finally, on a large scale experiment regarding the learning of robot inverse dynamics we show the substantial benefits of collaborative learning provided by our model.

Related work. Most GP-based multi-output models create correlated outputs by mixing a set of independent latent processes. The mixing can be a linear combination with fixed coefficients (see e.g. Teh et al., 2005; Bonilla et al., 2008). This is known in the geostatistics community as the “linear model of coregionalization” (Goovaerts, 1997). Such models may also be reformulated in a common Bayesian framework, for example by placing a spike and slab prior over the coefficients (Titsias and Lázaro-Gredilla, 2011). More complex dependencies can be induced

by using input-dependent coefficients (Wilson et al., 2012; Nguyen and Bonilla, 2013) or convolving processes (Boyle and Frean, 2005; Alvarez and Lawrence, 2009; Alvarez et al., 2010).

While we also use the mixing construction, the key difference in our model is the role of inducing variables. In particular, when used in previous models to reduce the computational costs (see e.g. Alvarez and Lawrence, 2009; Álvarez et al., 2010), the inducing points are integrated out or collapsed. In contrast, our model maintains an explicit representation of the posterior over the inducing variables that is learned using data from all outputs. This explicit representation facilitates scalable learning in a similar fashion to the approach in Hensman et al. (2013), making it applicable to very large datasets.

2 MODEL SPECIFICATION

Before diving into technical details of the model specification, we discuss the modeling philosophy behind our collaborative multi-output Gaussian processes. To learn the outputs jointly, we need a mechanism through which information can be transferred among the outputs. This is achieved in the model by allowing the outputs to share multiple sets of inducing variables, each of which captures a different pattern common to the outputs. These variables play a double pivotal role in the model: they collaboratively share information across the outputs and provide sufficient statistics so as to induce sparse processes.

Consider the joint regression of P tasks with inputs $\mathbf{X} = \{\mathbf{x}_n \in \mathcal{R}^D\}_{n=1}^N$ and outputs $\mathbf{y} = \{\mathbf{y}_i\}_{i=1}^P$ where $\mathbf{y}_i = \{y_{in}\}_{n=1}^N$. We model each output as a weighted combination of Q shared latent functions $\{g_j\}_{j=1}^Q$, plus an individual latent function $\{h_i\}_{i=1}^P$ unique to that output for greater flexibility. The Q shared functions have independent Gaussian process priors $g_j(\mathbf{x}) \sim \mathcal{GP}(0, k_j(\cdot, \cdot))$. Similarly, each individual function of an output also has a GP prior, i.e. $h_i(\mathbf{x}) \sim \mathcal{GP}(0, k_i^h(\cdot, \cdot))$.

As we want to sparsify these processes, we introduce a set of *shared inducing variables* \mathbf{u}_j for each $g_j(\mathbf{x})$, i.e. \mathbf{u}_j contains the values of $g_j(\mathbf{x})$ at the inducing inputs \mathbf{Z}_j . Likewise, we have individual inducing variables corresponding to each $h_i(\mathbf{x})$, which we denote with \mathbf{v}_i and their corresponding inducing inputs \mathbf{Z}_i^h . The inducing inputs lie in the same space as the inputs \mathbf{X} . For convenience, we assume all processes have the same number of inducing points, M . However we emphasize that this is not imposed in practice.

We denote the collective variables: $\mathbf{g} = \{\mathbf{g}_j\}$, $\mathbf{h} = \{\mathbf{h}_i\}$, $\mathbf{u} = \{\mathbf{u}_j\}$, $\mathbf{v} = \{\mathbf{v}_i\}$, $\mathbf{Z} = \{\mathbf{Z}_j\}$, and $\mathbf{Z}^h = \{\mathbf{Z}_i^h\}$

where $\mathbf{g}_j = \{g_j(\mathbf{x}_n)\}$, $\mathbf{h}_i = \{h_i(\mathbf{x}_n)\}$. Note that we reserve subscript i for indexing the outputs and their corresponding individual processes ($i = 1 \dots P$), j for the shared latent processes ($j = 1 \dots Q$), and n for the inputs ($n = 1 \dots N$).

2.1 PRIOR MODEL

From the definition of the GPs and the independence of the processes, the *prior* of the multi-output model can be written as:

$$p(\mathbf{g}|\mathbf{u}) = \prod_{j=1}^Q p(\mathbf{g}_j|\mathbf{u}_j) = \prod_{j=1}^Q \mathcal{N}(\mathbf{g}_j; \boldsymbol{\mu}_j, \tilde{\mathbf{K}}_j) \quad (1)$$

$$p(\mathbf{u}) = \prod_{j=1}^Q p(\mathbf{u}_j) = \prod_{j=1}^Q \mathcal{N}(\mathbf{u}_j; \mathbf{0}, k(\mathbf{Z}_j, \mathbf{Z}_j)) \quad (2)$$

$$p(\mathbf{h}|\mathbf{v}) = \prod_{i=1}^P p(\mathbf{h}_i|\mathbf{v}_i) = \prod_{i=1}^P \mathcal{N}(\mathbf{h}_i; \boldsymbol{\mu}_i^h, \tilde{\mathbf{K}}_i^h) \quad (3)$$

$$p(\mathbf{v}) = \prod_{i=1}^P p(\mathbf{v}_i) = \prod_{i=1}^P \mathcal{N}(\mathbf{v}_i; \mathbf{0}, k(\mathbf{Z}_i^h, \mathbf{Z}_i^h)), \quad (4)$$

where the corresponding means and covariances of the Gaussians are given by:

$$\boldsymbol{\mu}_j = k(\mathbf{X}, \mathbf{Z}_j)k(\mathbf{Z}_j, \mathbf{Z}_j)^{-1}\mathbf{u}_j \quad (5)$$

$$\boldsymbol{\mu}_i^h = k(\mathbf{X}, \mathbf{Z}_i^h)k(\mathbf{Z}_i^h, \mathbf{Z}_i^h)^{-1}\mathbf{v}_i \quad (6)$$

$$\tilde{\mathbf{K}}_j = k_j(\mathbf{X}, \mathbf{X}) - k(\mathbf{X}, \mathbf{Z}_j)k(\mathbf{Z}_j, \mathbf{Z}_j)^{-1}k(\mathbf{Z}_j, \mathbf{X}) \quad (7)$$

$$\tilde{\mathbf{K}}_i^h = k_i^h(\mathbf{X}, \mathbf{X}) - k(\mathbf{X}, \mathbf{Z}_i^h)k(\mathbf{Z}_i^h, \mathbf{Z}_i^h)^{-1}k(\mathbf{Z}_i^h, \mathbf{X}). \quad (8)$$

In the equations and hereafter, we omit the subscripts j, h, i from the kernels $k_j(\cdot, \cdot)$ and $k_i^h(\cdot, \cdot)$ when it is clear from the parameters inside the parentheses which covariance function is in action.

Equations (2) and (4) follow directly from the properties of GPs, while the expressions for $p(\mathbf{g}|\mathbf{u})$ and $p(\mathbf{h}|\mathbf{v})$ (Equations (1) and (3)) come from the conditionals of the multivariate Gaussian distributions. Instead of writing the joint priors $p(\mathbf{g}, \mathbf{u})$ and $p(\mathbf{h}, \mathbf{v})$, the above equivalent equations are given to emphasize the sufficient statistics role of \mathbf{u} and \mathbf{v} in the model. Here by sufficient statistics we mean, for any sparse process (say g_j), any other set of function values is independent of \mathbf{g}_j given the inducing variables \mathbf{u}_j .

2.2 LIKELIHOOD MODEL

As mentioned above, we assume that observations for each output are (noisy) linear combinations of the Q latent functions $g_j(\mathbf{x})$ plus an independent function $h_i(\mathbf{x})$. Hence we have that the likelihood with stan-

dard iid Gaussian noise is given by:

$$p(\mathbf{y}|\mathbf{g}, \mathbf{h}) = \prod_{i=1}^P \prod_{n=1}^N \mathcal{N}(y_{in}; \sum_{j=1}^Q w_{ij}g_j(\mathbf{x}_n) + h_i(\mathbf{x}_n), \beta_i^{-1}), \quad (9)$$

where w_{ij} are the corresponding weights and β_i is the precision of each Gaussian. As the latent values \mathbf{g} are specified conditioned on the inducing variables \mathbf{u} , this construction implies that each output is a weighted combination of the inducing values. We note that if \mathbf{u} and \mathbf{v} are marginalized out, we obtain the semiparametric latent factor model (Teh et al., 2005). However, doing so is against the purpose of our model which encourages sharing of outputs via the inducing variables. Furthermore, as we shall see in the next section, explicit representation of these variables is fundamental to scalable inference of the model.

3 INFERENCE

We approximate the posterior over the latent variables $\mathbf{g}, \mathbf{h}, \mathbf{u}, \mathbf{v}$ given observations \mathbf{y} using variational inference (Jordan et al., 1999). In section 3.1 we derive a lower bound of the marginal likelihood which has the key property of factorizing over the data points and outputs. Section 3.2 takes advantage of this factorization to derive stochastic variational inference, allowing the model to scale to very large datasets. Section 3.3 compares the complexity of the model with previous multi-output methods.

3.1 VARIATIONAL LOWER BOUND

In variational inference, we find the ‘‘closest’’ approximate distribution to the true posterior in terms of the KL divergence. We first observe that the true posterior distribution can be written as:

$$p(\mathbf{g}, \mathbf{h}, \mathbf{u}, \mathbf{v}|\mathbf{y}) = p(\mathbf{g}|\mathbf{u}, \mathbf{y})p(\mathbf{h}|\mathbf{v}, \mathbf{y})p(\mathbf{u}, \mathbf{v}|\mathbf{y}). \quad (10)$$

Here we recall the modeling assumption that each set of inducing variables is the sufficient statistics of the corresponding latent process. This motivates replacing the true posteriors over \mathbf{g} and \mathbf{h} with their conditional distributions given the inducing variables, leading to a distribution of the form:

$$q(\mathbf{g}, \mathbf{h}, \mathbf{u}, \mathbf{v}|\mathbf{y}) = p(\mathbf{g}|\mathbf{u})p(\mathbf{h}|\mathbf{v})q(\mathbf{u}, \mathbf{v}), \quad (11)$$

with

$$q(\mathbf{u}, \mathbf{v}) = \prod_{j=1}^Q \underbrace{\mathcal{N}(\mathbf{u}_j; \mathbf{m}_j, \mathbf{S}_j)}_{q(\mathbf{u}_j)} \prod_{i=1}^P \underbrace{\mathcal{N}(\mathbf{v}_i; \mathbf{m}_i^h, \mathbf{S}_i^h)}_{q(\mathbf{v}_i)}. \quad (12)$$

This technique has been used by Titsias (2009) and Hensman et al. (2013) to derive variational inference algorithms for the single output case. Since the conditionals $p(\mathbf{g}|\mathbf{u})$ and $p(\mathbf{h}|\mathbf{v})$ are known (Equations (1) and (3)), we only need to learn $q(\mathbf{u}, \mathbf{v})$ so as to minimize the divergence between the approximate posterior and the true posteriors. The quality of approximation depends entirely on the posterior over the inducing variables, thus underlining their pivotal role in the model as previously discussed.

To find the best $q(\mathbf{u}, \mathbf{v})$, we optimize the evidence lower bound (ELBO) of the log marginal:

$$\begin{aligned} \log p(\mathbf{y}) &\geq \int q(\mathbf{u}, \mathbf{v}) \log p(\mathbf{y}|\mathbf{u}, \mathbf{v}) d\mathbf{u}d\mathbf{v} \\ &- \sum_{j=1}^Q \text{KL}[q(\mathbf{u}_j)||p(\mathbf{u}_j)] - \sum_{i=1}^P \text{KL}[q(\mathbf{v}_i)||p(\mathbf{v}_i)], \end{aligned} \quad (13)$$

which is derived using Jensen's inequality and the fact that both of $q(\mathbf{u}, \mathbf{v})$ and $p(\mathbf{u}, \mathbf{v})$ fully factorize. Since $q(\mathbf{u}_j), q(\mathbf{v}_i), p(\mathbf{u}_j), p(\mathbf{v}_i)$ are all multivariate Gaussian distributions, the KL divergence terms are analytically tractable. To compute the expected likelihood term in the ELBO we first see that

$$\begin{aligned} \log p(\mathbf{y}|\mathbf{u}, \mathbf{v}) &\geq \langle \log p(\mathbf{y}|\mathbf{g}, \mathbf{h}) \rangle_{p(\mathbf{g}, \mathbf{h}|\mathbf{u}, \mathbf{v})} \\ &= \sum_{i=1}^P \sum_{n=1}^N \langle \log p(y_{in}|\mathbf{g}_n, h_{in}) \rangle_{p(\mathbf{g}|\mathbf{u})p(\mathbf{h}_i|\mathbf{v}_i)} \end{aligned} \quad (14)$$

where $\mathbf{g}_n = \{g_{jn} = (\mathbf{g}_j)_n\}_{j=1}^Q$. The inequality is due to Jensen's inequality and the equality is due to the factorization of the likelihood.

The ELBO can be computed by first solving for the individual expectations $\langle \log p(y_{in}|\mathbf{g}_n, h_{in}) \rangle$ over $p(\mathbf{g}|\mathbf{u})p(\mathbf{h}_i|\mathbf{v}_i)$ and then substituting these into Equation (13) (see the supplementary material for details). Hence the resulting lower bound is given by:

$$\begin{aligned} \mathcal{L} &= \sum_{i,n} \left(\log \mathcal{N}(y_{in}; \tilde{\mu}_{in}, \beta_i^{-1}) - \frac{1}{2} \beta_i \sum_{j=1}^Q w_{ij}^2 \tilde{k}_{jnn} \right. \\ &- \left. \frac{1}{2} \beta_i \tilde{k}_{inn}^h - \frac{1}{2} \beta_i \sum_{j=1}^Q \text{tr} w_{ij}^2 \mathbf{S}_j \mathbf{\Lambda}_{jn} - \beta_i \frac{1}{2} \text{tr} \mathbf{S}_i^h \mathbf{\Lambda}_{in} \right) \\ &- \sum_{j=1}^Q \left(\frac{1}{2} \log |\mathbf{K}_{jzz} \mathbf{S}_j^{-1}| + \frac{1}{2} \text{tr} \mathbf{K}_{jzz}^{-1} (\mathbf{m}_j \mathbf{m}_j^T + \mathbf{S}_j) \right) \\ &- \sum_{i=1}^P \left(\frac{1}{2} \log |\mathbf{K}_{izz} (\mathbf{S}_i^h)^{-1}| \right. \\ &\left. + \frac{1}{2} \text{tr} \mathbf{K}_{izz}^{-1} (\mathbf{m}_i^h (\mathbf{m}_i^h)^T + \mathbf{S}_i^h) \right), \end{aligned} \quad (15)$$

where $\mathbf{K}_{jzz} = k(\mathbf{Z}_j, \mathbf{Z}_j)$, $\mathbf{K}_{izz} = k(\mathbf{Z}_i^h, \mathbf{Z}_i^h)$, and:

$$\tilde{\mu}_{in} = \sum_{j=1}^Q w_{ij} \mathbf{A}_j(n, :) \mathbf{m}_j + \mathbf{A}_i^h(n, :) \mathbf{m}_i^h, \quad (16)$$

$$\mathbf{\Lambda}_{jn} = \mathbf{A}_j(n, :)^T \mathbf{A}_j(n, :), \quad (17)$$

$$\mathbf{\Lambda}_{in} = \mathbf{A}_i^h(n, :)^T \mathbf{A}_i^h(n, :), \quad (18)$$

with $\tilde{k}_{jnn} = (\tilde{\mathbf{K}}_j)_{nn}$; $\tilde{k}_{inn}^h = (\tilde{\mathbf{K}}_i^h)_{nn}$; $\mu_{jn} = (\boldsymbol{\mu}_j)_n$; $\mu_{in}^h = (\boldsymbol{\mu}_i^h)_n$; and we have defined the auxiliary matrices $\mathbf{A}_j = k(\mathbf{X}, \mathbf{Z}_j) \mathbf{K}_{jzz}^{-1}$ and $\mathbf{A}_i^h = k(\mathbf{X}_i, \mathbf{Z}_i^h) \mathbf{K}_{izz}^{-1}$ and used $\mathbf{A}_j(n, :)$ to denote the n -th row vector of \mathbf{A}_j . Notice that this ELBO generalizes the bound for standard GP regression derived in Hensman et al. (2013), which can be recovered by setting $P = Q = 1$, $w_{ij} = 1$ and $h_i(\mathbf{x}) = 0$.

The novelty of the variational lower bound in Equation (15) is that it decomposes across both inputs and outputs. This enables the use of stochastic optimization methods, which allow the model to handle very large datasets for which existing GP-based multi-output models are simply impractical.

3.2 STOCHASTIC VARIATIONAL INFERENCE

So far in the description of the model and inference we have implicitly assumed that every output has full observations at all inputs \mathbf{X} . To discern where learning occurs for each output, we make the missing data scenario more explicit. Specifically, each output i can have observations at a different set of inputs \mathbf{X}_i . We shall use \mathbf{o}_i to denote the indices of \mathbf{X}_i (in the set \mathbf{X}) and use the indexing operator $\mathbf{B}(\mathbf{o}_i)$ to select the rows corresponding to \mathbf{o}_i from any arbitrary matrix \mathbf{B} . We also overload \mathbf{y}_i as the observed targets of output i .

3.2.1 Learning the Parameters of the Variational Distribution

We can obtain the derivatives of the ELBO in Equation (15) wrt the variational parameters for optimization. The derivatives of \mathcal{L} wrt the parameters of $q(\mathbf{u}_j)$ are given by:

$$\frac{\partial \mathcal{L}}{\partial \mathbf{m}_j} = \sum_{i=1}^P \beta_i w_{ij} \mathbf{A}_j(\mathbf{o}_i)^T \mathbf{y}_i^{\setminus j} \quad (19)$$

$$- \left[\mathbf{K}_{jzz}^{-1} + \sum_{i=1}^P \beta_i w_{ij}^2 \mathbf{A}_j(\mathbf{o}_i)^T \mathbf{A}_j(\mathbf{o}_i) \right] \mathbf{m}_j,$$

$$\frac{\partial \mathcal{L}}{\partial \mathbf{S}_j} = \frac{1}{2} \mathbf{S}_j^{-1} - \frac{1}{2} \left[\mathbf{K}_{jzz}^{-1} + \sum_{i=1}^P \beta_i w_{ij}^2 \mathbf{A}_j(\mathbf{o}_i)^T \mathbf{A}_j(\mathbf{o}_i) \right], \quad (20)$$

where $\mathbf{y}_i^{\setminus j} = \mathbf{y}_i - \mathbf{A}_i^h(\mathbf{o}_i) \mathbf{m}_i^h - \sum_{j' \neq j} w_{ij'} \mathbf{A}_{j'}(\mathbf{o}_i) \mathbf{m}_{j'}$.

The derivatives of \mathcal{L} wrt the parameters of $q(\mathbf{v}_i)$ are given by:

$$\frac{\partial \mathcal{L}}{\partial \mathbf{m}_i^h} = \beta_i \mathbf{A}_i^h(\mathbf{o}_i)^T \mathbf{y}_i^{\setminus h} - \left[\mathbf{K}_{izz}^{-1} + \beta_i \mathbf{A}_i^h(\mathbf{o}_i)^T \mathbf{A}_i^h(\mathbf{o}_i) \right] \mathbf{m}_i, \quad (21)$$

$$\frac{\partial \mathcal{L}}{\partial \mathbf{S}_i^h} = \frac{1}{2} \mathbf{S}_i^{-1} - \frac{1}{2} \left[\mathbf{K}_{izz}^{-1} + \beta_i \mathbf{A}_i^h(\mathbf{o}_i)^T \mathbf{A}_i^h(\mathbf{o}_i) \right], \quad (22)$$

where $\mathbf{y}_i^{\setminus h} = \mathbf{y}_i - \sum_{j=1}^Q w_{ij} \mathbf{A}_j(\mathbf{o}_i, \cdot) \mathbf{m}_j$.

It can be seen that the derivatives of the parameters of $q(\mathbf{v}_i)$ only involve the observations of the output i . The derivatives of the parameters of $q(\mathbf{u}_j)$ involve the observations of all outputs but is a sum of contributions from individual outputs. Computation of the derivatives can therefore be easily distributed or parallelized.

Since the optimal distributions $q(\mathbf{u}_j)$ and $q(\mathbf{v}_i)$ are in the exponential family, it is more convenient to use stochastic variational inference (Hensman et al., 2012, 2013) to perform update of their canonical parameters. This works by taking a step of length l in the direction of the natural gradient approximated by mini-batches of the data. For instance, consider $q(\mathbf{u}_j)$ whose canonical parameters are $\Phi_1 = \mathbf{S}_j^{-1} \mathbf{m}_j$ and $\Phi_2 = -\frac{1}{2} \mathbf{S}_j^{-1}$. Their stochastic update equations at time $t+1$ are given by:

$$\Phi_{1(t+1)} = \mathbf{S}_{j(t)}^{-1} \mathbf{m}_{j(t)} + l \left(\sum_{i=1}^P \beta_i w_{ij} \mathbf{A}_j(\mathbf{o}_i)^T \mathbf{y}_i^{\setminus j} - \mathbf{S}_{j(t)}^{-1} \mathbf{m}_{j(t)} \right) \quad (23)$$

$$\Phi_{2(t+1)} = -\frac{1}{2} \mathbf{S}_{j(t)}^{-1} + l \left(\frac{1}{2} \mathbf{S}_{j(t)}^{-1} - \frac{1}{2} \mathbf{\Lambda} \right), \quad (24)$$

where $\mathbf{\Lambda} = \mathbf{K}_{jzz}^{-1} + \sum_{i=1}^P \beta_i w_{ij}^2 \mathbf{A}_j(\mathbf{o}_i)^T \mathbf{A}_j(\mathbf{o}_i)$.

3.2.2 Inducing Inputs and Hyper-parameters

To learn the hyperparameters, which in this model include the mixing weights, the covariance hyperparameters of the latent processes, and the noise precision of each output, we follow standard practice in GP inference. For this model this involves taking derivatives of the ELBO and applying standard stochastic gradient descent in alternative steps with the variational parameters, much like a variational EM algorithm. The derivatives are given in the supplementary material.

Learning of the inducing inputs, which was not considered in the single output case in Hensman et al. (2013), is also possible in our stochastic optimization approach. In the supplementary material, we show

Table 1: Comparison of the time and storage complexity of approximate inference of multi-output GP models. A&W, 2009 refers to Alvarez and Lawrence (2009). COGP is the only method with complexity *independent* of the number of inputs N and outputs P , thus it can scale to very large datasets.

METHOD	TIME	STORAGE
COGP, this paper	$\mathcal{O}(M^3)$	$\mathcal{O}(M^2)$
SLFM, (Teh et al., 2005)	$\mathcal{O}(QNM_t^2)$	$\mathcal{O}(QNM_t)$
MTGP, (Bonilla et al., 2008)	$\mathcal{O}(PNM_t^2)$	$\mathcal{O}(PNM_t)$
CGP-FITC (A&W, 2009)	$\mathcal{O}(PNM_t^2)$	$\mathcal{O}(PNM_t)$
GPRN, (Wilson et al., 2012)	$\mathcal{O}(PQN^3)$	$\mathcal{O}(PQN^2)$

that the additional cost of computing the derivatives of the lower bound wrt the inducing inputs is not significantly higher than the cost of updating the variational parameters. This makes optimizing the inducing locations a practical option, which can be critical in high-dimensional problems. Indeed, our experiments on a large scale multi-output problem show that automatic learning of the inducing inputs can lead to significant performance gain with little overhead in computation.

3.3 COMPLEXITY ANALYSIS

In this section we analyze the complexity of the model and compare it to existing multi-output approaches. For consistency, we first unify common notations used for all models. We use P as the number of outputs; N as the number of inputs; Q as the number of shared latent processes; and M_t as the *total* number of inducing inputs. It is worth noting that $M_t = (P + Q) \times M$ in our COGP model, assuming that each sparse process has equal number of inducing points. Also, COGP has P additional individual processes, one for each output.

The complexity of COGP can be read off by inspecting the ELBO in Equation (15), with the key observation that it contains a sum over the outputs as well as over the inputs. This means a mini-batch containing a small subset of the inputs and outputs can be used for stochastic optimization. Technically, the cost is $\mathcal{O}(M^3)$ or $\mathcal{O}(N_b M^2)$, where N_b is the size of the mini-batches, depending on which is larger between M and N_b . In practice, we may use $N_b > M$ as a large batch size (e.g. $N_b = 1000$) helps reduce stochasticity of the optimization. However, here we use $\mathcal{O}(M^3)$ for easier comparison with other models whose time and storage demands are given in Table 1. We see that COGP has a computational complexity that is independent of the size of the inputs and outputs, which makes it the only method capable of handling large scale problems.

3.4 PREDICTION

The predictive distribution of the i -th output for a test input \mathbf{x}_* is given by:

$$p(f_*|\mathbf{y}, \mathbf{x}_*) = \mathcal{N}(f_*; \sum_{j=1}^Q w_{ij} \mu_{j*} + \mu_{i*}^h, w_{ij}^2 s_{j*} + s_{i*}^h), \quad (25)$$

where μ_{j*} and s_{j*} are the mean and variance of the prediction for $g_{j*} = g_j(\mathbf{x}_*)$, i.e. $p(g_{j*}|\mathbf{y}, \mathbf{x}_*) = \mathcal{N}(g_{j*}; \mu_{j*}, s_{j*})$. Likewise, μ_{i*}^h and s_{i*}^h are the mean and variance of the prediction for $h_{i*} = h_i(\mathbf{x}_*)$, $p(h_{i*}|\mathbf{y}, \mathbf{x}_*) = \mathcal{N}(h_{i*}; \mu_{i*}^h, s_{i*}^h)$. These predictive means and variances are given by:

$$\mu_{j*} = \mathbf{k}_{j*z} \mathbf{K}_{jzz}^{-1} \mathbf{m}_j, \quad (26)$$

$$s_{j*} = k_{j**} - \mathbf{k}_{j*z} (\mathbf{K}_{jzz}^{-1} - \mathbf{K}_{jzz}^{-1} \mathbf{S}_j \mathbf{K}_{jzz}^{-1}) \mathbf{k}_{j*z}^T, \quad (27)$$

$$\mu_{i*}^h = \mathbf{k}_{i*z} \mathbf{K}_{izz}^{-1} \mathbf{m}_i^h, \quad (28)$$

$$s_{i*}^h = k_{i**} - \mathbf{k}_{i*z} (\mathbf{K}_{izz}^{-1} - \mathbf{K}_{izz}^{-1} \mathbf{S}_i \mathbf{K}_{izz}^{-1}) \mathbf{k}_{i*z}^T, \quad (29)$$

where $k_{j**} = k_j(\mathbf{x}_*, \mathbf{x}_*)$, $k_{i**}^h = k_i^h(\mathbf{x}_*, \mathbf{x}_*)$, \mathbf{k}_{j*z} is the covariance between \mathbf{x}_* and \mathbf{Z}_j , and \mathbf{k}_{i*z} is the covariance between \mathbf{x}_* and \mathbf{Z}_i^h .

4 EXPERIMENTS

We evaluate the proposed approach with four experiments. A toy problem is first used to study the transfer of learning between two related processes via the shared inducing points. We then compare the model with existing multi-output models on the tasks of predicting foreign exchange rate and air temperature. In the final experiment, we show that joint learning under sparsity can yield significant performance gain on a large scale dataset of inverse dynamics of a robot arm.

Since we are using stochastic optimization, the learning rates need to be chosen carefully. We found that the rates used in Hensman et al. (2013) also work well for our model. Specifically, we used the learning rates of 0.01 for the variational parameters, 1×10^{-5} for the covariance hyperparameters, and 1×10^{-4} for the weights, noise precisions, and inducing inputs. We also included a momentum term of 0.9 for all of the parameters except the variational parameters and the inducing inputs. All of the experiments are executed on an Intel(R) Core(TM) i7-2600 3.40GHz CPU with 8GB of RAM using Matlab R2012a.

4.1 TOY PROBLEM

In this toy problem, two related outputs are simulated from the same latent function $\sin(x)$ and corrupted by independent noise: $y_1(x) = \sin(x) + \epsilon$ and

$y_2(x) = -\sin(x) + \epsilon$, $\epsilon \sim \mathcal{N}(0, 0.01)$. Each output is given 200 observations with missing values in the $(-7, -3)$ interval for the first output and the $(4, 8)$ interval for the second output. We used $Q = 1$ latent sparse process with squared exponential kernel, $h_1(x) = h_2(x) = 0$, and $M = 15$ inducing inputs for our model.

Figure 1 shows the predictive distributions by our model (COGP) and independent GPs with stochastic variational inference (SVIGP, one for each output). The locations of the inducing inputs are fixed and identical for both methods. It is apparent from the figure that the independent GPs fail to predict the functions in the unobserved regions, especially for output 1. In contrast, by using information from the observed intervals of one output to interpolate the missing signal of the other, COGP makes perfect prediction for both outputs. This confirms the effectiveness of collaborative learning of sparse processes via the shared inducing variables. Additionally, we note that the inference procedure learned that the weights are $w_{11} = 1.07$ and $w_{21} = -1.06$ which accurately reflects the correlation between the two outputs.

4.2 FOREIGN EXCHANGE RATE PREDICTION

The first real world application we consider is to predict the foreign exchange rate w.r.t the US dollar of the top 10 international currencies (CAD, EUR, JPY, GBP, CHF, AUD, HKD, NZD, KRW, and MXN) and 3 precious metals (gold, silver, and platinum)¹. The setting of our experiment described here is identical to that in Álvarez et al. (2010). The dataset consists of all the data available for the 251 working days in the year of 2007. There are 9, 8, and 42 days of missing values for gold, silver, and platinum, respectively. We remove from the data the exchange rate of CAD on days 50–100, JPY on day 100–150, and AUD on day 150–200. Note that these 3 currencies are from very different geographical locations, making the problem more interesting. The 153 points are used for testing, and the remaining 3051 data points are used for training. Since the missing data corresponds to long contiguous sections, the objective here is to evaluate the capacity of the model to impute the missing currency values based on other currencies.

For preprocessing we normalized the outputs to have zero mean and unit variance. Since the exchange rates are driven by a small number of latent market forces (see e.g. Álvarez et al., 2010), we tried different values of $Q = 1, 2, 3$ and selected $Q = 2$ which gave the best model evidence (ELBO). We used the squared-

IGP	0.5996	0.4082

exponential covariance function for the shared processes and the noise covariance function for the individual process of each output. $M = 100$ inducing inputs (per sparse process) were randomly selected from the training data and fixed throughout training.

The real data and predictive distributions by our model are shown in Figure 2. They exhibit similar behaviors to those by the convolved model with inducing kernels in Álvarez et al. (2010). In particular, both models perform better at capturing the strong depreciation of the AUD than the fluctuations of the CAD and JPY currency. Further analysis of the dataset found that 4 other currencies (GBP, NZD, KRW, and MXN) also experienced the same trend during the days 150

– 200. This information from these currencies was effectively used by the model to extrapolate the values of the AUD.

We also report in Table 2 the predictive performance of our model compared to the convolved GPs model with exact inference (CGP, Alvarez and Lawrence, 2009) and independent GPs (IGP, one for each output). Our model outperforms both of CGP and IGP in terms of the standardized mean squared error (SMSE). CGP has lower negative log predictive density (NLPD), mainly due to the less conservative predictive variance of the exact CGP for the CAD currency. For reference, the convolved GPs with approximation via the variational inducing kernels (CGPVAR, Álvarez et al., 2010) has an SMSE of 0.2795 while the NLPD was not provided. Training took only 10 minutes for our model compared to 1.4 hours for the full CGP model.

4.3 AIR TEMPERATURE PREDICTION

Next we consider the task of predicting air temperature at 4 different locations in the south coast of England. The air temperatures are recorded by a network of weather sensors (named Bramblemet, Sotomet, Cambermet, and Chimet) during the period from

Table 3: Performance comparison on the air temperature dataset. Results are averages of 2 outputs over 5 repetitions.

METHOD	SMSE	NLPD
COGP	0.1077	2.1712
CGP	0.1125	2.2219
IGP	0.8944	12.5319

July 10 to July 15, 2013. Measurements were taken every 5 minutes, resulting in a maximum of 4320 observations. There are missing data for Bramblemet (100 points), Chimet (15 points), and Sotonmet (1002 points), possibly due to network outages or hardware failures. We further simulated failure of the sensors by removing the observations from the time periods [10.2 - 10.8] for Cambermet and [13.5 - 14.2] for Chimet. The removed data comprises 375 data points and is used for testing. The remaining data consisting of 15,788 points is used for training. Similar to the previous experiment, the objective is to evaluate the ability of the model to use the signals from the functioning sensors to extrapolate the missing signals.

We normalized the outputs to have zero mean and unit variance. We used $Q = 2$ sparse processes with the squared exponential covariance function and individual processes with the noise covariance function. $M = 200$ inducing inputs were randomly selected from the training set and fixed throughout training.

The real data and the predictive distributions by our model, CGP with exact inference (Alvarez and Lawrence, 2009), and independent GPs are shown in Figure 3. It is clear that the independent GP model is clueless in the test regions and thus simply uses the average temperature as its prediction. For Cambermet, both COGP and CGP can capture the rising in temperature from the morning until the afternoon and the fall afterwards. The performance of the models are summarized in Table 3, which shows that our model outperforms CGP in terms of both SMSE and NLPD. It took 5 minutes on average to train our model compared to 3 hours of CGP with exact inference.

It is also worth noting the characteristics of the sparse processes learned by our model as they correspond to different patterns in the data. In particular, one process has an inverse lengthscale of 136 which captures the global increase in temperature during the training period while the other has an inverse lengthscale of 0.5 to model the local variations within a single day.

Table 4: Performance comparison on the robot inverse dynamics dataset. In the last two lines, standard GP is applied to output 1 and the other method is applied to output 2. Results are averaged over 5 repetitions.

4.4 ROBOT INVERSE DYNAMICS

Our last experiment is with a dataset relating to an inverse dynamics model of a 7-degree-of-freedom anthropomorphic robot arm (Vijayakumar and Schaal, 2000). The data consists of 48,933 datapoints mapping from a 21-dimensional input space (7 joints positions, 7 joint velocities, 7 joint accelerations) to the corresponding 7 joint torques. It has been used in previous work (see e.g. Rasmussen and Williams, 2006; Vijayakumar and Schaal, 2000) but only for single task learning. Chai et al. (2008) considered multitask learning of robot inverse dynamics but on a different and much smaller dataset.

Here we consider joint learning for the 4th and 7th torques, where the former has 2,000 points while the latter has 44,484 points for training. The test set consists of 8,898 observations equally divided between the two outputs.

Since none of the existing multi-output models are applicable to problems of this scale, we compare with independent models that learn each output separately. Standard GP is applied to the first output as it has only 2,000 observations for training. For the second output, we used two baselines. The first is the subset of data (SOD) approach where 2,000 data points are randomly selected for training with a standard GP model. The second is the sparse GP with stochastic variational inference (SVIGP) using 500 inducing inputs and a batch size of 1,000. In case of COGP, we also used a batch size of 1,000 and 500 inducing points for the shared process ($Q = 1$) and each of the individual processes.

The performance of all methods in terms of SMSE and NLPD is given in Table 4. The benefits of learning the two outputs jointly are evident, as can be seen by the significantly lower SMSE and NLPD of COGP compared to the full GP for the first output (4th torque). While the SMSE of the second output is essentially the same for all methods, the NLPD of COGP is sub-

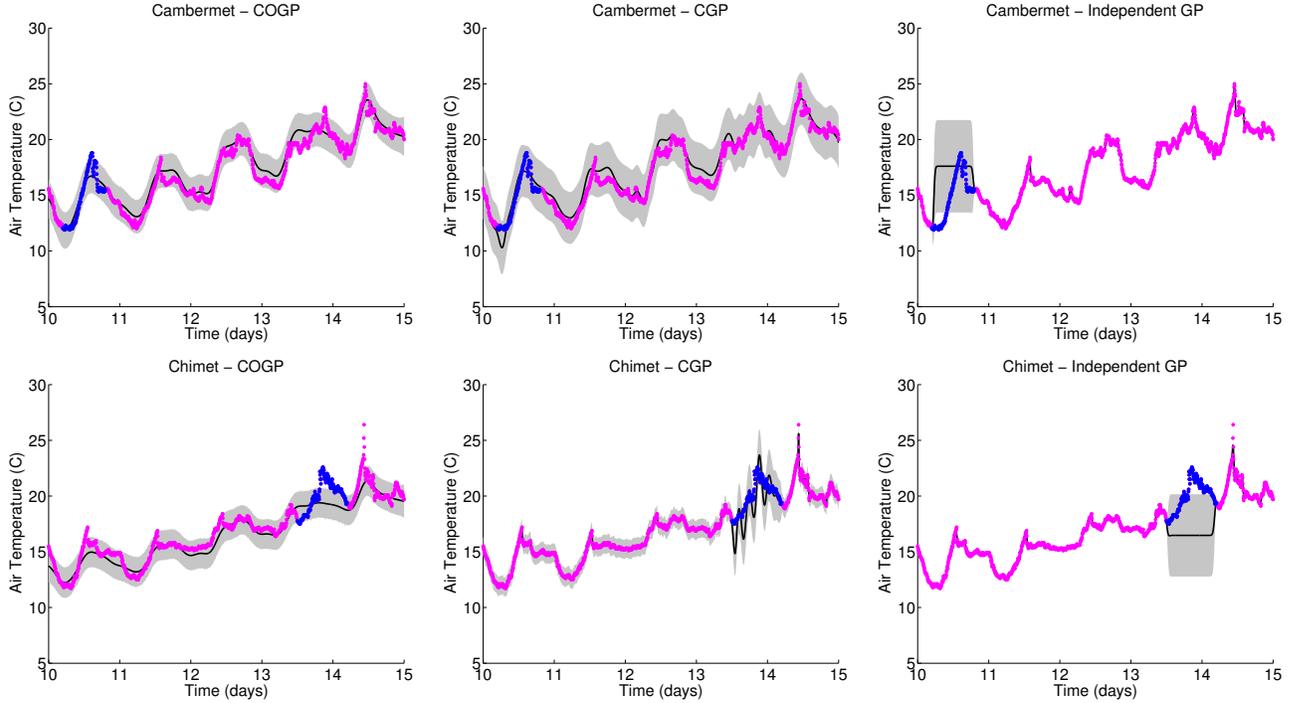

Figure 3: Real data and predictive distributions by our method (COGP, left figures), the convolved GP method with exact inference (CGP, middle figures), and full independent GPs (right figures) for the air temperature problem. The coding color scheme is the same as in Figure 1.

stantially better than that of the independent SVIGP model which has the same amount of training data for this torque. These results validate the impact of collaborative learning under sparsity assumptions, opening up new opportunities for improvement over single task learning with independent sparse processes.

Finally, we see on Table 4 that optimizing the inducing inputs can yield better performance than fixing them. More importantly, the overhead in computation is small, as demonstrated by the training times shown in Figure 4. For instance, the total training time is only 1.9 hours when learning with 500 inducing inputs compared to 1.6 hours when fixing them. As this dataset is 21-dimensional, this small difference in training time confirms that learning of the inducing inputs is a practical option even when dealing with problems of high dimensions.

5 DISCUSSION

We have presented scalable multi-output GPs for learning of correlated functions. The formulation around the inducing variables was shown to be conducive to effective and scalable joint learning under sparsity. We note that although our large scale experiments were done with over 40,000 observations – the largest publicly available multi-output dataset found,

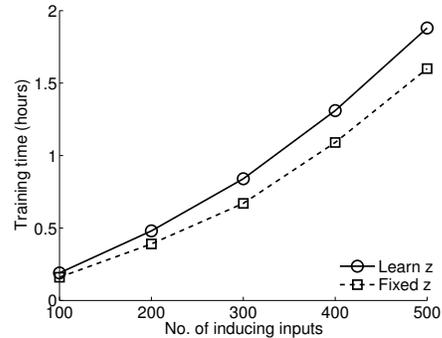

Figure 4: Learning of the inducing inputs is a practical option as the overhead in training time is small.

the model can easily handle much bigger datasets.

Combining predictions from linear models when training and test inputs differ

Thijs van Ommen

Centrum Wiskunde & Informatica
Amsterdam, The Netherlands

Abstract

Methods for combining predictions from different models in a supervised learning setting must somehow estimate/predict the quality of a model's predictions at unknown future inputs. Many of these methods (often implicitly) make the assumption that the test inputs are identical to the training inputs, which is seldom reasonable. By failing to take into account that prediction will generally be harder for test inputs that did not occur in the training set, this leads to the selection of too complex models. Based on a novel, unbiased expression for KL divergence, we propose XAIC and its special case FAIC as versions of AIC intended for prediction that use different degrees of knowledge of the test inputs. Both methods substantially differ from and may outperform all the known versions of AIC *even when the training and test inputs are iid*, and are especially useful for deterministic inputs and under covariate shift. Our experiments on linear models suggest that if the test and training inputs differ substantially, then XAIC and FAIC predictively outperform AIC, BIC and several other methods including Bayesian model averaging.

1 INTRODUCTION

In the statistical problem of model selection, we are given a set of models $\{\mathcal{M}_i \mid i \in \mathcal{I}\}$, each of the form $\mathcal{M}_i = \{g_i(\cdot \mid \theta) \mid \theta \in \Theta_i\}$, where the $g_i(\cdot \mid \theta)$ are density functions on (sequences of) data. We wish to use one of these models to explain our data and/or to make predictions of future data, but do not know which model explains the data best. It is well known that simply selecting the model containing the maximum likelihood distribution from among all the models leads to overfitting, so any expression of the quality of a model must somehow avoid this problem. One way to do this is by estimating each model's ability

to predict *unseen* data (this will be made precise below). This approach is used by many methods for model selection, including cross-validation, AIC (Akaike, 1973) and its many variants, Gelfand and Ghosh's D_k (1998), and BPIC (Ando, 2007). However, none of these methods takes into account that for supervised learning problems, the generalization error being estimated will vary with the test input variables. Instead, they implicitly assume that the test inputs will be *identical* to the training inputs.

In this paper, we derive an estimate of the generalization error that does take the input data into account, and use this to define a new model selection criterion XAIC, its special case FAIC, and the variants XAIC_C and FAIC_C (small sample corrections). We use similar assumptions as AIC, and thus our methods can be seen as relatives of AIC that are adapted to supervised learning when the training and test inputs differ. Our experiments show that our methods have excellent predictive performance, better even than Bayesian model averaging in some cases. Also, we show theoretically that AIC's unawareness of input variables leads to a bias in the selected model order, even in the seemingly safe case where the test inputs are drawn from the same distribution as the training inputs. No existing model selection method seems to address this issue adequately, making XAIC and FAIC more than "yet another version of AIC".

It is in fact quite surprising that, more than 40 years after its original invention, all the forms of AIC currently in use are biased in the above sense, and in theoretical analyses, conditional model selection methods are often even compared on a new point x constrained to be one of the x values in the training data (see e.g. Yang (2005)), even though in most practical problems, a new point x will *not* be drawn from this empirical training data distribution, but rather should be regarded as falling in one of the three cases considered in this paper: (a) it is drawn from the same distribution as the training data (but not necessarily equal to one of the training inputs); (b) it is drawn from a different distribution (covariate shift); (c) it is set to a fixed, observable value, usually not in the training set, but the process that gave rise

to this value may not be known.

1.1 GOALS OF MODEL SELECTION

When choosing among or combining predictions from different models, one can have different goals in mind. Whereas BIC and BMS (Bayesian model selection) focus on finding the most probable model, methods like AIC, cross-validation and SRM (structural risk minimization, Vapnik (1998)) aim to find the model that leads to the best *predictions* of future data. While AIC and cross-validation typically lead to predictions that converge faster to optimal in the sense of KL-divergence than those of BIC and BMS, it is also well-known that, unlike BIC and BMS, such methods are not statistically consistent (i.e. they do not find the smallest submodel containing the truth with probability 1 as $n \rightarrow \infty$); there is an inherent conflict between these two goals, see for example Yang (2007); Van Erven et al. (2007, 2012). Like AIC, the XAIC and FAIC methods developed here aim for predictive optimality rather than consistency, thus, if consistency is the main concern, they should not be used. We also stress at the outset that, unlike most other model selection criteria, the model selected by FAIC may *depend* on the new x whose corresponding y value is to be predicted; for different x , a different model may be selected based on the same training data. Since — as in many other model selection criteria — our goal is predictive accuracy rather than ‘finding the true model’, and since the dependence on the test x helps us to get substantially better predictions, we are not worried by this dependency.

FAIC thus cannot be said to select a ‘single’ model for a given training set — it merely outputs a *function* from x values to models. As such, it is more comparable with BMA (Bayesian model *averaging*) rather than BMS (*selection*). BMA is of course a highly popular method for data prediction; like FAIC, it adapts its predictions to the test input x (as we will see, FAIC tends to select a simpler model if there are not many training points near x ; BMA predicts with a larger variance if there are not many training points near x). BMA leads to the optimal predictions in the idealized setting where one takes expectation under the prior (i.e., in frequentist terms, we imagine nature to draw a model, and then a distribution within the chosen model, both from the prior used in BMA, and then data from the drawn distribution), and usually performs very well in practice as well. It is of considerable interest then that our XAIC and FAIC outperform Bayes by a fair margin in some of our experiments in Section 5.

1.2 IN-SAMPLE AND EXTRA-SAMPLE ERROR

Many methods for model selection work by computing some estimate of how well each model will do at predicting unseen data. This generalization error may be defined in various ways, and methods can further vary in the as-

sumptions used to find an estimate. AIC (Akaike, 1973) is based on the expression for the generalization error

$$-2 \mathbb{E}_{\mathbf{U}} \mathbb{E}_{\mathbf{V}} \log g_i(\mathbf{V} \mid \hat{\theta}_i(\mathbf{U})), \quad (1)$$

for model $\mathcal{M}_i = \{g_i(\cdot \mid \theta) \mid \theta \in \Theta_i\}$, where $\hat{\theta}_i(\mathbf{U})$ denotes the element of Θ_i which maximizes the likelihood of data \mathbf{U} , and where both random variables are independent samples of n data points each, both following the true distribution of the data. (We use capitals to denote sequences of data points, and boldface for random variables.) Throughout this paper, \log denotes the natural logarithm.) Up to an additive term which is the same for all models, the inner expectation is the KL divergence from the true distribution to $g_i(\cdot \mid \hat{\theta}_i(\mathbf{U}))$. An interpretation of (1) is that we first estimate the model’s parameters using a random sample \mathbf{U} , then judge the quality of this estimate by looking at its performance on an independent, identically distributed sample \mathbf{V} . AIC then works by estimating (1) for each model by the asymptotically unbiased estimator

$$-2 \log g_i(\mathbf{U} \mid \hat{\theta}_i(\mathbf{U})) + 2k, \quad (2)$$

and selecting the model minimizing this estimate. Thus AIC selects the model whose maximum likelihood estimate is expected to be closest to the truth in terms of KL divergence. In the sequel, we will consider only one model at a time, and therefore omit the model index.

In supervised learning problems such as regression and classification, the data points consist of two parts $u_i = (x_i, y_i)$, and the models are sets of distributions on the *output variable* \mathbf{y} conditional on the *input variable* x (which may or may not be random). We call these *conditional* models. The conditionality expresses that we are not interested in explaining the behaviour of x , only that of \mathbf{y} given x . Then (1) can be adapted in two ways: as the *extra-sample error*

$$-2 \mathbb{E}_{\mathbf{Y} \mid X} \mathbb{E}_{\mathbf{Y}' \mid X'} \log g(\mathbf{Y}' \mid X', \hat{\theta}(X, \mathbf{Y})), \quad (3)$$

and, replacing both X and X' by a single variable X , as the *in-sample error*

$$-2 \mathbb{E}_{\mathbf{Y} \mid X} \mathbb{E}_{\mathbf{Y}' \mid X} \log g(\mathbf{Y}' \mid X, \hat{\theta}(X, \mathbf{Y})), \quad (4)$$

where capital letters again denote sequences of data points. Contrary to (1), these quantities capture that the expected quality of a prediction regarding \mathbf{y} may vary with x .

An example of a supervised learning setting is given by *linear models*. In a linear model, an input variable x is represented by a *design vector* and a sequence of n inputs by an $n \times p$ *design matrix*; with slight abuse of notation, we use x and X to represent these. Then the densities $g(\mathbf{Y} \mid X, \mu)$ in the model are Gaussian with mean $X\mu$ and covariance matrix $\sigma^2 I_n$ for some fixed σ^2 . Because g is of the form $e^{-\text{squared error}}$, taking the negative logarithm as in (1) produces an expression whose main component is a sum of

squared errors; the residual sum of squared errors $\text{RSS}(\mathbf{Y})$ is the minimum for given data, which is attained by the maximum likelihood estimator. Alternatively, σ^2 may be another parameter in addition to μ if the true variance is unknown.

It is standard to apply ordinary AIC to supervised learning problems, for example for linear models with fixed variance where (2) takes the well-known form

$$\frac{1}{\sigma^2} \text{RSS}(\mathbf{Y}) + 2k, \quad (5)$$

where k is the number of parameters in the model. But because the standard expression behind AIC (1) makes no mention of X or X' , this corresponds to the tacit assumption that $X = X'$, so that the in-sample error is being estimated.

However, the extra-sample error is more appropriate as a measure of the expected performance on new data. AIC was intended to correct the bias that results from evaluating an estimator on the data from which it was derived, but because it uses the in-sample error, AIC evaluates estimators on new output data, but old input data. So we see that in supervised problems, a bias similar to the one it was intended to correct is still present in AIC.

1.3 CONTENTS

The remainder of this article is structured as follows. In Section 2, we develop our main results about the extra-sample error and propose a new model selection criterion based on this. It involves $\kappa_{X'}$, a term which can be calculated explicitly for linear models; we concentrate on these models in the remainder of the paper. Special cases of our criterion, including a focused variant, are presented in Section 3. In Section 4 we discuss the behaviour of our estimate of the extra-sample error, and find that without our modification, AIC's selected model orders are biased. Several experiments on simulated data are described in Section 5. Section 6 contains some further theoretical discussion regarding Bayesian prediction and covariate shift. Finally, Section 7 concludes. All proofs are in the supplementary material.¹

2 ESTIMATING THE EXTRA-SAMPLE ERROR

In this section, we will derive an estimate for the extra-sample error. Our assumptions will be similar to those used in AIC to estimate the in-sample error; therefore, we start with some preliminaries about the setting of AIC.

2.1 PRELIMINARIES

In the setting of AIC, the data points are independent but not necessarily identically distributed. The number of data points in \mathbf{Y} and \mathbf{Y}' is n . We define the Fisher information matrix $I(\theta)$ as $-\mathbb{E}_{\mathbf{Y}'} \frac{\partial^2}{\partial \theta^2} \log g(\mathbf{Y}' | \theta)$, and define the conditional Fisher information matrix $I(\theta | X')$ analogously. We write $\text{Cov}(\hat{\theta}(X, \mathbf{Y}) | X)$ for the conditional covariance matrix $\mathbb{E}_{\mathbf{Y}|X}[\hat{\theta}(X, \mathbf{Y}) - \mathbb{E}_{\mathbf{Y}|X} \hat{\theta}(X, \mathbf{Y})][\hat{\theta}(X, \mathbf{Y}) - \mathbb{E}_{\mathbf{Y}|X} \hat{\theta}(X, \mathbf{Y})]^\top$.

Under standard regularity assumptions, there exists a unique parameter value θ_o that minimizes the KL divergence from the true distribution, and this is what $\hat{\theta}(\mathbf{Y})$ converges to. Under this and other (not very restrictive) regularity assumptions (Shibata, 1989), it can be shown that (Burnham and Anderson, 2002)

$$-2 \log g(\mathbf{Y} | \hat{\theta}(\mathbf{Y})) + 2 \widehat{\text{tr}} \left\{ I(\theta_o) \text{Cov}(\hat{\theta}(\mathbf{Y})) \right\} \quad (6)$$

(where $\widehat{\text{tr}}$ represents an appropriate estimator of that trace) is an asymptotically unbiased estimator of (1). The model selection criterion TIC (Takeuchi's information criterion) selects the model which minimizes (6).

The estimator of the trace term that TIC requires has a large variance, making it somewhat unreliable in practice. AIC uses the very simple estimate $2k$ for TIC's trace term. This estimate is generally biased except when the true data-generating distribution is in the model, but obviously has 0 variance. Also, if some models are more misspecified than others, those models will have a worse log-likelihood. This term in AIC grows linearly in the sample size, so that asymptotically, those models will be disqualified by AIC. Thus AIC selects good models even when its penalty term is biased due to misspecification of the models.

This approach corresponds to making the following assumption in the derivation leading to AIC's penalty term:

Assumption 1 *The model contains the true data-generating distribution.*

It follows that θ_o specifies this distribution. We emphasize that this assumption is only required for AIC's derivation and does not mean that AIC necessarily works badly if applied to misspecified models. Under this assumption, the two matrices in (6) cancel, so the objective function becomes (2), the standard formula for AIC (Burnham and Anderson, 2002).

We now move to supervised learning problems, where the true distribution of the data and the distributions g in the models are conditional distributions of output values given input values. In this setting, the data are essentially iid in the sense that $g(\mathbf{Y} | X, \theta) = \prod_{i=1}^n g(\mathbf{y}_i | x_i, \theta)$. That is, the outputs are independent given the inputs, and if two input variables are equal, the corresponding output variables

¹Posted on arXiv

are identically distributed. Also, the definition of θ_o would need to be modified to depend on the training inputs, but since Assumption 1 now implies that $g(\mathbf{y} \mid x, \theta_o)$ defines the true distribution of \mathbf{y} given x for all x , we can take this as the definition of θ_o for supervised learning when Assumption 1 holds.

For supervised learning problems, AIC and TIC silently assume that X' either equals X or will be drawn from its empirical distribution. We want to remove this assumption.

2.2 MAIN RESULTS

We will need another assumption:

Assumption 2 For training data (X, \mathbf{Y}) and (unobserved) test data (X', \mathbf{Y}') ,

$$\begin{aligned} -\frac{1}{n} \mathbb{E}_{\mathbf{Y}|X} \log g(\mathbf{Y} \mid X, \theta_o) \\ = -\frac{1}{n'} \mathbb{E}_{\mathbf{Y}'|X'} \log g(\mathbf{Y}' \mid X', \theta_o), \end{aligned}$$

where n and n' denote the number of data points in X and X' , respectively.

This assumption ensures that the log-likelihood on the test data can be estimated from the training data. If \mathbf{X} and \mathbf{X}' are random and mutually iid, this is automatically satisfied when the expectations are taken over these inputs as well. While this assumption of randomness is standard in machine learning, there are other situations where X and X' are not random and Assumption 2 holds nevertheless. For instance, this is the case if $g(\mathbf{y} \mid x, \theta)$ is such that $y_i = f_\theta(x_i) + \mathbf{z}_i$, where the noise terms \mathbf{z}_i are zero-mean and iid (their distribution may depend on θ). This additive noise assumption is common in regression-like settings. Then Assumption 1 implies that Assumption 2 holds for all X, X' .

To get an estimator of the extra-sample error (3), we do not make any assumptions about the process generating X and X' but leave the variables free. We allow $n \neq n'$.

Theorem 1 Under Assumptions 1 and 2 and some standard regularity conditions (detailed in the supplementary material), and for n' either constant or growing with n ,

$$\begin{aligned} -2 \frac{n}{n'} \mathbb{E}_{\mathbf{Y}|X} \mathbb{E}_{\mathbf{Y}'|X'} \log g(\mathbf{Y}' \mid X', \hat{\theta}(X, \mathbf{Y})) \\ = -2 \mathbb{E}_{\mathbf{Y}|X} \log g(\mathbf{Y} \mid X, \hat{\theta}(X, \mathbf{Y})) + k + \kappa_{X'} + o(1), \end{aligned} \quad (7)$$

where $\kappa_{X'} = \frac{n}{n'} \text{tr} \left\{ I(\theta_o \mid X') \text{Cov}(\hat{\theta}(X, \mathbf{Y}) \mid X) \right\}$.

Moreover, if the true conditional distribution of \mathbf{Y} given X is Gaussian with fixed variance and the conditional distributions in the models are also Gaussian with that same

variance (as is the case in linear models with known variance), then the above approximation becomes exact.

We wish to use (7) as a basis for model selection. To do this, first note that (7) can be estimated from our training data using

$$-2 \log g(\mathbf{Y} \mid X, \hat{\theta}(X, \mathbf{Y})) + k + \kappa_{X'}. \quad (8)$$

Theorem 1 expresses that this is an asymptotically unbiased estimator of the extra-sample error. We see that the difference with standard AIC (2) is that the penalty $2k$ has been replaced by $k + \kappa_{X'}$. We propose to use (8) as the basis for a new model selection criterion *extra-sample AIC (XAIC)*, which chooses the model that minimizes an estimator of (8). What remains for this is to evaluate $\kappa_{X'}$, which may depend on the unknown true distribution, and on the test set through X' .

2.3 THE $\kappa_{X'}$ AND $o(1)$ TERMS FOR LINEAR MODELS

If the densities g are Gaussian, then $\kappa_{X'}$ does not depend on the unknown θ_o because the Fisher information is constant, so no additional estimation is necessary to evaluate it. Thus for a linear model with fixed variance, $\kappa_{X'}$ becomes

$$\begin{aligned} \kappa_{X'} &= \frac{n}{n'} \text{tr} \left\{ \left[\frac{1}{\sigma^2} X'^\top X' \right] \left[\sigma^2 (X^\top X)^{-1} \right] \right\} \\ &= \frac{n}{n'} \text{tr} \left[X'^\top X' (X^\top X)^{-1} \right]. \end{aligned}$$

If the variance is also to be estimated, it can be easily seen that $\kappa_{X'}$ will become this value plus one. In that case, the approximation in Theorem 1 is not exact (as it is in the known variance case), but the $o(1)$ term can be evaluated explicitly:

Theorem 2 For a linear model with unknown variance,

$$\begin{aligned} -2 \frac{n}{n'} \mathbb{E}_{\mathbf{Y}|X} \mathbb{E}_{\mathbf{Y}'|X'} \log g(\mathbf{Y}' \mid X', \hat{\theta}(X, \mathbf{Y})) \\ = -2 \mathbb{E}_{\mathbf{Y}|X} \log g(\mathbf{Y} \mid X, \hat{\theta}(X, \mathbf{Y})) \\ + k + \kappa_{X'} + \frac{(k + \kappa_{X'})(k + 1)}{n - k - 1}, \end{aligned}$$

where $\kappa_{X'}$ can again be computed from the data and equals $(n/n') \text{tr}(X'^\top X' (X^\top X)^{-1}) + 1$, and k is the number of parameters including σ^2 .

Theorem 2 presents an extra-sample analogue of the well-known small sample correction AIC_C (Hurvich and Tsai, 1989), which is derived similarly and uses a penalty of $2k + 2k(k + 1)/(n - k - 1)$. We define XAIC_C accordingly. Though the theorem holds exactly only in the specific case described, we believe that the extra penalty term will lead to better results in much more general settings in practice, as is the case with AIC_C (Burnham and Anderson, 2002).

3 MODEL SELECTION FOR EXTRA-SAMPLE PREDICTION

In this section, we discuss several concrete model selection methods, all based on the XAIC formula (8) and thus correcting AIC’s bias.

3.1 NONFOCUSED VERSIONS OF XAIC

Except in trivial cases, the extra-sample error (3) and its estimate (8) depend on the test inputs X' , so some knowledge of X' is required when choosing a model appropriate for extra-sample prediction. In a semi-supervised learning setting where X' itself is known at the time of model selection, we could evaluate (8) directly for each model. However, X' might not yet be known when choosing a model.

If \mathbf{X}' is not known but its distribution is, we can replace $\kappa_{\mathbf{X}'}$ by its expectation; for iid inputs, computing this reduces to computing $E_{\mathbf{X}'} I(\theta_o | \mathbf{x}')$.

If the distribution of \mathbf{X}' is also unknown, we need to estimate it somehow. If it is believed that \mathbf{X} and \mathbf{X}' follow the same distribution, the empirical distribution of \mathbf{X} could be used as an estimate of the distribution of \mathbf{X}' . Then AIC is retrieved as a special case. Section 4 will show that this is a bad choice even if \mathbf{X} and \mathbf{X}' follow the same distribution, so a smoothed estimate is recommended instead.

Of course, we are not restricted to the case where \mathbf{X} and \mathbf{X}' follow similar distributions. In the setting of covariate shift (Sugiyama and Kawanabe, 2012), the distributions are different but known (or can be estimated). This variant of XAIC is directly applicable to that setting, yielding an unbiased analogue of AIC.

3.2 FOCUSED MODEL SELECTION

It turns out there is a way to apply (8) even when nothing is known about the process generating X and X' . If our goal is prediction, we can set X' to the single point x' for which we need to predict the corresponding y' . Contrary to standard model selection approaches, we thus use x' already at the stage of model selection, rather than only inside the models. We define the model selection criterion *Focused AIC (FAIC)* as this special case of XAIC, and FAIC_C as its small sample correction.

A focused model selection method implements the intuition that those test points whose input is further away from the training inputs should be predicted with more caution; that is, with less complex models. As discussed in Section 1.1, methods that optimize predictive performance often are not consistent; this hurts in particular for test inputs far away from the training inputs. We expect that extra-sample adaptations of such methods (like XAIC) are also inconsistent, but that using the focused special case helps

to guard against this small chance of large loss.

Choosing a model specifically for the task at hand potentially lets us end up with a model that performs this task much better than a model found by a non-focused model selection method. However, there are situations in which focus is not a desirable property: the mapping from input values to predictions given by a focused model selection method will be harder to interpret than that of a non-focused method, as it is a combination of the models under consideration rather than a single one of them. Thus, if the experimenter’s goal is interpretation/transparency, a focused model selection method is not recommended; these methods are best applied when the goal is prediction.

Evaluating the x' -dependent model selection criterion separately for each x' leads to a regression curve which in general will not be from any one of the candidate models, but only piecewise so. It will usually have discontinuities where it switches between models. If the models contain only continuous functions and such discontinuities are undesirable, Akaike weights (Akaike, 1979; Burnham and Anderson, 2002) may be used to get a continuous analogue of the FAIC regression curve.

4 AIC VS XAIC (k VS κ_x) IN LINEAR MODELS

Intuitively, the quantity κ_x that appears as a penalty term in the XAIC formula (8) expresses a measure of dissimilarity between the test input x and the training inputs X . This measure is determined fully by the models and does not have to be chosen some other way. However, its properties are not readily apparent. Because κ_x can be computed exactly for linear models, we investigate some of its properties in that case.

One useful characterization of κ_x is the following: if we express the design vector x of the test point in a basis that is orthonormal to the empirical measure of the training set X , then $\kappa_x = \|x\|^2$.

For given X , x may exist such that κ_x is either greater or smaller than the number of parameters k . An example of $\kappa_x < k$ occurs for the linear model consisting of all linear functions with known variance (so $k = 2$). Then κ_x will be minimized when x lies at the mean of the input values in the training set, where $\kappa_x = 1$.

We will now consider the case where \mathbf{X} and \mathbf{x} are random and iid. We showed that the XAIC expression (8) is an unbiased estimator of the extra-sample error. AIC uses k in place of κ_x , and the above suggests the possibility that maybe the instances where $\kappa_x > k$ and those where $\kappa_x < k$ cancel each other out, so that AIC would also be approximately unbiased as an estimate of the extra-sample error. However, the following proposition shows

that, except in a trivial case, $\kappa_{\mathbf{x}}$ is on average greater than k . This means that in those settings, AIC underestimates the model’s extra-sample error.

(We should mention here that if \mathbf{X} and \mathbf{x} are random and mutually iid, then as $n \rightarrow \infty$, AIC’s bias goes to 0. The bias we show below concerns all finite n ; additionally, without focus, an extreme \mathbf{x} could result in a very biased AIC value even for large n .)

Proposition 3 *Consider a linear model \mathcal{M} with training inputs \mathbf{X} and test input \mathbf{x} iid such that $\mathbf{X}^\top \mathbf{X}$ is almost surely invertible. Let \mathcal{M}' be the submodel obtained by removing the final entry from every design vector. Then these models are related by $\mathbb{E} \kappa_{\mathbf{x}} \geq \mathbb{E} \kappa_{\mathbf{x}'} + 1$, with strict inequality if \mathbf{x} has at least two entries.*

It follows by induction on k that for random input data, AIC is biased as an estimate of the extra-sample error except in a special case with $k = 1$. Also, the bias becomes worse for larger models. This last fact is distressing, as it shows that when AIC assesses a sequence of nested models, the amount by which it overestimates their generalization ability grows with the model order. Thus the biases in the AIC scores lead to a bias in the selected model order, which was not evident from earlier work.

The XAIC formula (8) contains two terms that depend on the data: minus two times the log-likelihood, and the penalty term $\kappa_{X'}$. The log-likelihood measures distances between output values and is independent of X' , while $\kappa_{X'}$ expresses a property of input values and is largely unaffected by output values; in fact, in linear models its computation does not involve any (estimates based on) output values. Hence the variance of XAIC is no greater than that of AIC when comparing the two on fixed X, X' , so that XAIC’s reduction in bias does not come at the price of an increase in variance. However, focused model selection demands that X' is *not* held fixed, so that FAIC may have a larger variance than AIC. Similarly, if the distribution of \mathbf{X}' is being estimated as part of applying XAIC, the used estimator’s quality will affect the accuracy of the estimated generalization error.

5 EXPERIMENTS

We will now experimentally compare XAIC and FAIC (or more precisely, their small-sample corrected versions XAIC_C and FAIC_C) to several other model selection methods, in univariate and multivariate problems.

5.1 DESCRIPTION OF EXPERIMENTS

In the univariate experiments, linear models $\mathcal{M}_1, \dots, \mathcal{M}_7$ with unknown variance were considered. Model \mathcal{M}_i contained polynomials of degree $i - 1$ (and so had $i + 1$ parameters). The input values x of the training data were drawn

from a Gaussian distribution with mean 0 and variance 1, while the output values were generated as $\mathbf{y}_i = f(x_i) + \mathbf{z}$ with \mathbf{z}_i iid Gaussians with mean 0 and variance 0.1, and f some unknown true function. Given 100 training data points, each of the eight model selection methods under consideration had to select a model. The squared risk $(\hat{y} - f(x))^2$ of the chosen model’s prediction \hat{y} was computed for each of a range of values of the test point’s x , averaged over 100 draws of the training data. This experiment was performed for two different true functions: $f_1(x) = x + 2$ and $f_2(x) = |x|$.

In the multivariate experiments, each input variable was a vector (u_1, \dots, u_6) , and the models corresponded to all possible subsets of these 6 variables. Each model also included an intercept and a variance parameter. The true function was given by $f(u) = 2 + u_1 + 0.1u_2 + 0.03u_3 + 0.001u_4 + 0.003u_5$, and the additive noise was again Gaussian with variance 0.1. A set of $n' = 400$ test inputs was drawn from a standard Gaussian distribution, but the training inputs were generated differently in each experiment: from the same Gaussian distribution as the test inputs; from a uniform distribution on $[-\sqrt{3}, \sqrt{3}]^6$; or from a uniform ‘spike-and-slab’ mixture of two Gaussians with covariance matrices $(1/5)I_6$ and $(9/5)I_6$. Note that all three distributions have the same mean and covariance as the test input distribution, making these mild cases of covariate shift. For the Gaussian training case, we report the results for $n = 60$ and, after extending the same training set, for $n = 100$. Squared risks were averaged over the test set and further over 50 repeats of these experiments.

The experiments used the version of XAIC that is given a distribution of the test inputs, but not the test inputs themselves. In the multivariate experiments, XAIC used the actual (Gaussian) distribution of the test inputs. In the univariate case, two instances of XAIC were evaluated: one for test inputs drawn from the same distribution as the training inputs (standard Gaussian), and another (labelled XAIC_{C2}) for a Gaussian test input distribution with mean 0 and variance 4.

Bayesian model averaging (BMA) differs from the other methods in that it does not select a single model, but formulates its prediction as a weighted average over them; in our case, its prediction corresponds to the posterior mean over all models. Weighted versions exist of other model selection methods as well, such as Akaike weights (Akaike, 1979; Burnham and Anderson, 2002) for AIC and variants. In our experiments we saw that these usually perform similar to but somewhat better than their originals. In our univariate experiments, we decided against reporting these, as they are less standard. However, in the multivariate experiments, the weighted versions were all better than their selection counterparts, so both are reported separately to allow fair comparisons.

In our experiments, BMA used a uniform prior over the models. Within the models, Jeffreys’ noninformative prior (for which the selected μ would correspond to the maximum likelihood $\hat{\mu}$ used by other methods) was used for the variable selection experiments; for the polynomial case, it proved too numerically unstable for the larger models, so there BMA uses a weakly informative Gaussian prior (variance 10^2 on μ_2, \dots, μ_7 with respect to the Hermite polynomial basis, and Jeffreys’ prior on σ^2).

Of the model selection methods included in our experiments, AIC was extensively discussed in Section 2.1; as with XAIC and FAIC, we use here the small sample correction AIC_C (see Section 2.3). BIC (Schwarz, 1978) and BMS were mentioned in Section 1.1 as methods that attempt to find the most probable model given the data rather than aiming to optimize predictive performance; both are based on BMA, which computes the Bayesian posterior probability of each model. Three other methods were evaluated in our experiments; these are discussed below.

Like AIC, the much more recent focused information criterion (FIC) (Claeskens and Hjort, 2003) is designed to make good predictions. Unlike other methods, these predictions are for a *focus parameter* which may be any function of the model’s estimate, not just its prediction at some input value (though we only used the latter in our experiments). Unlike FAIC, it uses this focus not just for estimating a model’s variance, but also its bias; FAIC on the other hand uses a global estimate of a model’s bias based on Assumption 2. A model’s bias for the focus parameter is evaluated by comparing its estimate to that of the most complex model available.

Another more recent method for model selection is the subspace information criterion (SIC) (Sugiyama and Ogawa, 2001), which is applicable to supervised learning problems when our models are subspaces of some Hilbert space of functions, and our objective is to minimize the squared norm. Like FIC, SIC estimates the models’ biases by comparing their estimates to that of a larger model, but it includes a term to correct for this large model’s variance. In our experiments, we used the corrected SIC (cSIC) which truncates the bias estimate at 0.

Generalized cross-validation (GCV) (Golub et al., 1979) can be seen as a computationally efficient approximation of leave-one-out cross-validation for linear models. We included it in our experiments because Leeb (2008) shows that it performs better than other model selection methods when the test input variables are newly sampled.

5.2 RESULTS

Results from the two univariate experiments are shown in Figures 1 and 2 (squared risks) and in Table 1 (selected models). Squared risk results for the multivariate experi-

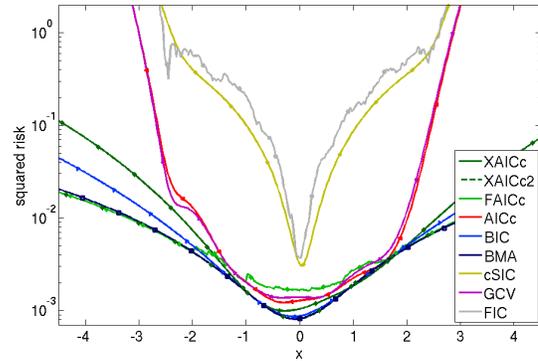

Figure 1: Squared risk of different model selection methods as a function of x when the true function is $f_1(x) = x + 2$.

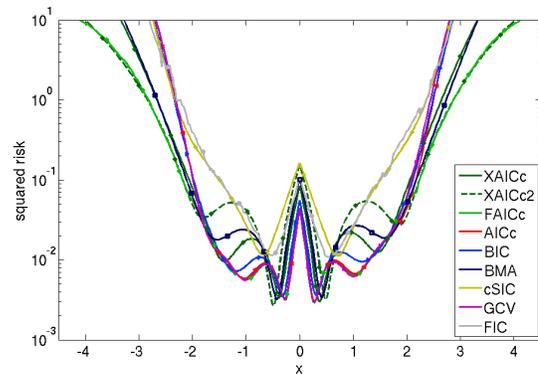

Figure 2: Squared risk of different model selection methods as a function of x when the true function is $f_2(x) = |x|$.

ments are given in Table 2 for the model selection methods, and in Table 3 for the model weighting/averaging variants.

XAIC and FAIC The characteristic behaviours of our methods are clearly visible in the univariate experiments. Both instances of XAIC perform well overall in both experiment. Of the two, $XAIC_C2$ was set up to expect test inputs further away from the center. As a result, it selects models more conservatively, and obtains smaller risk at such off-center test inputs. Its selections were very stable: in both experiments, $XAIC_C2$ selected the same model in each of the 100 runs.

We see that in the center of Figure 2, the simple model chosen by $XAIC_C2$ was outperformed by more complex models. FAIC exploits this by choosing a model adaptively for each test input. This resulted in good risk performance at all test inputs.

In the multivariate experiments, FAIC was the best method for the spike-and-slab training data, where there are pronounced differences in training point density surrounding different test points, so that selecting a different model for

Table 1: Average selected model index per method for f_1 and f_2 , at test inputs $x' = 0$ and 4 (if different).

each pays off. The performance of XAIC was more reliable overall, comparing very favourably to each of its competitors.

AIC Our methods XAIC and FAIC were derived as adaptations of AIC, and share its tendency to go for complex models as soon as there is some indication that their predictions might be worthwhile. This leads to good predictions on average, but also to inconsistency: when a simpler model contains the true distribution, AIC will continue to select more complex models with positive probability, no matter how large n grows. This may sometimes hurt predictive performance, because the accuracy of the estimated parameter will be smaller for more complex models; for details, we refer to Yang (2007); Van Erven et al. (2007, 2012). XAIC makes a better assessment of the generalization error, even when the training and test inputs follow the same distribution, so that it overfits less than AIC and may achieve much better risks. FAIC differs from AIC in another way: its tendency to choose more complex models is strengthened in areas where many data points are available (so that the potential damage of picking an overly complex model is smaller), while it is suppressed when few data points are available (and the potential damage is much greater).

This tendency is also apparent in Table 1. In the first experiment, where a small model contains the true distribution,

Table 3: Multivariate: squared risk for different training sets; model weighting/averaging

	spike-			
	Gaussian ($n = 60$)	uniform ($n = 60$)	and-slab ($n = 60$)	Gaussian ($n = 100$)
XAIC _{Cw}	0.0099	0.0108	0.0114	0.0063
FAIC _{Cw}	0.0100	0.0110	0.0110	0.0066
AIC _{Cw}	0.0101	0.0108	0.0119	0.0063
BICw	0.0096	0.0106	0.0111	0.0062
BMA	0.0100	0.0107	0.0113	0.0061

it causes FAIC to perform worse than AIC near $x = 0$. However, note that the vertical axis is logarithmic, so the difference appears larger than it is: when we average over the training input distribution, we find that FAIC performs better by a factor 20 in terms of squared risk.

In the multivariate experiments, XAIC again performs better than AIC, though the difference eventually disappears as n grows. With the notable exception of the spike-and-slab experiment, FAIC does not perform well here: in two of the experiments, it does worse than AIC. Part of the reason must be our observation at the end of Section 4: FAIC’s estimate of the generalization error, while unbiased, may potentially have a larger variance than (X)AIC’s estimate, and this is not always a good trade-off.

BIC and BMS/BMA BIC and BMS do not try to identify the model that will give the best predictions now, but instead attempt to find the most probable model given the data, which usually amounts to the simplest model containing the true distribution. This leads them to be conservative about selecting complex models. For similar reasons, Bayesian model averaging (BMA) puts only small weight on complex models. We see this in Figure 1, where BIC and BMA have good performance because they most often select the optimal second model (or in the case of BMA, give it the largest weight). However, for f_2 in Figure 2, it may be outperformed by FAIC or XAIC for test inputs away from the center. In the multivariate experiments, XAIC often performs better than BMS/BMA, and rarely much worse; the only instance of the latter is for the spike-and-slab data, where FAIC outperforms both. (See Section 6.1 for further discussion of BMA.)

FIC In all our experiments, FIC obtained large squared risks, and we see in Table 1 that its selection behaviour was the opposite of FAIC: for extreme x , FIC often selects a more complex model than near $x = 0$. This seems to happen because FIC uses the most complex model’s prediction at a given x to estimate each other model’s bias. Because the most complex model will usually have a significant variance, this resulted in FIC being misled in many of the experiments we examined. In particular, in areas with few

training inputs, FIC apparently usually believes the simpler models will perform badly because it attributes to them a large bias, so that the same model as elsewhere (or even a more complex one) is selected. Conversely, FIC was often observed to switch to an overly simple model near some input value where this model’s estimate happened to coincide with that of the most complex model.

SIC SIC obtained large risks in the univariate experiments due to underfitting. Its results in three of the four multivariate experiments were competitive, however.

GCV Based on Leeb (2008), we expected GCV might be one of the strongest competitors to XAIC. This was not clearly reflected in our experiments, where its performance was very similar to that of AIC.

6 DISCUSSION

6.1 RELATION TO THE BAYESIAN PREDICTIVE DISTRIBUTION

The quantity $\kappa_{x'}$ that occurs in FAIC has an interpretation in the Bayesian framework. If we do linear regression with known variance and a noninformative prior on μ , then after observing X , \mathbf{Y} and x' , the predictive distribution of \mathbf{y}' is $\mathbf{y}' \mid \mathbf{Y}, X, x' \sim \mathcal{N}(x'^{\top} \hat{\mu}, \sigma^2(1 + x'^{\top} (X^{\top} X)^{-1} x'))$. We see that $\kappa_{x'}$ and the variance of this predictive distribution obey a linear relation. Thus if BMA is allowed to give a distribution over output values as its prediction, then this distribution (a mixture of Gaussians with different variances) will reflect that some models’ predictions are more reliable than others. However, if the predictive distribution must be summarized by a point prediction, then such information is likely to be lost. For instance, if the point prediction \hat{y}' is to be evaluated with squared loss and \hat{y}' is chosen to minimize the expected loss under the predictive distribution (as in our experiments in Section 5), then \hat{y}' is a weighted average of posterior means for \mathbf{y}' given x' (one mean for each model, weighted by its posterior probability). The predictive variances are not factored into \hat{y}' , so that in this scenario, BMA does not use the information captured by $\kappa_{X'}$ that XAIC and FAIC rely on.

This is not to say that BMA *should* use this information: the consideration of finding the most probable model (BMS, BIC) or the full distribution over models (BMA) is not affected by the purpose for which the model will be used, so it should not depend on the input values in the test data through $\kappa_{X'}$. This suggests that there is no XBIC analogue to XAIC. For Bayesian methods such as DIC (Spiegelhalter et al., 2002) and BPIC (Ando, 2007) that aim for good predictions, on the other hand, extra-sample and focused equivalents may exist.

6.2 RELATION TO COVARIATE SHIFT

We observed at the end of Section 4 that of the two data-dependent terms in XAIC, the log-likelihood is independent of X' , while $\kappa_{X'}$ is (largely) unaffected by output values. An important practical consequence of this split between input and output values is that XAIC and FAIC look for models that give a good overall fit, not just a good fit at the test inputs. X' is then used to determine how well we can expect these models to generalize to the test set. So if we have two models and believe each to be able to give a good fit in a different region of the input space, then FAIC is not the proper tool for the task of finding these regions: FAIC considers global fit rather than local fit when evaluating a model, and within the model selects the maximum likelihood estimator, not an estimator specifically chosen for a local fit at input point x .

In this respect, our methods differ from those commonly used in the covariate shift literature (see Sugiyama and Kawanabe (2012); Pan and Yang (2010); some negative results are in Ben-David et al. (2010)), where typically a model (and an estimator within that model) is sought that will perform well on the test set only, using for example importance weighting. This is appropriate if we believe that no available model can give satisfactory results on both training and test inputs simultaneously. In situations where such models are believed to exist, our methods try to find them using all information in the training set.

7 CONCLUSIONS AND FUTURE WORK

We have shown a bias in AIC when it is applied to supervised learning problems, and proposed XAIC and FAIC as versions of AIC which correct this bias. We have experimentally shown that these methods give better predictive performance than other methods in many situations.

We see several directions for future work. First, the practical usefulness of our methods needs to be confirmed by further experiments. Other future work includes considering other model selection methods: determining whether they are affected by the same bias that we found for AIC, whether such a bias can be removed (possibly leading to extra-sample and focused versions of those methods), and how these methods perform in simulation experiments and on real data. In particular, BPIC (Ando, 2007) is a promising candidate, as its derivation starts with a Bayesian equivalent of (1). An XBPIC method would also be better able to deal with more complex models than a variant of AIC would have difficulty with, such as hierarchical Bayesian models, greatly increasing its practical applicability.

Abstract

Consider the classical problem of predicting the next bit in a sequence of bits. A standard performance measure is *regret* (loss in payoff) with respect to a set of experts. For example if we measure performance with respect to two constant experts one that always predicts 0's and another that always predicts 1's it is well known that one can get regret $O(\sqrt{T})$ with respect to the best expert by using, say, the weighted majority algorithm [LW89]. But this algorithm does not provide performance guarantee in any interval. There are other algorithms (see [BM07, FSSW97, Vov99]) that ensure regret $O(\sqrt{x \log T})$ in any interval of length x . In this paper we show a randomized algorithm that in an amortized sense gets a regret of $O(\sqrt{x})$ for any interval when the sequence is partitioned into intervals arbitrarily. We empirically estimated the constant in the $O()$ for T upto 2000 and found it to be small – around 2.1. We also experimentally evaluate the efficacy of this algorithm in predicting high frequency stock data.

1 INTRODUCTION

Consider the following classical game of predicting a binary ± 1 sequence. An algorithm A sees a binary sequence $\{b_t\}_{t \geq 1}$, one bit at a time, and attempts to predict the next bit b_t from the past history b_1, \dots, b_{t-1} . The *payoff* A_T of the algorithm in T steps is the number of correct guesses minus the number of the wrong guesses. In other words, let $\tilde{b}_t \in [-1, 1]$ be the prediction for the t^{th} bit based on the previous bits then:

$$A_T := \sum_{1 \leq t \leq T} b_t \tilde{b}_t.$$

The payoff per time step $b_t \tilde{b}_t$ is essentially equivalent to the well known absolute loss function $|b_t - \tilde{b}_t|$ (see for example [CBL06], chapter 8).¹

One can view this game as an idealized “stock prediction” problem as follows. In each unit time, the stock price goes up or down by precisely \$1, and the algorithm bets on this event. If the bet is right, the player wins one dollar, and otherwise loses one dollar. Not surprisingly, in general, it is impossible to guarantee a positive payoff for all possible scenarios (sequences). However, one could hope to give some guarantees on the payoff of the algorithm based on certain properties of the sequence.

For example one can compare the payoff to the better of two choices (experts), which correspond to two constant algorithms: first one, where $\tilde{b}_t = +1$ and the second one where $\tilde{b}_t = -1$ for all t . Note that the best of these experts gets payoff $|\sum_{1 \leq t \leq T} b_t|$, which corresponds to the “optimal in hindsight” expert among the two choices. The *regret* of an algorithm is defined as how much worse the algorithm performs as opposed to the best of the two experts (in hindsight, after seeing the sequence). This has been studied in a number of papers, including

¹since when $|b_t| = 1$, $|b_t - \tilde{b}_t| = |b_t| |b_t - \tilde{b}_t| = |1 - b_t \tilde{b}_t| = 1 - b_t \tilde{b}_t$. Thus the absolute loss function is the negative of our payoff in one step plus a shift of 1. Also b_t values from $\{-1, 1\}$ or $\{0, 1\}$ are equivalent by a simple scaling and shifting transform.

This work was done while this author was at Microsoft Research.

[Cov65, LW89, Cov91, ACBFS02, AB09]. A classical result says that one can obtain a regret of $\Theta(\sqrt{T})$ for a sequence of length T , via, say, the weighted majority algorithm [LW89]. Formally, for a sequence $X = b_1, \dots, b_T$, let $h(X) = \sum_{1 \leq t \leq T} b_t$ denote the “height” of the sequence when plotted cumulatively as a chart. Then we have the following theorem:

Theorem 1.1 [Cov65, CBFH⁺97] *There is an algorithm that achieves payoff $\geq |h(X)| - \alpha\sqrt{T}$. It is also known that the optimal value of $\alpha \rightarrow \sqrt{2/\pi}$ as $T \rightarrow \infty$.*

However, an algorithm that only focuses on the overall regret does not exploit short term trends in the sequence and only relies on a ‘global’ long term bias in the full string. Consider for example a sequence that may not have a high overall bias but has many intervals in which there may be a high level of bias. Our result is that for any partitioning of the sequence into intervals, one can essentially get a regret proportional to \sqrt{x} for each interval of length x in an amortized sense (Theorem 1.3). Although our results are stated for bits they work even when b_t is a real number in $[-1, 1]$. We note that even though similar bounds have been obtained before ([BM07, FSSW97, Vov99] and, more recently, [HS09, KP11]), the penalty on an interval of length x is $O(\sqrt{x \log T})$ in these previous results. Note that in adversarial settings one is interested in a prediction algorithm that can get a positive payoff even if the sequence departs slightly from random; or we may ask what is the smallest amount non-randomness that can be “noticed” by the prediction algorithm. So while our result may seem like just shaving a $\log T$ factor, the reason \sqrt{x} is much better than $\sqrt{x \log T}$ is that in certain adversarial settings (like financial markets), the uptrend or downtrend in total per interval may not be too far from that of a random sequence. Note that a random ± 1 sequence of length x has a height of magnitude $\Theta(\sqrt{x})$ in expectation. So we are saying that even if the height of a sequence of length x is some constant multiple of \sqrt{x} , we get a positive payoff.

The bit prediction problem we consider is closely related to the two experts problem (or multi-armed bandits problem with full information). In each round each expert has a payoff in the range $[0, 1]$ that is unknown to the algorithm. For two experts, let b_{1t}, b_{2t} denote the payoffs of the two experts at time t . The algorithm pulls each arm (expert) with probability $\hat{b}_{1t}, \hat{b}_{2t} \in [0, 1]$ respectively where $\hat{b}_{1t} + \hat{b}_{2t} = 1$. The (expected) payoff of the algorithm in this setting is $A'_T := \sum_{t=1}^T b_{1t}\hat{b}_{1t} + b_{2t}\hat{b}_{2t}$.

We will be concerned with the following payoff function in this paper:

Definition 1.2 (Interval payoff function: P_α)

Let X_1, \dots, X_k denote a partition of the sequence X into a disjoint union of k intervals, that is, X is the concatenation of these k subsequences. We will use $h(X_i)$ to denote the

sum of the bits in the interval X_i and $|X_i|$ to denote the length of X_i .

The interval payoff function, $P_\alpha(X)$ is defined as the maximum value of the expression

$$\sum_{i=1}^k \left(|h(X_i)| - \alpha \sqrt{|X_i|} \right)$$

over all $1 \leq k \leq |X|$ and all partitions X_1, \dots, X_k of X .

We say that a payoff function $f : \{-1, 1\}^T \rightarrow \mathbb{R}$ is feasible if there is a bit prediction algorithm which on sequence X achieves payoff at least $f(X)$.

Theorem 1.3 (Main Theorem) *There is an absolute constant $0 < \alpha < 10$ independent of T such that the interval payoff function P_α is feasible.*

For the two experts problem our result translates to the following guarantee:

$$A'_T \geq \sum_{i=1}^k \left(\max_{j \in \{1, 2\}} \left(\sum_{t \in X_i} b_{jt} \right) - \frac{\alpha}{2} \sqrt{|X_i|} \right).$$

Here $\sum_{t \in X_i} b_{jt}$ is the payoff of the j^{th} expert in the interval X_i .

This result can be viewed as incurring a penalty of $\alpha\sqrt{|X_i|}$ for each interval X_i . We theoretically show that the optimal value of α is at most 10 (Section 2). We empirically estimated the optimal α for T up to 2000 and found it to be small – around 2.1 (Section 4.1).

We stress here that the algorithm doesn’t need to know the partition or the length of the partition in advance. We also note that our guarantee does not hold for each interval individually but when we look at the net payoff in an amortized sense, we may account for a regret of at most $\alpha\sqrt{|X|}$ for an interval of length X . In fact, the guarantee is impossible to achieve in a non-amortized sense. We show that if we measure regret based on the performance of an algorithm in a given interval then one will have to trade-off regrets at different time scales. The following observation is proven in the full version [PP13].

Observation 1.4 *There is no prediction algorithm that can guarantee a regret of $O(\sqrt{|Y|})$ on all intervals Y for all input sequences.*

Regarding the computation of P_α , we show:

Theorem 1.5 *The value of $P_\alpha(S)$ for a particular sequence S of length T can be computed using dynamic programming in time $O(T^3)$.*

For a given T , let $\alpha_0(T)$ denote the minimum α such that P_α is feasible for all sequences of length T . It is possible to

determine α_0 using the following well known observation by Cover.

Observation 1.6 (Cover [Cov65]) *A payoff function $f : \{-1, 1\}^T \rightarrow \mathbb{R}$ is feasible if and only if $E_S[f(S)] \leq 0$ where S is a uniformly random sequence in $\{-1, 1\}^T$.*

This is achieved by a prediction algorithm that predicts $\tilde{b}_t = \frac{E_U[f(s.1.U)] - E_U[f(s.(-1).U)]}{2}$ where s is the sequence of bits seen so far, U is a suffix sequence chosen uniformly at random and $s.b.U$ denotes the concatenated sequence starting with s followed by bit b followed by the sequence U . Note that $\tilde{b}_t \in [-1, 1]$ as long as for all s , $|E_U[f(s.1.U)] - E_U[f(s.(-1).U)]| \leq 2$

Algorithm and Running time: Theorem 1.5 and Observation 1.6 suggest a simple algorithm for achieving payoff function P_α . Take the sequence s seen so far, append a $+1$ and then a random sequence to make it into a complete sequence of length T . Compute $P_\alpha(S)$ for the resulting sequence S . Do this again replacing the $+1$ by a -1 . Predict \tilde{b}_t to be the half of the difference in the two cases.

We note that a deterministic algorithm achieving the guarantee of Theorem 1.3 may take exponential time since it would need to find $P_\alpha(S)$ for every random completion of the bits seen so far. Alternatively, there is a simple randomized algorithm which achieves the same payoff in expectation by taking a different random completion for every prefix. A naive implementation of this randomized algorithm will take T^3 time for each bit being predicted. We show a simple variant that reduces this to $O(\log T)$ time with pre-computation.

Theorem 1.7 *There is a randomized algorithm that achieves the payoff guarantee P_α of Theorem 1.3 in expectation and spends $O(T^2)$ time per step. There is also a randomized algorithm that achieves payoff $P_{\alpha'}$ with $\alpha' = c\alpha$ and spends only $O(\log T)$ time per step. Here $c := \frac{\sqrt{2}}{\sqrt{2}-1}$.*

These algorithm use pre-computed information that takes time $O(T^2)$ and $O(T \log T)$ time to compute for the first and the second algorithm respectively.

Generalization to real numbers: In the full version [PP13], we show that a variant of the guarantee holds in a semi-adversarial model where a string of real numbers may be chosen instead of bits. The model combines worst case and average case settings where the signs of the real numbers may be chosen adversarially (that is, in the worst case) but the magnitudes of the real numbers come from a pre-specified distribution independently and randomly.

Experimental results: We implement our algorithm, the weighted majority algorithm, an algorithm based on Autoregressive Integrated Moving Average (ARIMA) and an algorithm of [KP11], and compare their performance when predicting financial time series data. Specifically, we con-

sider the high frequency price data of 5 stocks, and we apply these algorithms to predict the per minute price changes in an online fashion taking the values in each day as a separate sequence. That is we predict the next minute returns of mid-prices for each stock based on its previous 1 minute returns in the day. We perform this experiment over 189 trading days for each stock and find that on an average our algorithm performs better than other prediction algorithms based on regret minimization but is outperformed by the ARIMA algorithm. On the other hand, as we discussed above, our algorithm has certain provable guarantees for every sequence which the ARIMA algorithm lacks. The experimental setup and results are described in more detail in Section 4.

1.1 Related work

There is large body on work on regret style analysis for prediction. Numerous works including [Cov65, CBFH⁺97] have examined the optimal amount of regret achievable with respect to two or more experts. A good reference for the results in this area is [CBL06]. It is well known that in the case of static experts, the optimal regret achievable is exactly equal to the Rademacher complexity of the predictions of the experts (chapter 8 in [CBL06]). Recent works such as [ALW06, AWY08, MS08] have extended this analysis to other settings. Measures other than the standard regret measure have been studied in [RST10]. The question of what can be achieved if one would like to have a significantly better guarantee with respect to a fixed expert or a distribution of experts was asked before in [EDKMW08, KP11]. Tradeoffs between regret and minimum payoff were also examined in [Vov98], where the author studied the set of values of a, b for which an algorithm can have payoff $aOPT + b \log N$, where OPT is the payoff of the best arm and a, b are constants.

Regret minimization algorithms with performance guarantees within each interval have been studied in [BM07, FSSW97, Vov99] and more recently in [HS09, KP11]. As we mentioned, some of these algorithms achieve a regret of $O(\sqrt{x \log T})$ for every interval of size x in a sequence of length T . A related work which also seeks to exploit short term trends in the sequence is [HW98], where the regret bound proportional to \sqrt{Tk} in the best case where k is the number of intervals (see [CBL06], Corollary 5.1). The main difference between the work of [HW98] and our results is that their algorithm requires fixing the number of intervals, k , in advance whereas our algorithm works simultaneously for all k . Also note that their regret guarantee is always higher than the payoff function P_α for a sequence of length T achieving equality only in the special case when all intervals are of equal length T/k .

Numerous papers (for example [Blu97, HSSW98, AHKS06]) have implemented algorithms inspired from

regret style analysis and applied it on financial and other types of data.

1.2 Overview of the proof

In this section we give a high level idea of our proof, the formal proof appears in Section 2.

To prove the main theorem we want to compute the minimum α such that $E_S[P_\alpha(S)] \leq 0$ (See Observation 1.6). We first introduce a variant of the payoff function $P_\alpha(S)$ as follows. Instead of computing the maximum value of $\sum_i |h(X_i)| - \alpha\sqrt{|X_i|}$ over all possible partitions, we will only allow partitions where the intervals are of the form $(2^i j, 2^i(j+1)]$; that is, intervals that are obtained by dividing the string into segments of length that are some power of 2. We will refer to such intervals as ‘aligned’ intervals (Definition 2.3). Further we will only look at T values that is some power of 2. Note that any interval can be broken into at most $\log T$ aligned intervals. Let $P_\alpha^A(S)$ denote the maximum value of $\sum_i |h(X_i)| - \alpha\sqrt{|X_i|}$ with partitions into aligned intervals. We first show that

Lemma 1.8 *If $E[P_\alpha^A(S)] \leq 0$ then $E[P_{c\alpha}(S)] \leq 0$ where $c := \frac{\sqrt{2}}{\sqrt{2}-1}$.*

Next we show

Theorem 1.9 *There is an absolute constant $\alpha \leq 2.8$ such that $E[P_\alpha^A(S)] \leq 0$.*

We prove Theorem 1.9 recursively for T that are increasing powers of 2. We inductively show that the distribution of $P_\alpha^A(S)$ is stochastically upper bounded by a shifted exponential distribution (Definition 2.4) with certain parameters (Equation 2.1), where S is a uniformly random sequence of length T . Since we are dealing with splits into aligned intervals, we can assume that either the best split for S is the whole interval, or the mid-point of S is one of the splitting points. For the first case, we may upper bound the payoff function using Hoeffding’s bound (Theorem 2.2), while for the second case we may inductively assume that the distribution of payoffs for the subsequences is stochastically bounded by a shifted exponential distribution. We then separately bound each of these distributions by the shifted exponential distribution.

2 FEASIBILITY OF PAYOFF FUNCTION

P_α

2.1 Preliminaries

Definition 2.1 (Binomial distribution B_n) *Let $x_1, x_2, \dots, x_n \in \{-1, 1\}$ be uniformly and independently distributed. Then the sum*

$$Y := \sum_{i=1}^n x_i$$

is said to be binomially distributed. We denote the distribution as B_n .

Theorem 2.2 (Hoeffding’s bound) [Hoe63]

$$\Pr[|B_n| \geq y \cdot \sqrt{n}] \leq 2 \cdot \exp\left(-\frac{y^2}{2}\right)$$

Definition 2.3 (Aligned interval)

We assume here that T is a power of 2. An aligned interval is one which is obtained by breaking $[1, T]$ into 2^i equal parts for $i \in [0, \log T]$ and picking one of the parts. So for instance the first part is always $[1, T/2^i]$; each aligned interval can be written as $[jT/2^i + 1, (j+1)T/2^i]$ for non negative integers i and j .

We denote the interval payoff function corresponding to Definition 1.2 which allows only aligned splits as P_α^A .

Definition 2.4 (Shifted Exponential distribution) *The probability density function $f_{\mu, \sigma, n}$ of shifted exponential distribution with mean $\sigma\sqrt{n}$ and shift $\mu\sqrt{n}$ is defined as follows:*

$$\begin{aligned} f_{\mu, \sigma, n}(y) &:= \frac{1}{\sigma\sqrt{n}} \exp\left(-\frac{y - \mu\sqrt{n}}{\sigma\sqrt{n}}\right) & \forall y \geq \mu\sqrt{n} \\ f_{\mu, \sigma, n}(y) &:= 0 & \forall y \leq \mu\sqrt{n} \end{aligned}$$

We denote a random variable distributed according to $f_{\mu, \sigma, n}$ as $F_{\mu, \sigma, n}$. That is, $\Pr[F_{\mu, \sigma, n} \geq y] = \int_y^\infty f_n(s) ds = \exp\left(-\frac{y - \mu\sqrt{n}}{\sigma\sqrt{n}}\right)$ when $y \geq \mu\sqrt{n}$ and 1 otherwise.

2.2 Proof of feasibility

The following lemma is a restatement of lemma 1.8 and is proven using a standard doubling trick

Lemma 2.5 *If P_α^A is feasible then $P_{c\alpha}$ is also feasible, where $c := \frac{\sqrt{2}}{\sqrt{2}-1}$.*

Proof:

Let X_1, X_2, \dots, X_k denote a partition of a given sequence S . We split each interval X_i into a disjoint union of aligned intervals Y_{i1}, \dots, Y_{il} . We will then show that the identity

$$\sum_{j=1}^l \sqrt{|Y_{ij}|} \leq c \cdot \sqrt{|X_i|}$$

always holds where $|I|$ denotes the length of the interval I . This suffices to prove the theorem since $h(X_i) \leq \sum_{j=1}^l h(Y_{ij})$.

For notational simplicity, let $I = X_i$ and $x = |I|$. If I is an aligned interval we are done, otherwise we write it as the minimal union of aligned intervals (take out the largest aligned interval in I and repeat). There are three possibilities:-

1. $I = I_1 \cup I_2$ is a union of two intervals of size $x/2$ each (eg. the interval $[T/4 + 1, 3T/4]$)
2. $I = I_1 \cup I_2 \cup \dots \cup I_l$, where each I_j is of a different size. Note that all interval sizes on the right are powers of 2 and strictly less than x
3. $I = J \cup J'$ where each J can be written as a union of intervals as in 1 or 2 above

In the first case,

$$\sqrt{|I_1|} + \sqrt{|I_2|} \leq 2 \cdot \sqrt{x/2} = \sqrt{2} \cdot \sqrt{x}$$

In the second case,

$$\sum_{j=1}^l \sqrt{|I_j|} \leq \sqrt{x} \cdot \sum_{j=1}^{\infty} \sqrt{1/2^j} = \frac{1}{\sqrt{2}-1} \cdot \sqrt{x}$$

In the third case,

$$\begin{aligned} \sqrt{|J|} + \sqrt{|J'|} &\leq \frac{1}{\sqrt{2}-1} \cdot \sqrt{|J|} + \\ \frac{1}{\sqrt{2}-1} \cdot \sqrt{|J'|} &\leq \frac{\sqrt{2}}{\sqrt{2}-1} \cdot \sqrt{x} \end{aligned}$$

■

We are now ready to prove Theorem 1.9.

Proof: [Proof of Theorem 1.9] We need to show that for all $T \geq 1$, $\mathbb{E}_{x \in \{-1,1\}^T} [P_\alpha^A(x)] \leq 0$. After that, the theorem follows from Observation 1.6 (it is easy to check that the condition required for required for $\tilde{b}_t \in [-1,1]$ given in Observation is satisfied by P_α^A).

We will prove the theorem by induction. We will show that when n is a power of 2,

$$\forall y \in \mathbb{R} \quad \Pr_{x \in \{-1,1\}^n} [P_\alpha^A(x) \geq y] \leq \Pr[F_{\mu,\sigma,n} \geq y] \quad (2.1)$$

for some $\mu := \mu(\alpha)$ and $\sigma := \sigma(\alpha)$. Here $F_{\mu,\sigma,n}$ is as in Definition 2.4.

Note that this would imply $\mathbb{E}_{x \in \{-1,1\}^n} [P_\alpha^A(x)] \leq \mathbb{E}[F_{\mu,\sigma,n}] = (\mu + \sigma)\sqrt{n}$. We will show that for a suitable choice of α , the term $\mu + \sigma \leq 0$, and this suffices to prove the theorem.

It remains to prove Equation 2.1. For the base case, $n = 1$, we see that the equation is satisfied for $\mu \geq 1 - \alpha$, $\sigma > 0$. We will now show that it is satisfied for $2n$ whenever it is satisfied for n (for appropriate μ and σ).

Now, for a sequence $x := (x_1, x_2) \in \{-1,1\}^n \times \{-1,1\}^n$, $P_\alpha^A(x) = \max(P_\alpha^A(x_1) + P_\alpha^A(x_2), |h(x)| - \alpha \cdot \sqrt{2n})$. So for every x such that $P_\alpha^A(x) \geq y$ we must have either $P_\alpha^A(x_1) + P_\alpha^A(x_2) \geq y$ or that $h(x) - \alpha \cdot \sqrt{2n} \geq y$. Thus,

$$\Pr_{x \in \{-1,1\}^{2n}} [P_\alpha^A(x) \geq y] \quad (2.2)$$

$$\leq \Pr_{x_1, x_2 \in \{-1,1\}^n} [P_\alpha^A(x_1) + P_\alpha^A(x_2) \geq y] \quad (2.3)$$

$$+ \Pr_{x \in \{-1,1\}^{2n}} [h(x) - \alpha \cdot \sqrt{2n} \geq y] \quad (2.4)$$

$$\leq \Pr[F_{\mu,\sigma,n} + F'_{\mu,\sigma,n} \geq y] \quad (2.5)$$

$$+ \Pr_{x \in \{-1,1\}^{2n}} [h(x) - \alpha \cdot \sqrt{2n} \geq y] \quad (2.6)$$

Here F and F' are independent random variables distributed as in Definition 2.4. We will show that the first and second term are each bounded by $\frac{1}{2} \Pr[F_{2n} \geq y]$ which is sufficient to prove Equation 2.1. Note that we only need to consider $y \geq \mu\sqrt{2n}$ since for smaller values of y we have

$$\Pr_{x \in \{-1,1\}^{2n}} [P_\alpha^A(x) \geq y] \leq \Pr[F_{2n} \geq y] = 1$$

Henceforth, we will use shorthands $f_n := f_{\mu,\sigma,n}$ and $F_n := F_{\mu,\sigma,n}$.

The first term can be written as:-

$$\begin{aligned} \Pr[F_n + F'_n \geq y] &= \int_y^\infty \int_{-\infty}^\infty f_n(s) \cdot f_n(w-s) \, ds \, dw \\ &= \int_y^\infty \int_{\mu\sqrt{n}}^{w-\mu\sqrt{n}} f_n(s) \cdot f_n(w-s) \, ds \, dw \end{aligned}$$

where the second equation follows from the fact that $f_n(s) = 0$ for $s < \mu\sqrt{n}$ and $f_n(w-s) = 0$ for

$s > w - \mu\sqrt{n}$. Thus, we need to show for all $y \geq \mu\sqrt{2n}$:

$$\begin{aligned}
& \int_y^\infty \int_{\mu\sqrt{n}}^{w-\mu\sqrt{n}} f_n(s) \cdot f_n(w-s) \, ds \, dw \leq \frac{1}{2} \Pr[F_{2n} \geq y] \\
\iff & \frac{1}{\sigma^2 n} \int_y^\infty \int_{\mu\sqrt{n}}^{w-\mu\sqrt{n}} \exp\left(-\frac{w+2\mu\sqrt{n}}{\sigma\sqrt{n}}\right) \, ds \, dw \\
& \leq \frac{1}{2} \exp\left(-\frac{y-\mu\sqrt{2n}}{\sigma\sqrt{2n}}\right) \\
\iff & \frac{1}{\sigma^2 n} \int_y^\infty \int_{\mu\sqrt{n}}^{w-\mu\sqrt{n}} \exp\left(-\frac{w-2\mu\sqrt{n}}{\sigma\sqrt{n}}\right) \, ds \, dw \\
& \leq \frac{1}{2} \exp\left(-\frac{y-\mu\sqrt{2n}}{\sigma\sqrt{2n}}\right) \\
\iff & \frac{1}{\sigma^2 n} \int_y^\infty (w-2\mu\sqrt{n}) \exp\left(-\frac{w-2\mu\sqrt{n}}{\sigma\sqrt{n}}\right) \, dw \\
& \leq \frac{1}{2} \exp\left(-\frac{y-\mu\sqrt{2n}}{\sigma\sqrt{2n}}\right)
\end{aligned}$$

In the third line we implicitly assume that $y \geq 2\mu\sqrt{n}$, since otherwise the left hand side is less than 0 and the equation is satisfied.

Note that the integral is of the form $\int u \cdot e^{-cu}$ which integrates to $-\left(\frac{u+1/c}{c}\right) \cdot e^{-cu}$. Thus, integrating and substituting $z := y - 2\mu\sqrt{n}$ we need to show for all $z \geq 0$,

$$\begin{aligned}
& \frac{1}{\sigma\sqrt{n}} \cdot (z + \sigma\sqrt{n}) \cdot \exp\left(-\frac{z}{\sigma\sqrt{n}}\right) \\
& \leq \frac{1}{2} \exp\left(-\frac{z + (\sqrt{2}-1)\mu\sqrt{2n}}{\sigma\sqrt{2n}}\right) \\
\iff & \frac{2z}{\sigma\sqrt{n}} + 2 \\
& \leq \exp\left(\frac{z}{\sigma\sqrt{n}} - \frac{z + (\sqrt{2}-1)\mu\sqrt{2n}}{\sigma\sqrt{2n}}\right) \\
\iff & \frac{2z}{\sigma\sqrt{n}} + 2 \\
& \leq \exp\left(\frac{(\sqrt{2}-1)z}{\sigma\sqrt{2n}}\right) \cdot \exp\left((\sqrt{2}-1)\frac{-\mu}{\sigma}\right)
\end{aligned}$$

Substituting $w := \frac{z}{\sigma\sqrt{n}}$, we need for all $w \geq 0$,

$$\begin{aligned}
& 2w + 2 \\
& \leq \exp\left(\frac{(\sqrt{2}-1)w}{\sqrt{2}}\right) \cdot \exp\left((\sqrt{2}-1)\frac{-\mu}{\sigma}\right) \\
\iff & \frac{2w + 2}{\exp\left(\frac{(\sqrt{2}-1)w}{\sqrt{2}}\right)} \leq \exp\left((\sqrt{2}-1)\frac{-\mu}{\sigma}\right)
\end{aligned}$$

The left hand side is maximized at $w = 1/\sqrt{2}$ and the value of left hand side at that point is around 2.78. Thus, if $(-\mu/\sigma) \geq 2.47$ then the equation is always satisfied.

We now turn to bounding the second term 2.6. We need to show for all $y \geq \mu\sqrt{2n}$,

$$\begin{aligned}
& \Pr_{x \in \{-1,1\}^{2n}}[|x| - \alpha \cdot \sqrt{2n} \geq y] \leq \frac{1}{2} \Pr[F_{2n} \geq y] \\
\iff & \Pr[|B_{2n}| \geq y + \alpha \cdot \sqrt{2n}] \leq \frac{1}{2} \Pr[F_{2n} \geq y] \\
\iff & \Pr[|B_{2n}| \geq (z + \alpha) \cdot \sqrt{2n}] \leq \frac{1}{2} \Pr[F_{2n} \geq z \cdot \sqrt{2n}] \\
\iff & 2 \cdot \exp\left(-\frac{(z + \alpha)^2}{2}\right) \leq \frac{1}{2} \Pr[F_{2n} \geq z \cdot \sqrt{2n}]
\end{aligned}$$

where the last line follows from Theorem 2.2, and in the second last line we substitute $z := y/\sqrt{2n}$.

Thus, we need to show for all $z \geq \mu$,

$$4 \cdot \exp\left(-\frac{(z + \alpha)^2}{2}\right) \leq \exp\left(-\frac{z\sqrt{2n} - \mu\sqrt{2n}}{\sigma\sqrt{2n}}\right)$$

Substituting $w := z - \mu$, we need to show for all $w \geq 0$,

$$\begin{aligned}
& \exp\left(-\frac{(w + \mu + \alpha)^2}{2} + \frac{w}{\sigma}\right) \leq 0.25 \\
\iff & -\frac{(w + \mu + \alpha)^2}{2} + \frac{w}{\sigma} \leq -1.4
\end{aligned}$$

The left hand side is maximized at $w + \mu + \alpha = 1/\sigma$ and for that value of w the inequality is given by

$$\frac{-1}{2\sigma^2} + \frac{1/\sigma - \mu - \alpha}{\sigma} \leq -1.4 \iff \mu + \alpha \geq 1.4\sigma + \frac{0.5}{\sigma}$$

Also, recall that to bound the first term we needed $-\frac{\mu}{\alpha} \geq 2.47$. Let's set $\mu := -2.47\sigma$. Then we need

$$\alpha \geq (1.4 + 2.47)\sigma + \frac{0.5}{\sigma} = 3.87\sigma + \frac{0.5}{\sigma}$$

The right hand side is minimized at $\sigma = \frac{1}{\sqrt{2 \cdot 3.87}} \approx 0.36$, and substituting we get that $\alpha = 2.8$ is feasible. Recall that we also needed $\mu + \alpha \geq 1$ from the base case which is already satisfied for this choice of parameters. ■

3 ALGORITHM AND RUNNING TIME

We will now prove theorem 1.5.

Proof: [Proof of Theorem 1.5] We give a simple $O(T^2)$ space and $O(T^3)$ time algorithm.

For every subinterval (i, j) of the sequence, $i, j \in [T]$ the DP table stores $P_\alpha(S_{ij})$ where S_{ij} is the subsequence of S containing bits from position i to position j , inclusive. For $i = j$, this value is always $1 - \alpha$. For $j > i$, to compute the value of $P_\alpha(S_{ij})$, we need to take the maximum over two quantities. The first quantity is $|h(S_{ij})| - \alpha \cdot \sqrt{j - i + 1}$ which corresponds to splitting the subsequence into a single interval. This can be readily computed in constant time if we pre-compute the height of every subsequence, which can be done in $O(T^2)$ space and time. The second quantity is the maximum over all $k \in \{i, i + 1, \dots, j\}$ of $P_\alpha(S_{ik}) + P_\alpha(S_{kj})$. This corresponds to splitting the subsequence at k and then recursively computing the best payoff in each of the two intervals created. This quantity can be computed in time $j - i + 1$ since for each k we just need to read off the appropriate values ($P_\alpha(S_{ik})$ and $P_\alpha(S_{kj})$) from the DP table. ■

Next we prove Theorem 1.7

Proof: [Proof of Theorem 1.7]

Let $X \in \{-1, 1\}^T$ be the input sequence we are required to predict. Using Observation 1.6, it is easy to see that the following algorithm achieves payoff $P_\alpha(X)$ in expectation. For every $t \in \{0, 1, \dots, T - 1\}$:

1. Let $s \in \{-1, 1\}^t$ be the sequence of bits seen so far.
2. Let U_t be a sequence drawn uniformly at random from $\{-1, 1\}^{T-t-1}$ (independently for each t). Let $s_1 := s \cdot 1 \cdot U$ and $s_{-1} := s \cdot (-1) \cdot U$.
3. Make the prediction $\tilde{b} := (P_\alpha(s_1) - P_\alpha(s_{-1}))/2$ for the next bit.

The key idea is that we will draw a random sequence of length T and use its suffix of length $\{-1, 1\}^{T-t-1}$ as U_t . In advance we pre-compute enough information to make the

prediction as fast as possible. For each $t \in \{0, 1, \dots, T - 1\}$ we pre-compute the following information for each U_t :

1. $h(U_t^1)$ for every prefix U_t^1 of U_t
2. $P_\alpha(U_t^2)$ for every suffix U_t^2 of U_t

The pre-computation takes $O(T^2)$ time as P_α is computed only for each suffix.

Let's describe how to use this pre-computed information to compute $P_\alpha(s_1)$ at time t (the computation of $P_\alpha(s_{-1})$ is similar). Let $1 \leq i \leq t$ and $t + 2 \leq j \leq T$. Then it is easy to check that

$$P_\alpha = \max_{i,j} (P_\alpha(s_{1i}) + P_\alpha(U_{jT}) + |h(s_{(i+1)t})| + |h(U_{(t+1)(j-1)})| - \alpha \cdot \sqrt{j - i - 1})$$

Here for a sequence S , S_{ij} is the subsequence of S containing bits from position i to position j , inclusive. Note that we think of U_t as being indexed from $t + 1$ to T where the $(t + 1)^{th}$ bit is 1 (since we are dealing with s_1). The second and fourth term are part of our pre-computation. The first and third terms can be computed on the fly and stored in the table as we increase t from 1 to T . Thus, for each i and j we can compute this expression in constant time and hence we can produce a prediction in $O(T^2)$ time per step.

The second part of the theorem is proved in a similar manner by using only aligned intervals for splitting the sequence (Definition 2.3) and observing that the number of aligned intervals spanning a given position is at most $O(\log T)$. The algorithm achieves payoff at least $P_{\alpha'}$ because of Lemma 1.8. ■

4 EXPERIMENTAL RESULTS

In this section we describe our experimental setup and findings.

The first part of the experiment is to experimentally estimate the value of α_0 . In general we may think of α_0 as a function of T . In Section 2 we saw that $\alpha_0(T)$ is bounded from above by an absolute constant for all T . In Section 4.1 below we estimate the values of α_0 for a range of T .

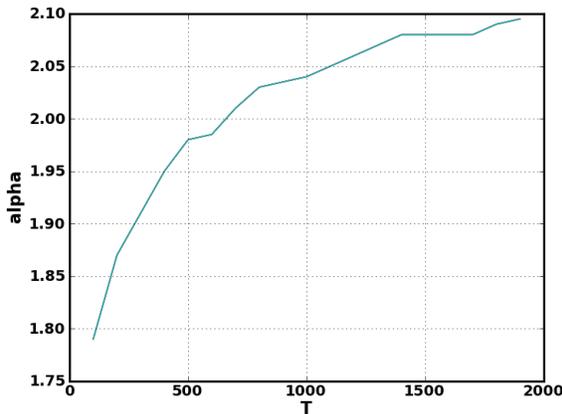

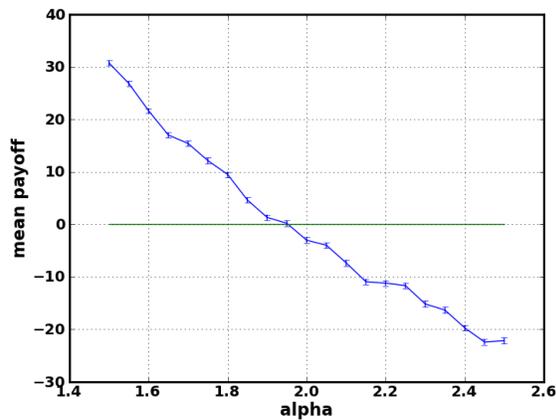

The second part of the experiment is to implement our algorithm and compare its performance against 3 other prediction algorithms. This is described in Section 4.2 below.

4.1 Computation of α_0

We denote by $\alpha_0(T)$ the minimum value of α such that the payoff function P_α is feasible for sequences of length T . For a particular T , this value can be computed using Theorem 1.5. While Theorem 1.5 requires us to compute the

payoff function over all sequences of length T (to compute the expectation), we can experimentally approximate this by taking sufficiently many random sequences of length T and looking at the expectation of the sample. We are interested in $T = 389$ which is the number of minutes in a trading day for which we have returns data (there are 390 minutes in a typical trading day and the returns for the first minute is undefined).

Note that the standard error of the sample mean is obtained as the sample standard deviation divided by \sqrt{n} where $n = 400$ is the number of trials. The chart on the left shows the mean payoff and standard error for various values of α for $T = 389$.

From the figure we see that $\alpha = 1.96$ is a good estimate for $\alpha_0(T)$ for $T = 389$. The figure on the right shows estimated values of α_0 for various T .

4.2 Comparison of predictive performance

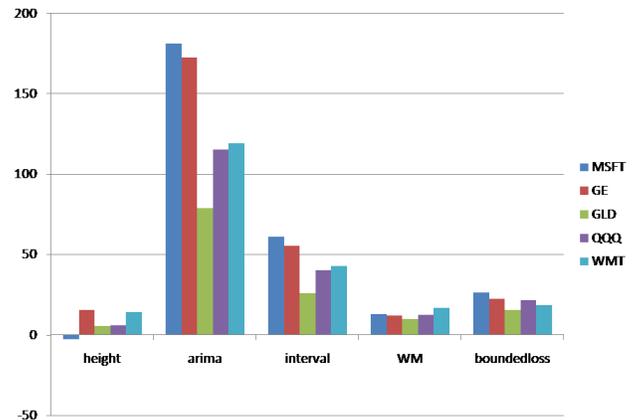

The algorithms we consider are:-

1. The baseline buy and hold strategy that achieves payoff equal to the height (height)
2. The algorithm described in this paper (interval)

3. Weighted Majority algorithm (WM)
4. The algorithm of [KP11] (Algorithm 4, section 5) (boundedloss)
5. An algorithm based on Auto Regressive Integrated Moving Average (arima)

Note that algorithms 2-4 are based on ideas from regret minimization with provable guarantees while the fifth is a commonly used model for predicting time series data. To implement the fourth algorithm we use the function `AUTO.ARIMA()` in R which is part of the library `FORECAST`.

The prediction task we consider is to predict the next minute returns for a stock over a single trading day using only the previous 1 minute returns of the given stock for the given day. More precisely, we define the price of a stock at a given time taking the average of the best bid price and best ask price at that time as reported by the New York Stock Exchange (NYSE). We perform this prediction experiment over 189 days for the following 5 US stocks/ETFs from various sectors: MSFT, GE, GLD, QQQ and WMT. This gives us performance data for each algorithm for a total of $389 \times 189 \times 5 = 367,605$ data points. The results obtained are shown in the figure below.

We note that while our algorithm performs better in practice than other regret minimization based prediction algorithms with provable guarantees, it is outperformed by the ARIMA model.

Abstract

A popular approach for online decision making in large MDPs is time-bounded tree search. The effectiveness of tree search, however, is largely influenced by the action branching factor, which limits the search depth given a time bound. An obvious way to reduce action branching is to consider only a subset of potentially good actions at each state as specified by a provided partial policy. In this work, we consider offline learning of such partial policies with the goal of speeding up search without significantly reducing decision-making quality. Our first contribution is to study learning algorithms based on reducing our learning problem to i.i.d. supervised learning. We give a reduction-style analysis of three such algorithms, each making different assumptions, which relates the supervised learning objectives to the sub-optimality of search using the learned partial policies. Our second contribution is to describe concrete implementations of the algorithms within the popular framework of Monte-Carlo tree search. Finally, the third contribution is to evaluate the learning algorithms in two challenging MDPs with large action branching factors, showing that the learned partial policies can significantly improve the anytime performance of Monte-Carlo tree search.

1 INTRODUCTION

Lookahead tree search is a common approach for time-bounded decision making in large Markov Decision Processes (MDPs). Actions are selected by estimating action values at the current state by building a finite-horizon lookahead tree using an MDP model or simulator. A variety of algorithms are available for building such trees, including instances of Monte-Carlo Tree Search (MCTS) such as UCT (Kocsis and Szepesvári, 2006), Sparse Sam-

pling (Kearns et al., 2002), and FSSS (Walsh et al., 2010), along with model-based search approaches such as RTDP (Barto et al., 1995) and AO* (Bonet and Geffner, 2012). Given time constraints, however, the performance of these approaches depends on the action branching factor, which is often considerable and greatly limits the feasible search depth. An obvious way to address this problem is to provide prior knowledge for explicitly pruning bad actions from consideration. In this paper, we consider offline learning of such prior knowledge in the form of partial policies.

A partial policy is a function that quickly returns an action subset for each state and can be integrated into search by pruning away actions not included in the subsets. Thus, a partial policy can significantly speedup search if it returns small action subsets, provided that the overhead for applying the partial policy is small enough. If those subsets typically include high-quality actions, then we might expect little decrease in decision-making quality. Although learning partial policies to guide tree search is a natural idea, it has received surprisingly little attention, both in theory and practice. In this paper we formalize this learning problem from the perspective of “speedup learning”. We are provided with a distribution over search problems in the form of a root state distribution and a search depth bound. The goal is to learn partial policies that significantly speedup depth D search, while bounding the expected regret of selecting actions using the pruned search versus no pruning.

In order to solve this learning problem, there are at least two key choices that must be made: 1) Selecting a training distribution over states arising in lookahead trees, and 2) Selecting a loss function that the partial policy is trained to minimize with respect to the chosen distribution. The key contribution of our work is to consider a family of reduction-style algorithms that answer these questions in different ways. In particular, we consider three algorithms that reduce partial policy learning to i.i.d. supervised learning problems characterized by choices for (1) and (2). Our main results bound the sub-optimality of tree search using the learned partial policies in terms of the expected loss of the supervised learning problems. Interestingly, these re-

sults for learning partial policies mirror similar reduction-style results for learning (complete) policies via imitation, e.g. (Ross and Bagnell, 2010; Syed and Schapire, 2010; Ross et al., 2011).

We empirically evaluate our algorithms in the context of learning partial policies to speedup MCTS in two challenging domains with large action branching factors: 1) the classic dice game, Yahtzee, and 2) a real-time strategy game, Galcon. The results show that using the learned partial policies to guide MCTS leads to significantly improved anytime performance in both domains. Furthermore, we show that several other existing approaches for injecting knowledge into MCTS are not as effective as using partial policies for action pruning and can often hurt search performance rather than help.

2 PROBLEM SETUP

We consider sequential decision making in the framework of Markov Decision Processes (MDPs) and assume basic familiarity. An MDP is a tuple (S, A, P, R) , where S is a finite set of states, A a finite set of actions, $P(s'|s, a)$ is the transition probability of arriving at state s' after executing action a in state s , and $R(s, a) \in [0, 1]$ is the reward function giving the reward of taking action a in state s . The typical goal of MDP planning and learning is to compute a policy for selecting an action in any state, such that following the policy (approximately) maximizes some measure of long-term expected reward.

In practice, regardless of the long-term reward measure, for large MDPs, the offline computation of high-quality policies over all environment states is impractical. In such cases, a popular action-selection approach is online tree search, where at each encountered environment state, a time-bounded search is carried out in order to estimate action values. Note that this approach requires the availability of either an MDP model or an MDP simulator in order to construct search trees. In this paper, we assume that a model or simulator is available and that online tree search has been chosen as the action selection mechanism. Next, we formally describe the paradigm of online tree search, introduce the notion of partial policies for pruning tree search, and then formulate the problem of offline learning of such partial policies.

Online Tree Search. We will focus on depth-bounded search assuming a search depth bound of D throughout, which bounds the length of future action sequences to be considered. Given a state s , we denote by $T(s)$ the depth D expectimax tree rooted at s . $T(s)$ alternates between layers of state nodes and action nodes, labeled by states and actions respectively. The children of each state node are action nodes for each action in A . The children of an action node a with parent labeled by s are all states s' such that $P(s'|s, a) > 0$. Figure 1(a) shows an example of a

depth two expectimax tree. The depth of a state node is the number of action nodes traversed from the root to reach it, noting that leaves of $T(s)$ will always be action nodes.

The optimal value of a state node s at depth d , denoted by $V_d^*(s)$, is equal to the maximum value of its child action nodes, which we denote by $Q_d^*(s, a)$ for child a . We define $Q_d^*(s, a)$ to be $R(s, a)$ if $d = D - 1$ (i.e. for leaf action nodes) and otherwise $R(s, a) + E[V_{d+1}^*(s')]$, where $s' \sim P(\cdot|s, a)$ ranges over children of a . The optimal action policy for state s at depth d will be denoted by $\pi_d^*(s) = \arg \max_a Q_d^*(s, a)$. Given an environment state s , online search algorithms such as UCT or RTDP attempt to completely or partially search $T(s)$ in order to approximate the root action values $Q_0^*(s, a)$ well enough to identify the optimal action $\pi_d^*(s)$. It is important to note that optimality in our context is with respect to the specified search depth D , which may be significantly smaller than the expected planning horizon in the actual environment. This is a practical necessity that is often referred to as receding-horizon control. Here we simply assume that an appropriate search depth D has been specified and our goal is to speedup planning within that depth.

Search with Partial Policies. One way to speedup depth D search is to prune actions from $T(s)$. In particular, if a fixed fraction σ of actions are removed from each state node, then the size of the tree would decrease by a factor of $(1 - \sigma)^D$, potentially resulting in significant computational savings. For this purpose we will utilize partial policies. A depth D (non-stationary) partial policy ψ is a sequence $(\psi_0, \dots, \psi_{D-1})$ where each ψ_d maps a state to an action subset. Given a partial policy ψ and root state s , we can define a pruned tree $T_\psi(s)$ that is identical to $T(s)$, except that each state s at depth d only has subtrees for actions in $\psi_d(s)$, pruning away subtrees for any child $a \notin \psi_d(s)$. Figure 1(b) shows a pruned tree $T_\psi(s)$, where ψ prunes away one action at each state. It is straightforward to incorporate ψ into a search algorithm by only expanding actions at state nodes that are consistent with ψ .

We define the state and action values relative to $T_\psi(s)$ the same as above and let $V_d^\psi(s)$ and $Q_d^\psi(s, a)$ denote the depth d state and action value functions. We will denote the highest-valued, or greedy, root action of $T_\psi(s)$ by $G_\psi(s) = \arg \max_{a \in \psi_0(s)} Q_0^\psi(s, a)$. This is the root action that a depth D search procedure would attempt to return in the context of ψ . Note that a special case of partial policies is when $|\psi_d(s)| = 1$ for all s and d , which means that ψ defines a traditional (complete) deterministic MDP policy. In this case, V_d^ψ and Q_d^ψ represent the traditional depth d state value and action value functions for policies. We say that a partial policy ψ subsumes a partial policy ψ' if for each s and d , $\psi'_d(s) \subset \psi_d(s)$. In this case, it is straightforward to show that for any s and d , $V_d^{\psi'}(s) \leq V_d^\psi(s)$.

Clearly, a partial policy can reduce the complexity of

search. However, we are also concerned with the quality of decision making using $T_\psi(s)$ versus $T(s)$, which we will quantify in terms of expected regret. The regret of selecting action a at state s relative to $T(s)$ is equal to $V_0^*(s) - Q_0^*(s, a)$, noting that the regret of the optimal action $\pi_0^*(s)$ is zero. We prefer partial policies that result in root decisions with small regret over the root state distribution that we expect to encounter, while also supporting significant pruning. For this purpose, if μ_0 is a distribution over root states, we define the expected regret of ψ with respect to μ_0 as $\text{REG}(\mu_0, \psi) = E[V_0^*(s_0) - Q_0^*(s_0, G_\psi(s_0))]$, where $s_0 \sim \mu_0$.

Learning Problem. We consider an offline learning setting where we are provided with a model or simulator of the MDP in order to train a partial policy that will be used later for online decision making. That is, the learning problem provides us with a distribution μ_0 over root states (or a representative sample from μ_0) and a depth bound D . The intention is for μ_0 to be representative of the states that will be encountered during online use. In this work, we are agnostic about how μ_0 is defined for an application. However, a typical example and one used in our experiments, is for μ_0 to correspond to the distribution of states encountered along trajectories of a receding horizon controller that makes decisions based on unpruned depth D search.

Given μ_0 and D , our “speedup learning” goal is to learn a partial policy ψ with small expected regret $\text{REG}(\mu_0, \psi)$, while providing significant pruning. That is, we want to approximately imitate the decisions of depth D unpruned search via a much less expensive depth D pruned search. In general, there will be a tradeoff between the potential speedup and expected regret. At one extreme, it is always possible to achieve zero expected regret by selecting a partial policy that does no pruning and hence no speedup. At the other extreme, we can remove the need for any search by learning a partial policy that always returns a single action (i.e. a complete policy). However, for many complex MDPs, it can be difficult to learn computationally efficient, or reactive, policies that achieve small regret. Rather, it may be much easier to learn partial policies that prune away many, but not all actions, yet still retain high-quality actions. While such partial policies lead to more search than a reactive policy, the regret can be much less.

In practice, we seek a good tradeoff between the two extremes, which will depend on the application. Instead of specifying a particular trade-off point as our learning objective, we develop learning algorithms in the next section that provide some ability to explore different points. In particular, the algorithms are associated with regret bounds in terms of supervised learning objectives that measurably vary with different amounts of pruning.

Algorithm 1 A template for learning a partial policy $\psi = (\psi_0, \dots, \psi_{D-1})$. The template is instantiated by specifying the pairs of distributions and cost functions (μ_d, C_d) for $d \in \{0, \dots, D-1\}$. LEARN is an i.i.d. supervised learning algorithm that aims to minimize the expected cost of each ψ_d relative to C_d and μ_d .

```

1: procedure PARTIALPOLICYLEARNER( $\{(\mu_d, C_d)\}$ )
2:   for  $d = 0, 1, \dots, D - 1$  do
3:     Sample a training set of states  $S_d$  from  $\mu_d$ 
4:      $\psi_d \leftarrow \text{LEARN}(S_d, C_d)$ 
5:   end for
6:   return  $\psi = (\psi_0, \psi_1, \dots, \psi_{D-1})$ 
7: end procedure

```

3 LEARNING PARTIAL POLICIES

Given μ_0 and D , we now develop reduction-style algorithms for learning partial policies. The algorithms reduce partial policy learning to a sequence of D i.i.d. supervised learning problems, each producing one partial policy component ψ_d . The supervised learning problem for ψ_d will be characterized by a pair (μ_d, C_d) , where μ_d is a distribution over states, and C_d is a cost function that, for any state s and action subset $A' \subseteq A$ assigns a prediction cost $C_d(s, A')$. The cost function is intended to measure the quality of A' with respect to including actions that are high quality for s . Typically the cost function is monotonically decreasing in A' and $C_d(s, A) = 0$.

In this section we assume the availability of an i.i.d. supervised learner LEARN that takes as input a set of states drawn from μ_d , along with C_d , and returns a partial policy component ψ_d that is intended to minimize the expected cost of ψ_d on μ_d , i.e. minimize $E[C_d(s, \psi_d(s))]$ for $s \sim \mu_d$. In practice, the specific learner will depend on the cost function and we describe our particular implementations in Section 4. Rather, in this section, we focus on defining reductions that allow us to bound the expected regret of ψ by the expected costs of the ψ_d returned by LEARN. The generic template for our reduction algorithms is shown in Algorithm 1.

In the following, our state distributions will be specified in terms of distributions induced by (complete) policies. In particular, given a policy π , we let $\mu_d(\pi)$ denote the state distribution induced by drawing an initial state from μ_0 and then executing π for d steps. Since we have assumed an MDP model or simulator, it is straightforward to sample from $\mu_d(\pi)$ for any provided π . Before proceeding we state a simple proposition that will be used to prove our regret bounds.

Proposition 3.1. *If a complete policy π is subsumed by partial policy ψ , then for any initial state distribution μ_0 , $\text{REG}(\mu_0, \psi) \leq E[V_0^*(s_0)] - E[V_0^\pi(s_0)]$, for $s_0 \sim \mu_0$.*

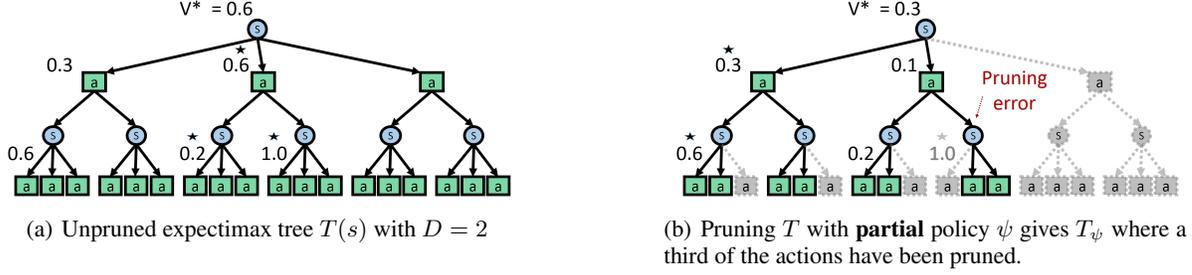

Figure 1: Unpruned and pruned expectimax trees with depth $D = 2$ for an MDP with $|A| = 3$ and two possible next states.

Proof. Since π is subsumed by ψ , we know that $Q_0^\psi(s, G_\psi(s)) = V_0^\psi(s) \geq V_0^\pi(s)$. Since for any a , $Q_0^*(s, a) \geq Q_0^\psi(s, a)$, we have for any state s , $Q_0^*(s, G_\psi(s)) \geq V_0^\pi(s)$. The result follows by negating each side of the inequality, followed by adding $V_0^*(s)$, and taking expectations. \square

Thus, we can bound the regret of a learned ψ if we can guarantee that it subsumes a policy whose expected value has bounded sub-optimality. Next we present three reductions for doing this, each having different requirements and assumptions.

3.1 OPI : OPTIMAL PARTIAL IMITATION

Perhaps the most straightforward idea for learning a partial policy is to attempt to find a partial policy that is usually consistent with trajectories of the optimal policy π^* . That is, each ψ_d should be learned so as to maximize the probability of containing actions selected by π_d^* with respect to the optimal state distribution $\mu_d(\pi^*)$. This approach is followed by our first algorithm called Optimal Partial Imitation (OPI). In particular, Algorithm 1 is instantiated with $\mu_d = \mu_d(\pi^*)$ (noting that $\mu_0(\pi^*)$ is equal to μ_0 as specified by the learning problem) and C_d equal to zero-one cost. Here $C_d(s, A') = 0$ if $\pi_d^*(s) \in A'$ and $C_d(s, A') = 1$ otherwise. Note that the expected cost of ψ_d in this case is equal to the probability that ψ_d does not contain the optimal action, which we will denote by $e_d^*(\psi) = \Pr_{s \sim \mu_d(\pi^*)}(\pi_d^*(s) \notin \psi_d(s))$.

A naive implementation of OPI is straightforward. We can generate length D trajectories by drawing an initial state from μ_0 and then selecting actions (approximately) according to π_d^* using standard unpruned search. Defined like this, OPI has the nice property that it only requires the ability to reliably compute actions of π_d^* , rather than requiring that we also estimate action values accurately. This allows us to exploit the fact that search algorithms such as UCT often quickly identify optimal actions, or sets of near-optimal actions, well before the action values have converged.

Intuitively we should expect that if the expected cost e_d^* is

small for all d , then the regret of ψ should be bounded, since the pruned search trees will generally contain optimal actions for state nodes. The following clarifies this dependence. For the proof, given a partial policy ψ , it is useful to define a corresponding complete policy ψ^+ such that $\psi_d^+(s) = \pi_d^*(s)$ whenever $\pi_d^*(s) \in \psi_d(s)$ and otherwise $\psi_d^+(s)$ is the lexicographically least action in $\psi_d(s)$. Note that ψ^+ is subsumed by ψ .

Theorem 3.2. *For any initial state distribution μ_0 and partial policy ψ , if for each $d \in \{0, \dots, D - 1\}$, $e_d^*(\psi) \leq \epsilon$, then $REG(\mu_0, \psi) \leq \epsilon D^2$.*

Proof. Given the assumption that $e_d^*(\psi) \leq \epsilon$ and that ψ^+ selects the optimal action whenever ψ contains it, we know that $e_d^*(\psi^+) \leq \epsilon$ for each $d \in \{0, \dots, D\}$. Given this constraint on ψ^+ we can apply Lemma 3¹ from (Syed and Schapire, 2010) which implies $E[V_0^{\pi^+}(s_0)] \geq E[V_0^*(s_0)] - \epsilon D^2$, where $s_0 \sim \mu_0$. The result follows by combining this with Prop. 3.1. \square

This result mirrors work on reducing imitation learning to supervised classification (Ross and Bagnell, 2010; Syed and Schapire, 2010), showing the same dependence on the planning horizon. While space precludes details, it is straightforward to construct an example problem where the above regret bound is shown to be tight. This result motivates a learning approach where we have LEARN attempt to return ψ_d that each maximizes pruning (returns small action sets) while maintaining a small expected cost.

3.2 FT-OPI : FORWARD TRAINING OPI

OPI has a potential weakness, similar in nature to issues identified in prior work on imitation learning (Ross and Bagnell, 2010; Ross et al., 2011). In short, OPI does not train ψ to recover from its own pruning mistakes. Consider a node n in the optimal subtree of a tree $T(s_0)$ and suppose

¹The main result of (Syed and Schapire, 2010) holds for stochastic policies and requires a more complicated analysis that results in a looser bound. Lemma 3 is strong enough for deterministic policies.

that the learned ψ erroneously prunes the optimal child action of n . This means that the optimal subtree under n will be pruned from $T_\psi(s)$, increasing the potential regret. Ideally, we would like the pruned search in $T_\psi(s)$ to recover from the error gracefully and return an answer based on the best remaining subtree under n . Unfortunately, the distribution used to train ψ by OPI was not necessarily representative of this alternate subtree under n , since it was not an optimal subtree of $T(s)$. Thus, no guarantees about the pruning accuracy of ψ can be made under n .

In imitation learning, this type of problem has been dealt with via “forward training” of non-stationary policies (Ross et al., 2011) and a similar idea works for us. The Forward Training OPI (FT-OPI) algorithm differs from OPI only in the state distributions used for training. The key idea is to learn the partial policy components ψ_d in sequential order from $d = 0$ to $d = D - 1$ and then training ψ_d on a distribution induced by $\psi_{0:d-1} = (\psi_0, \dots, \psi_{d-1})$, which will account for pruning errors made by $\psi_{0:d-1}$. Specifically, recall that for a partial policy ψ , we defined ψ^+ to be a complete policy that selects the optimal action if it is consistent with ψ and otherwise the lexicographically least action. The state distributions used to instantiate FT-OPI is $\mu_d = \mu_d(\psi_{0:d-1}^+)$ and the cost function remains zero-one cost as for OPI. We will denote the expected cost of ψ_d in this case by $e_d^+(\psi) = \Pr_{s \sim \mu_d(\psi_{0:d-1}^+)}(\pi_d^*(s) \notin \psi_d(s))$, which gives the probability of pruning the optimal action with respect to the state distribution of $\psi_{0:d-1}^+$.

Note that as for OPI, we only require the ability to compute π^* in order to sample from $\mu_d(\psi_{0:d-1}^+)$. In particular, note that when learning ψ_d , we have $\psi_{0:d-1}$ available. Hence, we can sample a state for μ_d by executing a trajectory of $\psi_{0:d-1}^+$. Actions for ψ_d^+ can be selected by first computing π_d^* and selecting it if it is in ψ_d and otherwise selecting the lexicographically least action.

As shown for the forward training algorithm for imitation learning (Ross et al., 2011), we give below an improved regret bound for FT-OPI under an assumption on the maximum sub-optimality of any action. The intuition is that if it is possible to discover high-quality subtrees, even under sub-optimal action choices, then FT-OPI can learn on those trees and recover from errors.

Theorem 3.3. *Assume that for any state s , depth d , and action a , we have $V_d^*(s) - Q_d^*(s, a) \leq \Delta$. For any initial state distribution μ_0 and partial policy ψ , if for each $d \in \{0, \dots, D - 1\}$, $e_d^+(\psi) \leq \epsilon$, then $REG(\mu_0, \psi) \leq \epsilon \Delta D$.*

Proof. The theorem’s assumptions imply that ψ^+ and the search tree $T(s)$ satisfies the conditions of Theorem 2.2 of (Ross et al., 2011). Thus we can infer that $E[V_0^{\pi^+}(s_0)] \geq E[V_0^*(s_0)] - \epsilon \Delta D$, where $s_0 \sim \mu_0$. The result follows by combining this with Proposition 3.1. \square

Thus, when Δ is significantly smaller than D , FT-OPI has the potential to outperform OPI given the same bound on zero-one cost. In the worst case $\Delta = D$ and the bound will equal to that of OPI.

3.3 FT-QCM: FORWARD TRAINING Q-COST MINIMIZATION

While FT-OPI addressed one potential problem with OPI, they are both based on zero-one cost, which raises other potential issues. The primary weakness of using zero-one cost is its inability to distinguish between highly sub-optimal and slightly sub-optimal pruning mistakes. It was for this reason that FT-OPI required the assumption that all action values had sub-optimality bounded by Δ . However, in many problems, including those in our experiments, that assumption is unrealistic, since there can be many highly sub-optimal actions (e.g. ones that result in losing a game). This motivates using a cost function that is sensitive to the sub-optimality of pruning decisions.

In addition, it can often be difficult to learn a ψ that achieves both, a small zero-one cost and also provides significant pruning. For example, in many domains, in some states there will often be many near-optimal actions that are difficult to distinguish from the slightly better optimal action. In such cases, achieving low zero-one cost may require producing large action sets. However, learning a ψ that provides significant pruning while reliably retaining at least one near-optimal action may be easily accomplished. This again motivates using a cost function that is sensitive to the sub-optimality of pruning decisions, which is accomplished via our third algorithm, Forward Training Q-Cost Minimization (FT-QCM)

The cost function of FT-QCM is the minimum sub-optimality, or Q-cost, over unpruned actions. In particular, we use $C_d(s, A') = V_d^*(s) - \max_{a \in A'} Q_d^*(s, a)$. Our state distribution will be defined similarly to that of FT-OPI, only we will use a different reference policy. Given a partial policy ψ , define a new complete policy $\psi^* = (\psi_0^*, \dots, \psi_{D-1}^*)$ where $\psi_d^*(s) = \arg \max_{a \in \psi_d(s)} Q_d^*(s, a)$, so that ψ^* always selects the best unpruned action. We define the state distributions for FT-QCM as the state distribution induced by ψ^* , i.e. $\mu_d = \mu_d(\psi_{0:d-1}^*)$. We will denote the expected Q-cost of ψ at depth d to be $\Delta_d(\psi) = E[V_d^*(s_d) - \max_{a \in \psi_d(s_d)} Q_d^*(s_d, a)]$, where $s_d \sim \mu_d(\psi_{0:d-1}^*)$.

Unlike OPI and FT-OPI, this algorithm requires the ability to estimate action values of sub-optimal actions in order to sample from μ_d . That is, sampling from μ_d requires generating trajectories of ψ_d^* , which means we must be able to accurately detect the action in $\psi_d(s)$ that has maximum value, even if it is a sub-optimal action. The additional overhead for doing this during training depends on the search algorithm being used. For many algorithms,

near-optimal actions will tend to receive more attention than clearly sub-optimal actions. In those cases, as long as $\psi_d(s)$ includes reasonably good actions, there may be little additional regret. The following regret bound motivates the FT-QCM algorithm.

Theorem 3.4. *For any initial state distribution μ_0 and partial policy ψ , if for each $d \in \{0, \dots, D-1\}$, $\Delta_d(\psi) \leq \Delta$, then $\text{REG}(\mu_0, \psi) \leq 2D^{\frac{3}{2}}\sqrt{\Delta}$.*

Proof. Consider any pair of non-negative real numbers (ϵ, δ) such that for any d , the probability is no more than ϵ of drawing a state from $\mu_d(\psi^*)$ with Q-cost (wrt ψ) greater than δ . That is $\Pr(C_d(s_d, \psi_d(s_d)) \geq \delta) \leq \epsilon$. We will first bound $\text{REG}(\mu_0, \psi)$ in terms of ϵ and δ .

Let Π_δ be the set of policies for which all selected actions have regret bounded by δ . It can be shown by induction on the depth that for any $\pi \in \Pi_\delta$ and any state s , $V_0^\pi(s) \geq V_0^*(s) - \delta D$. For the chosen pair (ϵ, δ) we have that for a random trajectory t of ψ^* starting in a state drawn from μ_0 there is at most an ϵD probability that the Q-cost of ψ^* on any state of t is greater than δ . Thus, compared to a policy that always has Q-cost bounded by δ , the expected reduction in total reward of ψ for initial state distribution μ_0 is no more than ϵD^2 . This shows that

$$\begin{aligned} E[V_0^{\psi^*}(s_0)] &\geq \min_{\pi \in \Pi_\delta} E[V_0^\pi(s_0)] - \epsilon D^2 \\ &\geq E[V_0^*(s_0)] - \delta D - \epsilon D^2 \end{aligned}$$

Since ψ^* is subsumed by ψ , Proposition 3.1 implies that $\text{REG}(\mu_0, \psi) \leq \delta D + \epsilon D^2$.

We now reformulate the above bound in terms of the bound on expected Q-cost Δ assumed by the theorem. Since Q-costs are non-negative, we can apply the Markov inequality to conclude that $\Pr(C_d(s_d, \psi_d(s_d)) \geq \delta) \leq \frac{\Delta_d(\psi)}{\delta} \leq \frac{\Delta}{\delta}$. The pair $(\frac{\Delta}{\delta}, \delta)$ then satisfies the above condition for ψ^* . Thus, we get $\text{REG}(\mu_0, \psi) \leq \delta D + \frac{\Delta}{\delta} D^2$. The bound is minimized at $\delta = \sqrt{D\Delta}$, which yields the result. \square

FT-QCM tries to minimize this regret bound by minimizing $\Delta_d(\psi)$ via supervised learning at each step. Importantly, as we will show in our experiments, it is often possible to maintain small expected Q-cost with significant pruning, while the same amount of pruning would result in a much larger zero-one cost. It is an open problem as to whether this bound is tight in the worst case.

4 IMPLEMENTATION DETAILS

In this section, we describe our concrete implementation of the above abstract algorithms using the MCTS algorithm UCT (Kocsis and Szepesvári, 2006) for tree search.

UCT is a popular MCTS algorithm, perhaps most famous for leading to significant advances in computer Go (Gelly et al., 2006; Gelly and Silver, 2007). Space precludes a

complete description and we only outline the high-level ideas and issues relevant to our work. Given a root state and a time budget, UCT executes a series of Monte-Carlo simulations in order to build an asymmetric search tree that explores more promising parts of the tree first, compared to less promising parts. The key idea behind UCT is to utilize a variant of the multi-armed bandit algorithm UCB (Auer et al., 2002) for selecting actions during the Monte-Carlo simulations. The objective is to balance the exploration of less frequently visited parts of the tree versus exploring nodes that look most promising. State and action values for nodes in the UCT tree are estimated based on the average reward of Monte-Carlo trajectories that go through the nodes. In the limit, UCT will converge to optimal state and action values. In practice, the values computed in a UCT tree after a finite time budget are most accurate for higher quality actions, since they tend to be explored more often. It is straightforward to integrate a partial policy into UCT, by simply removing pruned actions from consideration.

Partial Policy Representation. Our partial policies operate by simply ranking the actions at a state and then pruning a percentage of the bottom actions. Specifically, partial policy components have the form $\psi_d(s | w_d, \sigma_d)$, parameterized by an n -dimensional weight vector w_d and pruning fraction $\sigma_d \in [0, 1)$. Given a state s , each action a is ranked according to the linear ranking function $f_d(s, a) = w_d^T \phi(s, a)$, where $\phi(s, a)$ is a user provided n -dimensional feature vector that describes salient properties of state-action pairs. Using f_d we can define a total order over actions, breaking ties lexicographically. $\psi_d(s | w_d, \sigma_d)$ is then equal to the set of the $\lceil (1 - \sigma_d)|A| \rceil$ highest ranked actions. This representation is useful as it allows us to separate the training of f_d from the selection of the pruning fraction.

Generating Training States. Each of our algorithms requires sampling training states from trajectories of particular policies that either require approximately computing π_d^* (OPI and FT-OPI) or also action values for sub-optimal actions (FT-QCM). Our implementation of this is to first generate a set of trees using substantial search, which provides us with the required policy or action values and then to sample trajectories from those trees.

More specifically, our learning algorithm is provided with a set of root states S_0 sampled from the target root distribution μ_0 . For each $s_0 \in S_0$ we run UCT for a specified time bound, which is intended to be significantly longer than the eventual online time bound. Note that the resulting trees will typically have a large number of nodes on the tree fringe that have been explored very little and hence will not be useful for learning. Because of this we select a depth bound D for training such that nodes at that depth or less have been sufficiently explored and have meaningful action values. The trees are then pruned until depth D .

Given this set of trees we can then generate trajectories using the MDP simulator of the policies specified for each algorithm. For example, OPI simply requires running trajectories through the trees based on selecting actions according to the optimal action estimates. The state at depth d along each trajectory is added to the data set for training ψ_d . FT-QCM samples states for training ψ_d by generating length d trajectories of $\psi_{0:d-1}^*$. Each such action selection requires referring to the estimated action values and returning the best one that is not pruned. The final state on the trajectory is then added to the training set for ψ_d . Note that since our approach generates multiple trajectories from each tree the training sets for each ψ_d are not truly i.i.d. This is an acceptable trade-off in practice since tree construction is expensive and this approach allows for many examples to be generated per tree.

Supervised Learner. It remains to specify how we implement the LEARN procedure. Each training set will consist of pairs $\{(s_i, c_i)\}$ where s_i is a state and c_i is a vector that assigns a cost to each action. For OPI and FT-OPI the cost vector assigns 0 to the optimal action and 1 to all other actions. For FT-QCM the c_i give the Q-costs of each action. We learn the partial policy by first learning the ranking function in a way that attempts to rank low-cost actions as highly as possible and then select an appropriate pruning percentage based on the learned ranker.

For rank learning, we follow a common approach of converting the problem to cost-sensitive binary classification. In particular, for a given example (s, c) we create a cost-sensitive classification example for each pair of actions a_1 and a_2 of the form $(\phi(s, a_1) - \phi(s, a_2), c(a_2) - c(a_1))$. Learning a linear classifier for such an example will attempt to rank a_1 above or below a_2 according to the cost difference. We apply an existing cost-sensitive learner (Langford, 2011) to learn a weight vector based on the pairwise data. Note that for zero-one loss, we do not create pairwise examples involving just sub-optimal actions since their cost difference will always be zero.

Finally, after learning the ranking function for a particular ψ_d , we must select an appropriate pruning percentage σ_d . In practice, we do this by analyzing the expected cost of ψ_d for a range of pruning values and select a pruning value that yields reasonably small costs. Section 6 gives details of the selections for our experiments.

5 RELATED WORK

While there is a large body of work on integrating learning and planning, to the best of our knowledge, we do not know of any work on learning partial policies for speeding up online MDP planning.

There are a number of efforts that study model-based reinforcement learning (RL) for large MDPs that utilize tree

search methods for planning with the learned model, e.g. RL using FSSS (Walsh et al., 2010), Monte-Carlo AIXI (Veness et al., 2011), and TEXPLORE (Hester and Stone, 2013). However, these methods focus on model/simulator learning and do not attempt to learn to speedup tree search using the learned models, which is the focus of our work.

A more related body of work is on learning search control knowledge in deterministic planning and games. One thread of work has been on learning knowledge for STRIPS-style deterministic planners, e.g. learning heuristics and policies for guiding best-first search (Yoon et al., 2008) or state ranking functions (Xu et al., 2009). The problem of learning improved leaf evaluation heuristics has also been studied in the context of deterministic real-time heuristic search (Bulitko and Lee, 2006). As one more example, evaluation functions have been learned for game tree search based on learning from “principle variations” of deep searches (Veness et al., 2009). The training data for this approach is similar in spirit to that of our OPI algorithm. Since these algorithms have been developed for deterministic settings, it is not straightforward to adapt them to the general MDP setting. Further, none of these existing methods, to our knowledge, have provided a theoretical analysis of the possible regret of using the learned knowledge, which is one of our main contributions.

There have been a number of efforts for utilizing domain-specific knowledge in order to improve/speedup MCTS, many of which are covered in a recent survey (Browne et al., 2012). A popular technique is to use a bias term $f(s, a)$ for guiding action selection during search. f is hand-provided in (Chaslot et al., 2007; Couëtoux et al., 2011) and learned in (Gelly and Silver, 2007; Sorg et al., 2011). Generally there are a number of parameters that dictate how strongly $f(s, a)$ influences search and how that influence decays as search progresses. In our experience, tuning the parameters for a particular problem can be tedious and difficult to do in a domain-independent way. Similar issues hold for the approach in (Gelly and Silver, 2007) which attempts to learn an approximation of Q^* and then initializes search nodes with the estimate. In (Sorg et al., 2011), control knowledge is learned via policy-gradient techniques in the form of a reward function and used to guide MCTS with the intention of better performance given a time budget. So far, however, the approach has not been analyzed formally and has not been demonstrated on large MDPs. Experiments in small MDPs have also not demonstrated improvement in terms of wall clock time over vanilla MCTS.

Finally, MCTS methods often utilize hand-coded or learned “default policies” (e.g., MoGo (Gelly et al., 2006)) to improve anytime performance. While this has shown some promise in specific domains such as Go, where the policies can be highly engineered for efficiency, we have found that the computational overhead of using learned default poli-

cies is often too high a price to pay. In particular, most such learned policies require the evaluation of a feature vector at each state encountered, or for each state-action pair. This may cause orders of magnitude fewer trajectories to be executed compared to vanilla MCTS. In our experience, this can easily lead to degraded performance per unit time. Furthermore, there is little formal understanding about how to learn such rollout policies in principled ways, with straightforward approaches often yielding decreased performance (Silver and Tesauro, 2009).

6 EXPERIMENTS

We consider learning partial policies in two domains.

Yahtzee is a classic dice game with ≈ 17 actions on average. Actions correspond to selecting subsets of dice to roll and selecting categories to score. The objective is to maximize the sum of category scores. We use 26 features for learning the partial policy which encode the impact of a roll action or select action for each of the 13 categories.

Galcon is a two-player real-time strategy game with approximately 174 actions per move on average (max. ≈ 800). The objective is to maximize one’s own population on a 2-D grid of planets by directing variable-sized fleets of units between planets to capture enemy planets or fortify one’s own. Transitions are stochastic when opposing populations battle over a planet. We use 20 real-valued state-action features that coarsely encode the impact of an action on population size, planet ownership, etc.

In what follows, we experiment with the two extreme algorithms, OPI and FT-QCM. The intermediate algorithm FT-OPI is excluded in this paper due to the time required to perform large-scale evaluations across a wide spectrum of time bounds. Preliminary experiments suggest that FT-OPI performs between OPI and FT-QCM.

Setup. For training we provide our learning algorithms with root states generated by playing 100 full games allowing UCT 64 seconds per move per tree. This produces thousands of root states along with the search trees, which we use for training as described in Section 4. Due to the large action and stochastic branching factors, even with 64 seconds per move, we selected $D = 3$ for learning since the value estimates produced by UCT for deeper nodes were not accurate. Note that in our evaluations we do not limit the rollouts of UCT to depth 3, rather the rollouts proceed until terminal states, which provide a longer term heuristic evaluation for tree nodes.² In order to select the pruning fractions σ_d , in results not shown for space reasons, we plotted the supervised losses achieved for various learned ranking functions for a variety of σ_d . We found that in

²When UCT generates tree nodes at depths greater than D , in these experiments we prune using ψ_D . However, we have confirmed experimentally that typically such nodes are not visited frequently enough for pruning to have a significant impact.

Galcon a value of $\sigma_d = 0.75$ provided a good trade-off point since the supervised average costs began to sharply increase beyond that point. For Yahtzee we found that $\sigma_d = 0.75$ was a good trade-off point for all depths except the root. At the root we used a less aggressive pruning fraction $\sigma_0 = 0.5$ since the cost increased more quickly with σ_0 . Finally, all of our online evaluations of the learned partial policies within UCT are averaged across 1000 games and 95% confidence intervals are plotted.

FT-QCM v OPI. Figures 2(a) and 2(d) compare the search performance of UCT given various amounts of time per move, when using the partial policies learned by FT-QCM to that learned by OPI. FT-QCM has clear wins across most of the anytime curve, with OPI achieving parity at sufficiently large budgets in both domains. In results not shown for space reasons, we repeated this experiment for a variety of sets of the pruning fraction σ_d . In all cases, OPI never outperforms FT-QCM for any setting of σ_d and at best, achieves parity. Based on this result the remainder of our experimental evaluation is based on FT-QCM.

FT-QCM v baselines. We now compare the performance of pruning with FT-QCM partial policies to other approaches for injecting control knowledge into UCT. Most other approaches require an action scoring function of some form, for which we use the ranking function f_0 learned for the root partial policy by FT-QCM. The first baseline is *vanilla* UCT without any knowledge injection. Second, we use (decaying) heuristic bias (*HB*) in UCT as discussed in the related work, using the best settings found by experimenting with different methods of setting the bias component. Our third baseline uses a softmax policy, parameterized by f_0 , as the default policy (*DP*). During a rollout, an action is sampled with probability $\exp(f_0(s, a)) / \sum_{a' \in A(s)} \exp(f_0(s, a'))$ instead of uniform random selection. Our fourth and last baseline, *greedy*, does not search and selects root actions greedily according to the learned root ranking function. Note that this final baseline can be viewed as an attempt to apply traditional imitation learning to our problem.

Figures 2(b) and 2(e) give the results for Galcon and Yahtzee. For Galcon, which is two-player, the curves correspond to each method playing against *vanilla* UCT using the same budget on wall-clock time. The heuristic bias (*HB*) technique is unable to show any improvement over *vanilla* when evaluated in terms of performance versus wall-clock time. This is likely due to f_0 being inaccurate and highly biased when used as an evaluation function. Furthermore, tuning the complex interaction of Q estimates, exploration bonus and noisy bias terms is challenging and time-consuming. Note that *HB* does not decrease search performance unlike the informed default policy (*DP*) baseline. Here, the cost of using the expensive softmax rollout policy dwarfs any benefit. *DP* only seems to “pay for itself” at the largest budgets where parity is

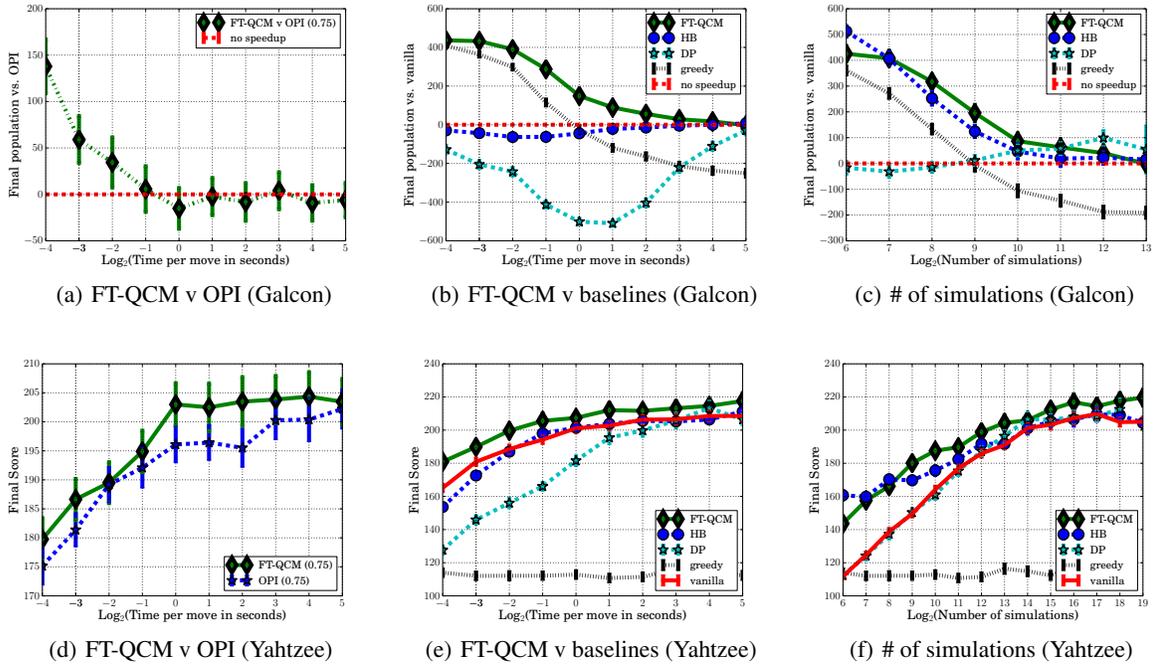

Figure 2: The first column shows a comparison between partial policies learned by FT-QCM and OPI when used inside UCT for different time bounds. In (a), the baseline player is OPI instead of *vanilla* (b,c). The second column shows the main experimental result where *FT-QCM* consistently outperforms baselines in both domains. *DP* and *HB* are surprisingly bad when knowledge costs are taken into account. The third column shows performance under zero knowledge costs by measuring the budget in simulation counts. Again, *FT-QCM* does well consistently but now *DP* and *HB* perform better.

achieved with the other baselines. The last baseline *greedy* demonstrates the limited strength of the reactive policy which is only competitive in Galcon when the search is very time-constrained. In Yahtzee, *greedy* is not competitive at any budget. We note that we have attempted to apply alternative imitation learning approaches to arrive at improved reactive policies, with little improvement. It appears that our feature representation is not powerful enough to accurately discriminate optimal actions. By relaxing our goal to learning a partial policy and integrating with search, we are able to benefit significantly from learning.

In both domains, FT-QCM outperforms every baseline at every budget considered. In Galcon, it has large wins on the left of the anytime curve and smaller wins on the right (not visible due to scale). In Yahtzee as well, FT-QCM achieves higher scores consistently. Furthermore, it continues to improve even at the largest budgets. In Yahtzee, increasing average score above 200 is extremely challenging and FT-QCM’s performance improvement is significant.

The cost of knowledge. It is initially surprising that the heuristic bias and informed default policy methods do not improve over *vanilla* MCTS. It turns out these methods do well as long as the cost of using knowledge is set to zero. That is, budgets are specified in terms of the number of simulations conducted by UCT instead of wall-clock time.

The difference is shown in Figures 2(c) and 2(f) where all the planners were re-run using simulations instead of time. Now *HB* outperforms *vanilla* in both domains while *DP* is competitive or wins by small amounts. However, our method FT-QCM is again better across most of the anytime curve in both domains. This result shows the importance of evaluating in terms of wall-clock time, which has not always been common practice in prior work.

7 SUMMARY

We have shown algorithms for offline learning of partial policies for reducing the action branching factor in time-bounded tree search. The algorithms leverage a reduction to i.i.d supervised learning and are shown to have bounds on the worst case regret. Experiments on two challenging domains show significantly improved anytime performance in Monte-Carlo Tree Search. One line of future work involves more sophisticated uses of partial policies during search (e.g., progressive widening, time-aware search control) for further improvements in anytime performance. We are also interested in iterating the learning process, where we use a learned ψ to guide deeper search in order to generate training data for learning an even better ψ .

Abstract

We consider the question of how unlabeled data can be used to estimate the true accuracy of learned classifiers. This is an important question for any autonomous learning system that must estimate its accuracy without supervision, and also when classifiers trained from one data distribution must be applied to a new distribution (e.g., document classifiers trained on one text corpus are to be applied to a second corpus). We first show how to estimate error rates exactly from unlabeled data when given a collection of competing classifiers that make independent errors, based on the agreement rates between subsets of these classifiers. We further show that *even when the competing classifiers do not make independent errors, both their accuracies and error dependencies can be estimated* by making certain relaxed assumptions. Experiments on two data real-world data sets produce estimates within a few percent of the true accuracy, using solely unlabeled data. These results are of practical significance in situations where labeled data is scarce and shed light on the more general question of how the consistency among multiple functions is related to their true accuracies.

1 INTRODUCTION

Estimating accuracy of classifiers is central to machine learning and many other fields. Traditionally, one estimates accuracy of a function based on its performance over a set of labeled test examples. This paper considers the question of under what conditions is it possible to estimate accuracy based instead on *unlabeled data*. We show that accuracy can be estimated exactly from unlabeled data in the case that at least three different approximations to the same function are available, so long as these functions make independent errors and have better than chance ac-

curacy. More interestingly, we show that even if one does not assume independent errors, one can still estimate accuracy given a sufficient number of competing approximations to the same function, by viewing the degree of independence of those approximations as an optimization criterion. We present experimental results demonstrating the success of this approach in estimating classification accuracies to within a few percentage points of their true value, in two diverse domains.

We consider a “multiple approximations” problem setting in which we have several different approximations, $\hat{f}_1, \dots, \hat{f}_N$, to some target boolean classification function, $f : \mathcal{X} \rightarrow \{0, 1\}$, and we wish to know the true accuracies of each of these different approximations, using only unlabeled data. The multiple functions can be from any source - learned or manually constructed. One example of this setting that we consider here is taken from the Never Ending Language Learning system (NELL) [Carlson et al., 2010]. NELL learns classifiers that map noun phrases (NPs) to boolean categories such as fruit, food and vehicle. For each such boolean classification function, NELL learns several different approximations based on different views of the NP. One approximation is based on the orthographic features of the NP (e.g., if the NP ends with the letter string “burgh”, it may be a city), whereas another uses phrases surrounding the NP (e.g., if the NP follows the word sequence “mayor of”, it may be a city). Our aim in this paper is to find a way to estimate the error rates of each of the competing approximations to f , using only unlabeled data (e.g., many unlabeled NPs in the case of NELL).

2 RELATED WORK

Other researchers have considered variants of this “multiple approximations” setting. For example, [Blum and Mitchell, 1998] introduced the co-training algorithm which uses unlabeled data to train competing approximations to a target function by forcing them to agree on classifications of unlabeled examples. Others have used the disagreement rate between competing approximations as a distance met-

ric to perform model selection and regularization [Schurmans et al., 2006; Bengio and Chapados, 2003]. Balcan et al. [2013] used disagreement along with an ontology to estimate the error of the prediction vector for multi-class prediction, from unlabeled data, under an assumption of independence of the input features given the labeling. Parisi et al. [2014] proposed a spectral method used to rank classifiers based on accuracy and combine their outputs to produce one final label, also under an assumption of independence of the input features given the labeling. Moreover, there has been work at developing more robust semi-supervised learning algorithms by using the concept of agreement rates [Collins and Singer, 1999] or some task specific constraints [Chang et al., 2007] to decide what should be added to the training data set. However, very few have tried to directly estimate actual per function error rates using agreement rates. In [Dasgupta et al., 2001] the authors PAC-bound the error rates using the pairwise agreement rates only, under the assumption that the functions make independent errors, and [Madani et al., 2004] estimate the average error of two predictors using their disagreements. [Donmez et al., 2010] is one of the few to estimate per-function error rates from unlabeled data. Here, the authors estimate the prediction risk for each function under the assumption that the true probability distribution of the output labels is known. Much of the emphasis of their work is on methods that use the known label distribution to estimate the error rate even of a single classifier, but agreements are used as well, especially under the assumption of conditional independence. In contrast, we propose here several methods for estimating actual function error rates from agreement rates, without making these assumptions.

The main contributions of this paper include: (1) formulating the problem of estimating the error rate of each of several approximations to the same function, based on their agreement rates over *unlabeled data*, as an optimization problem, (2) providing two different analytical methods that estimate error rates from agreement rates in this setting, one based on a set of simultaneous equations relating accuracies, agreements, and error dependencies, and a second, based on maximizing data likelihood, and (3) demonstrating the success of these two methods in two very different real-world problems. We consider our proposed methods a first step towards developing a self-reflection framework for autonomous learning systems.

3 PROPOSED METHODS

We introduce two different methods to estimate the error rates of binary functions in the multiple approximations setting described in section 1. Both methods are based on the idea of looking at the consistency between the different functions' predictions in order to determine the error rates of those functions. The first method consists of matching

the sample agreement rates of the functions with the exact formulas of those agreement rates written in terms of the functions' error rates. For the second method, we formulate the functions' predictions consistency as a probabilistic model and solve for the maximum likelihood estimate (MLE) of their error rates. Both methods estimate the individual error rates for each function, as well as the joint error rates of all possible subsets of those functions, based on the predictions made by these functions over a sample of unlabeled instances X_1, \dots, X_S .

In the following sections we denote the input data by X and the true binary output label by Y . We assume the input data X are drawn from some unknown distribution $P(X) = \mathcal{D}$, and $Y \in \{0, 1\}$. Let us consider N functions, $\hat{f}_1(X), \dots, \hat{f}_N(X)$ which attempt to model the mapping from X to Y . For example, each function might be the result of a different learning algorithm, or might use a different subset of the features of X as input. We define the error event $E_{\mathcal{A}}$ of a set of functions \mathcal{A} as an event in which every function in \mathcal{A} makes an incorrect prediction:

$$E_{\mathcal{A}} = \bigcap_{i \in \mathcal{A}} [\hat{f}_i(X) \neq Y], \quad (1)$$

where \cap denotes the set intersection operator and where \mathcal{A} contains the indices of the functions. We define the error rate of a set of functions \mathcal{A} (i.e. the probability that all functions in \mathcal{A} make an error together) as:

$$e_{\mathcal{A}} = \mathbb{P}_{\mathcal{D}}(E_{\mathcal{A}}), \quad (2)$$

where $\mathbb{P}_{\mathcal{D}}(\cdot)$ denotes the probability of an event under the distribution over the input data X .

3.1 AGREEMENT RATES METHOD

Let us define the agreement rate $a_{\mathcal{A}}$, for a set of functions \mathcal{A} as the probability that all of the functions' outputs¹ are the same:

$$a_{\mathcal{A}} = \mathbb{P}_{\mathcal{D}}\left(\left\{\hat{f}_i(X) = \hat{f}_j(X), \forall i, j \in \mathcal{A} : i \neq j\right\}\right). \quad (3)$$

This quantity can be defined in terms of the error rates of the functions in \mathcal{A} . In order to understand how we can write the agreement rate in terms of error rates let us consider a simple example where $\mathcal{A} = \{i, j\}$ (i.e. consider just the pairwise agreement rate between the functions f_i and f_j). The probability of two functions agreeing is equal to the probability that both make an error, plus the probability that neither makes an error:

$$a_{\{i,j\}} = \mathbb{P}_{\mathcal{D}}(E_{\{i\}} \cap E_{\{j\}}) + \mathbb{P}_{\mathcal{D}}(\bar{E}_{\{i\}} \cap \bar{E}_{\{j\}}), \quad (4)$$

where $\bar{\cdot}$ denotes the complement of a set. By using De Morgan's laws and the inclusion-exclusion principle we obtain,

¹Here, "outputs" is equivalent to "predictions".

using the notation defined in equation (2), an expression for the agreement rate between the two functions, in terms of their individual error rates, and their joint error rate:

$$a_{\{i,j\}} = 1 - e_{\{i\}} - e_{\{j\}} + 2e_{\{i,j\}}. \quad (5)$$

In the same way we obtain the following general result for the agreement rate of a set of functions \mathcal{A} of arbitrary size:

$$\begin{aligned} a_{\mathcal{A}} &= \mathbb{P}_{\mathcal{D}} \left(\bigcap_{i \in \mathcal{A}} E_i \right) + \mathbb{P}_{\mathcal{D}} \left(\bigcap_{i \in \mathcal{A}} \bar{E}_i \right), \\ &= e_{\mathcal{A}} + 1 - \mathbb{P}_{\mathcal{D}} \left(\bigcup_{i \in \mathcal{A}} E_i \right), \\ &= e_{\mathcal{A}} + 1 + \sum_{k=1}^{|\mathcal{A}|} \left[(-1)^k \sum_{\substack{I \subseteq \mathcal{A} \\ |I|=k}} e_I \right], \end{aligned} \quad (6)$$

where \cup denotes the set union operator and $|\cdot|$ denotes the number of elements in a set. For the first line we used the fact that the two events, $\{\bigcap_{i \in \mathcal{A}} E_i\}$ and $\{\bigcap_{i \in \mathcal{A}} \bar{E}_i\}$, are mutually exclusive, for the second line we used one of De Morgan's laws and for the last line we used the inclusion-exclusion principle.

In the next section we examine the most basic case, assuming that functions make independent errors and have error rates below 0.5, showing that we can solve exactly for the error rates provided that we have at least 3 different functions. In the subsequent section we examine the most general case, assuming that we have N functions that make errors with unknown inter-dependencies, and show that we can formulate this as a constrained numerical optimization problem whose objective function reflects a soft prior assumption regarding the error dependencies. Experimental results presented in a later section demonstrate the practical utility of this approach, producing estimated error rates that are within a few percentage points of the true error rates, *using only unlabeled data*.

KEY IDEA

The significance of equations (5) and (6) is that they relate the different agreement rates $a_{\mathcal{A}}$, which are easily estimated from *unlabeled* data, to the true error rates $e_{\mathcal{A}}$ of the functions, which are difficult to estimate without labeled data. Note that if we have a system of such equations with rank equal to the number of error rates mentioned, then we can solve exactly for these error rates in terms of the observed agreement rates. This is not the case in general, because given a set of functions, $\hat{f}_1, \dots, \hat{f}_N$, we obtain $2^N - N - 1$ agreement rate equations (one for each subset of two or more functions) expressed in terms of $2^N - 1$ error rates (one for each non-empty subset of functions). However, if we assume that the errors made by the N individual functions are independent, then we can express all of the $2^N - 1$ error rates in terms of N single-function error rates (e.g., $e_{\{i,j\}} = e_{\{i\}}e_{\{j\}}$) and we can then solve exactly for all error rates (given the additional assumption that error rates are better than chance). Furthermore, if we are unwilling to make the strong assumption that errors of individual functions are independent, then we can instead solve for the set of error rates that minimize the dependence among errors (e.g., among the infinite solutions to the underdetermined set of equations, we choose the solution that minimizes $\sum_{i,j} (e_{\{i,j\}} - e_{\{i\}}e_{\{j\}})^2$ - this idea can be easily extended to larger subsets than simply pairs of functions). The key idea in this paper is that the correspondence between easily-observed agreement rates and hard-to-observe error rates given by these equations can be used as a practical basis for estimating true error rates from unlabeled data.

3.1.1 3 Functions That Make Independent Errors

When we have 3 functions that make independent errors we can replace the $e_{\{i,j\}}$ term in equation (5) with the term $e_{\{i\}}e_{\{j\}}$. In this case we have only 3 unknown variables (i.e. the individual function error rates) and we have $\binom{3}{2} = 3$ equations (i.e. equation (5), for $1 \leq i < j \leq 3$). Therefore, we can directly solve for each error rate in terms of the three observed agreement rates:

$$e_{\{i\}} = \frac{c \pm (1 - 2a_{\{j,k\}})}{\pm 2(1 - 2a_{\{j,k\}})}, \quad (7)$$

where $i \in \{1, 2, 3\}$, $j, k \in \{1, 2, 3\} \setminus i$ with $j < k$ and:

$$c = \sqrt{(2a_{\{1,2\}} - 1)(2a_{\{1,3\}} - 1)(2a_{\{2,3\}} - 1)}, \quad (8)$$

where, for a set B and an element of that set b , the notation $B \setminus b$ denotes the set containing all elements in B except b . In practical applications, we can estimate the agreement rates among the competing functions, using a sample of unlabeled data X_1, \dots, X_S , as follows:

$$\hat{a}_{\{i,j\}} = \frac{1}{S} \sum_{s=1}^S \mathbb{I} \left\{ \hat{f}_i(X_s) = \hat{f}_j(X_s) \right\}, \quad (9)$$

where $\mathbb{I}\{\cdot\}$ evaluates to one if its argument statement is true and to zero otherwise.

In most practical applications the competing functions do not make independent errors. We next consider the more difficult problem of estimating the error rates from agreement rates, but without assuming independence of the function error events.

3.1.2 N Functions That Make Dependent Errors

When we have N functions that make dependent errors we rely on the agreement rate equation (6). We consider the agreement rates for all sets $\mathcal{A} = \{\mathcal{A} \subseteq \{1, \dots, N\} : |\mathcal{A}| \geq 2\}$ of functions (the agreement rate is uninformative for less

than two functions) and we obtain $2^N - N - 1$ equations by matching equation (6) to the sample agreement rate for each possible subset of functions. Given a sample of unlabeled data X_1, \dots, X_S , the sample agreement rate is defined as:

$$\hat{a}_{\mathcal{A}} = \frac{1}{S} \sum_{s=1}^S \mathbb{I} \left\{ \hat{f}_i(X_s) = \hat{f}_j(X_s), \forall i, j \in \mathcal{A} : i \neq j \right\}, \quad (10)$$

and is an unbiased estimate of the true agreement rate. Moreover, our unknown variables are all the individual function error rates along with all of the possible joint function error rates (let us denote the vector containing all those variables by e); that is a total of $2^N - 1$ unknown variables.

The set of $2^N - N - 1$ equations involving $2^N - 1$ unknown variables yields an underdetermined system of equations with an infinite number of possible solutions. We therefore cast this problem as a constrained optimization problem where the agreement equations form constraints that must be satisfied and where we seek the solution that minimizes the following objective:

$$c(e) = \sum_{\mathcal{A}: |\mathcal{A}| \geq 2} \left(e_{\mathcal{A}} - \prod_{i \in \mathcal{A}} e_i \right)^2. \quad (11)$$

It can be seen that we are basically trying to minimize the dependence between the error events², while satisfying all of the agreement rates constraints. We saw in section 3.1.1 that if we assume that the error events are independent, then we can obtain an exact solution. By defining our optimization problem in this way we are effectively relaxing this constraint by saying that we want to find the error rates that satisfy our constraints and that are, at the same time, as independent as possible. Most existing methods trying to estimate function error rates using only unlabeled data assume that the error events are independent; the main novelty of this method lies in the fact that *we relax all those assumptions* and make no hard or strict assumptions about our functions.

Note that we could also define different objective functions based on information we might have about our function approximations or based on different assumptions we might want to make. For example, one could try minimizing the sum of the squares of all the error rates (i.e. the L_2 norm of e) in order to obtain the most optimistic error rates that satisfy the agreement rates constraints. The novelty of our method partly lies in the formulation of the error rates estimation problem using only unlabeled data as a constrained optimization problem.

In this section we defined the model we are using for this method and the optimization problem we wish to solve. We call this method the AR method (i.e. Agreement Rates

²That can be seen from the fact that when the error events are independent we have that $e_{\mathcal{A}} = \prod_{i \in \mathcal{A}} e_i$.

method). In section 3.3 we define additional constraints that both this method and the maximum likelihood method (described in the next section) use.

3.2 MAXIMUM LIKELIHOOD METHOD

In this section we define a probabilistic model of the consistency in the functions' outputs, considering the most general case of having N functions that make potentially dependent errors. Let us denote the outputs of the functions on an i.i.d. sample of data X_1, \dots, X_S by $\hat{Y}_s = [\hat{f}_1(X_s), \dots, \hat{f}_N(X_s)]$, for $s \in \{1, \dots, S\}$. The \hat{Y}_s 's are independent and therefore we can define the likelihood of our model as:

$$L(e) = \mathbb{P}_{\mathcal{D}} \left(\hat{Y}_1, \dots, \hat{Y}_S | e \right) = \prod_{s=1}^S \mathbb{P}_{\mathcal{D}} \left(\hat{Y}_s | e \right), \quad (12)$$

where the parameter vector e contains all of the possible error events probabilities. More specifically, it contains all the e_I , for all $I \subseteq \{1, \dots, N\}$ and $|I| \in \{1, \dots, N\}$.

Now, \hat{Y}_s contains all the function outputs given data sample X_s . In order to compute $\mathbb{P}_{\mathcal{D}}(\hat{Y}_s | e)$ we need to consider the following two cases:

1. All functions agree with each other (i.e. \hat{Y}_s is a vector of all 1's or all 0's).
2. The functions can be split into two non-empty groups: those that output 1 and those that output 0.

The groups of functions with the same output can also be viewed as maximal cliques in the graph whose nodes consist of the functions and whose edges consist of the agreements between the functions (i.e. when there is an agreement between two functions there is an edge connecting their corresponding nodes in the graph and when there is no agreement between them there is no edge). By using this representation we call the first case the "one clique case" and the second case the "two cliques case". We are now going to consider those two cases separately.

One Clique Case: Let us denote the set of all function indices in the clique by \mathcal{C} (i.e. $\mathcal{C} = \{1, \dots, N\}$). In this case, either all functions make an error or none of them does. Therefore, for the probability of the current sample we have that:

$$\begin{aligned} \mathbb{P}_{\mathcal{D}}(\hat{Y}_s | e) &= \mathbb{P}_{\mathcal{D}} \left(\bigcap_{i \in \mathcal{C}} E_i \right) + \mathbb{P}_{\mathcal{D}} \left(\bigcap_{i \in \mathcal{C}} \bar{E}_i \right), \\ &= e_{\mathcal{C}} + 1 - \mathbb{P}_{\mathcal{D}} \left(\bigcup_{i \in \mathcal{C}} E_i \right), \\ &= e_{\mathcal{C}} + 1 + \sum_{k=1}^{|\mathcal{C}|} \left[(-1)^k \sum_{\substack{I \subseteq \mathcal{C} \\ |I|=k}} e_I \right], \end{aligned} \quad (13)$$

following an equivalent derivation to the one we used when defining the agreement rates in section 3.1.

Two Cliques Case: Let us denote the set of function indices in the first clique by \mathcal{C}_1 and those in the second clique by \mathcal{C}_2 . Then, we have two possible events:

1. All functions in \mathcal{C}_1 make an error and none of the functions in \mathcal{C}_2 makes an error.
2. All functions in \mathcal{C}_2 make an error and none of the functions in \mathcal{C}_1 makes an error.

Let $\mathbb{P}_{\mathcal{D}}^1(\hat{\mathbf{Y}}_s|e)$ denote the probability of $\hat{\mathbf{Y}}_s$ given that the first event of those two occurs, and let $\mathbb{P}_{\mathcal{D}}^2(\hat{\mathbf{Y}}_s|e)$ denote the probability of $\hat{\mathbf{Y}}_s$ given that the second event of those two occurs. It can be easily seen that those two events are mutually exclusive and so we have that $\mathbb{P}_{\mathcal{D}}(\hat{\mathbf{Y}}_s|e) = \mathbb{P}_{\mathcal{D}}^1(\hat{\mathbf{Y}}_s|e) + \mathbb{P}_{\mathcal{D}}^2(\hat{\mathbf{Y}}_s|e)$.

Following an equivalent derivation to the one we used when defining the agreement rates in section 3.1 we have that:

$$\begin{aligned} \mathbb{P}_{\mathcal{D}}^1(\hat{\mathbf{Y}}_s|e) &= \mathbb{P}_{\mathcal{D}}\left(\left[\bigcap_{i \in \mathcal{C}_1} E_i\right] \cap \left[\bigcap_{j \in \mathcal{C}_2} \bar{E}_j\right]\right), \\ &= \mathbb{P}_{\mathcal{D}}\left(\left[\bigcap_{i \in \mathcal{C}_1} E_i\right] \cap \overline{\left[\bigcup_{j \in \mathcal{C}_2} E_j\right]}\right), \quad (14) \\ &= e_{\mathcal{C}_1} + \sum_{k=1}^{|\mathcal{C}_2|} \left[(-1)^k \sum_{\substack{I \subseteq \mathcal{C}_2 \\ |I|=k}} e_{\{I \cup \mathcal{C}_1\}}\right]. \end{aligned}$$

For the second line we used one of De Morgan's laws and for the last line we used a modified form of the inclusion-exclusion principle. To understand the step we used to obtain the last line in the above equation let us consider a simple case with example events A , B_1 and B_2 . It is clear from the Venn diagram in figure 1, on the right, that:

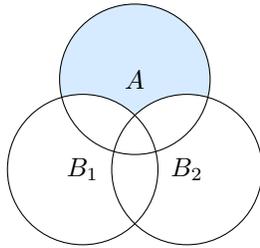

Figure 1: Venn diagram for the simple example used to explain our last step in equation (14).

$$\begin{aligned} \mathbb{P}(A \cap \overline{[B_1 \cup B_2]}) &= \mathbb{P}(A) \\ &\quad - \mathbb{P}(A \cap B_1) - \mathbb{P}(A \cap B_2) \quad (15) \\ &\quad + \mathbb{P}(A \cap B_1 \cap B_2). \end{aligned}$$

Our last step in equation (14) follows from extending this result using the inclusion-exclusion principle. In the same way we also get that:

$$\mathbb{P}_{\mathcal{D}}^2(\hat{\mathbf{Y}}_s|e) = e_{\mathcal{C}_2} + \sum_{k=1}^{|\mathcal{C}_1|} \left[(-1)^k \sum_{\substack{I \subseteq \mathcal{C}_1 \\ |I|=k}} e_{\{I \cup \mathcal{C}_2\}}\right]. \quad (16)$$

Having defined our likelihood function all that remains is to describe the optimization problem that we are solving to obtain the maximum likelihood estimate for e . We use the negative of the natural logarithm of the likelihood function (i.e. the log-likelihood function) as our objective function, which we want to minimize, and the details of how we perform the optimization are described in section 3.3. We call this the MLE method.

3.2.1 Regularization

In this subsection we define a method which is a slight modification of the above MLE method, in that it uses a modified objective function. The objective function considered in our MLE method is non-convex and hence has many local maxima. In order to avoid getting stuck into one of those local maxima, or at least try to avoid it, we here add a regularization term to the objective function. Following the same argument we used in constructing the objective function of the AR method, we define our new objective function, which we wish to minimize, as:

$$c(e) = -\log L(e) + \lambda \sum_{\mathcal{A}:|\mathcal{A}|\geq 2} \left(e_{\mathcal{A}} - \prod_{i \in \mathcal{A}} e_i\right)^2, \quad (17)$$

where λ is a hyperparameter whose value can be chosen arbitrarily. We call this the maximum a posteriori (MAP) method because the added term is equivalent to adding a Gaussian prior of a special form to the error rates estimates³. As we will see in the experiments section the performance of this method will depend on the value chosen for λ .

3.3 OPTIMIZATION

In sections 3.1 and 3.2 we defined the optimization problems corresponding to each of our methods. For all methods we use the TOMLAB Base Module v.7.7 “conSolve” solver. In the following sections we discuss: (1) some additional constraints that apply to all methods, (2) extensions of our approach to the case where multiple approximations are learned for each of several different target functions, and (3) an approximation that can make our methods much faster, more scalable and maybe even more accurate.

3.3.1 Error Rates Constraints

Our unknown variables include both individual function error rates and joint function error rates of those events. We need to impose constraints on the values that the joint function error rates can take. These constraints follow from basic rules of probability and set theory; they represent bounding joint event probabilities using the corresponding marginal event probabilities. These constraints are defined

³ λ can be interpreted as a function of the variance of that prior.

by the following equation:

$$e_{\mathcal{A}} \leq \min_{i \in \mathcal{A}} e_{\mathcal{A} \setminus i}, \quad (18)$$

for $|\mathcal{A}| \geq 2$. Furthermore, regarding the individual function error rates, it is easy to see that if we transform all e_i , for $i = 1, \dots, N$, to $1 - e_i$, the resulting agreement rates are equal to the original ones. A similar result holds for the likelihood function. In order to make our models identifiable we add the constraint that $e_i \in [0, 0.5)$, for $i = 1, \dots, N$, which simply means that our functions/binary classifiers perform better than chance. It is thus a very reasonable constraint⁴.

3.3.2 Dealing With Multiple Classification Problems

Up to this point we have assumed that there is a single target function and multiple approximations to that function. More generally though, we might have multiple target functions, or problem settings, and a common set of learning algorithms used for learning each one of those. For example, this is the case in NELL, where the different target functions correspond to different boolean classification problems (e.g., classifying NPs as “cities” or not, as “locations” or not, etc.). Multiple learning methods are utilized to approximate each one of those target functions (e.g., a classifier based on the NP orthography, a second classifier based on the NP contexts, etc.), so that each such classification problem, or target function, corresponds to an instance of our “multiple approximations” problem setting.

Of course we can apply our AR or our MLE methods to estimate accuracies separately for each target classification problem (and that is what we actually did in our experiments described in section 4). However, when we have multiple target functions to be learned and multiple learning methods shared across each, there is an interesting opportunity to further couple the error estimates across these different target functions. In equations (11) and (17) we introduced terms to minimize the dependency between the error rates of competing approximations. In the case where we have multiple target functions, we might introduce additional terms to capture other relevant assumptions. For example, we could introduce a term to minimize the difference in error dependencies between two learning methods across multiple classification problems (e.g., we could choose to minimize the difference in error dependencies between orthography-based and context-based classifiers trained for different classification problems).

3.3.3 Approximating High Order Error Rates

Once the agreement rate estimates (number of occurrences of each clique formation in the case of the MLE method

⁴It is important to understand here that in order for our methods to work in the first place, this constraint *must* hold for the classifiers that we are considering.

and the MAP method) have been calculated, the execution time of the optimization procedure for all proposed methods does not depend on the number of provided data samples⁵, S . It does however depend on the number of functions, N . This can be easily seen by considering the number of unknown variables we have which is equal to $2^N - 1$. As will be shown in section 4, the performance of all methods, in terms how good the obtained function error rate estimates are, increases with an increasing number of functions, N . It is therefore not a good idea to try to reduce N . So, we instead propose a way to reduce the execution time of the optimization procedure by approximating high order error rates, instead of estimating them directly.

We can estimate high order joint function error rates⁶ using lower order function error rates by using the following formula, for $|\mathcal{A}| > M_e$, where M_e is chosen arbitrarily:

$$e_{\mathcal{A}} = \frac{1}{|\mathcal{A}|} \sum_{i \in \mathcal{A}} e_{\mathcal{A} \setminus i} e_i. \quad (19)$$

With a high value of M_e we obtain better estimates but execution time is larger, and vice-versa. This estimate is based on the fact that the higher the order of the function error rates, the less significant the impact of an independence assumption between them.

Furthermore, the only available information regarding high order error rates comes from high order sample agreement rates⁶, $\hat{a}_{\mathcal{A}}$, which will likely be very noisy estimates of the true agreement rates. That is because there will be very few data samples where all of the functions in \mathcal{A} will agree and therefore the sample agreement rate will be computed using only a small number of data samples resulting in a noisy estimate of the true agreement rate. This motivates not directly estimating high order error rates, but instead approximating them using low order error rates. In fact, in the case that the sample agreement rates are too noisy, this approximation might even increase the quality of the obtained error rate estimates. By approximating high order error rates in the way described earlier, we are effectively ignoring the corresponding high order sample agreement rates (i.e. they are not used in our estimation) for the AR method.

⁵Even the execution time of the optimization procedure for the MLE method, which seems to depend on S , does not actually depend on it because there is only a fixed number of possible clique combinations one can obtain for a given number of functions, N . That number is equal to $2^N - 1$. In a large data sample we will have a lot of repeated samples in terms of the maximal cliques that they result in. We can compute the log-likelihood term for each one of those cliques only once and multiply it by the number of samples in which they each appear. This way our algorithm’s execution time only depends on N .

⁶By “order” of an error rate, $e_{\mathcal{A}}$, or agreement rate, $a_{\mathcal{A}}$, we mean the number of functions in set \mathcal{A} , or simply $|\mathcal{A}|$.

4 EXPERIMENTS

We present here experiments using two very different data sets, to explore the ability of our methods to estimate error rates in realistic settings without domain-specific tuning. For both data sets we used a set of labeled data examples to perform our experiments. We used the data samples without their corresponding labels to estimate agreement rates, and to then estimate error rates using our methods. We used the same examples with their labels to estimate each function’s true error rate, which we call from here on the “true error rate” of the function.

NELL Data Set: This data set consists of data samples where we use four binary logistic regression (LR) classifiers to predict whether a NP belongs to a specific category in the NELL knowledge base (e.g. is Monongahela a river?). The domain in this case is defined by the category (e.g. “beverage” and “river” are two different domains) and the four classifiers used were the following: (1) **ADJ:** A LR classifier that uses as features the adjectives that occur with the NP over millions of web pages, (2) **CMC:** A LR classifier that considers orthographic features of the NP (e.g. does the NP end with the letter string “burgh”? - more details can be found in [Carlson et al., 2010]), (3) **CPL:** A LR classifier that uses as features words and phrases that appear with the NP, and (4) **VERB:** A LR classifier that uses as features verbs that appear with the NP. Table 1 lists the NELL categories that we used as the domains in our experiments, along with the number of labeled examples available per category. Note the NP features used by these four classifiers are somewhat independent given the correct classification label.

Brain Data Set: Functional Magnetic Resonance Imaging (fMRI) data were collected while 8 subjects read a chapter from a popular novel [Rowling, 2012], one word at a time. The classification task is to find which of two 40 second long story passages correspond to an unlabeled 40 second time series of fMRI neural activity. For this binary classification task, we consider eight different classifiers, each making its prediction based on a different representation of the text passage (e.g., the number of letters in each word of the text passage, versus the part of speech of each word, versus emotions experienced by characters in the story, etc.). In this case different domains correspond to 11 different locations in the brain and we have 924 labeled examples per location. Additional details can be found in [Wehbe et al., 2014].

Our experimental results for both data sets are presented and discussed in the following two sections. As a performance measure we use the mean absolute deviation (MAD) between the true function error rates and the function error rates estimated from unlabeled data (i.e. we sum the absolute values of the element-wise differences of the true error

Table 1: A listing of the 15 NELL categories we used as the domains in our experiments, along with the number of labeled examples available per category.

Category	# Examples	Category	# Examples
animal	20,733	food	19,566
beverage	18,932	fruit	18,911
bird	19,263	muscle	21,606
bodypart	21,840	person	21,700
city	21,778	protein	21,811
disease	21,827	river	21,723
drug	20,452	vegetable	18,826
fish	19,162		

rates vector and the estimated error rates vector). We compute the MAD for the individual function error rates alone, for the pairwise function error rates (i.e. for $|\mathcal{A}| = 2$) alone and for all function error rates together. Note the higher order error rates are quite small, because it is rare for every one of the competing functions to simultaneously err. Therefore, we consider the individual and pairwise function error rates to be most diagnostic of how well our approach is working.

4.1 NELL DATA SET RESULTS

We initially applied the AR method using only the ADJ, the CPL and the VERB classifiers, while assuming that they make independent errors. The method for estimating error rates in this case is described in section 3.1.1. In this case we estimate only the individual function error rates. The resulting MAD is 2.82×10^{-2} ; that is, the average error estimate is within a few percent of the true error. Although encouraging, this MAD is poor in comparison to our less restricted methods described below, and indicates that the assumption that the classifiers make independent errors is an incorrect in this case (and in most other cases as a matter of fact). Some of the obtained error rates are not even within the interval $[0, 0.5]$ and are thus obviously incorrect, since we know by the construction of the problem that the true error rates lie in this interval. From now on we consider only the more general case of N functions that make dependent errors, thus making no independence assumptions.

Table 2 presents results for all three of our methods used with the entire NELL data set. It includes the results obtained when using all available data samples (i.e. the numbers shown in table 1) and when using only 50 data samples per category. It is clear from this table that the more data samples we have the better our methods perform, presumably due to the the more accurate estimates of the true agreement rates for the AR method, and for the other two methods, to the larger volume of evidence we have to incorporate into our likelihood. Furthermore, we see that the AR method performs significantly better than the other two methods. This could possibly be attributed to the fact that

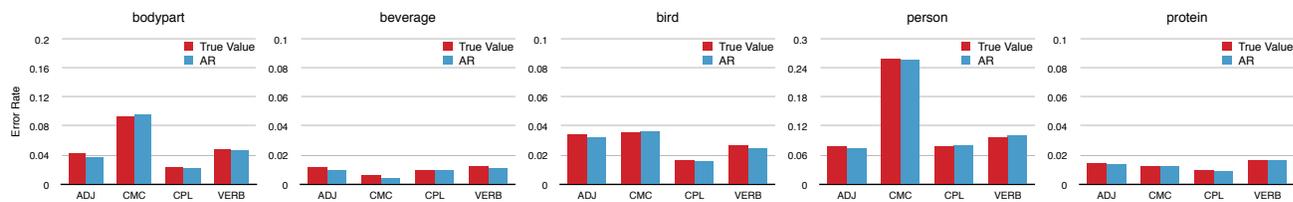

Figure 2: True errors (red bars) versus errors estimated from unlabeled data using AR method (blue bars), for four competing function approximations (ADJ, CMC, CPL and VERB), to five different target function domains (i.e. “bodypart”, “beverage”, “bird”, “person” and “protein”) using the NELL data set. Note each plot uses a different vertical scale to make it easier to observe the accuracy of the error rates estimates.

Table 2: Mean absolute deviation (MAD) of individual (Ind.), pairwise (Pair.) and all function error rates for the NELL data set, for all three proposed methods and for the cases where we use all of the available data samples and only 50 data samples per domain.

$\times 10^{-2}$	All Data Samples			50 Data Samples		
	Ind.	Pair.	All	Ind.	Pair.	All
AR	0.49	0.31	0.29	0.82	0.39	0.40
MLE	2.77	2.19	1.84	20.06	19.96	15.42
MAP	1.54	1.30	1.08	13.11	15.17	11.14

for this method we solve a convex optimization problem, whereas for the other two we solve a non-convex one and we possibly get stuck in local minima. Better numerical optimization solvers could possibly help with that. Finally, the MAP method performs better than the MLE method, presumably reflecting the correctness of our prior which attempts to minimize dependencies in errors across competing approximations. We did discover that the performance of the MAP method depends strongly on the choice of the λ parameter. In this case we selected $\lambda = 10$ simply because that value gave the regularization term the same order of magnitude as the log-likelihood term in the objective function. Moreover, now it becomes clear why the 2.82×10^{-2} MAD that we obtained when we assumed independent error events is quite a bad result. The AR method manages to achieve an MAD that is almost 6 times better than that.

We also run an experiment by using the approximation described in section 3.3.3 and setting $M_e = 2$ (i.e. considering only pairwise agreement rates). The individual functions MAD in this case was 0.52×10^{-2} , the pairwise one was 0.35×10^{-2} and the overall one was 0.31×10^{-2} . These results are worse than the ones we obtained without using this approximation, as expected, but they are still very good. This is important because it shows that this proposed approximation method is useful (there was a significant speedup as well - the code run 3 times faster).

From these results it is clear that the AR method, which also happens to be the simplest and fastest of the three methods we propose, performs better than the other proposed methods, for this data set, and also does not require tuning any parameters (as opposed to the MAP method).

INDEPENDENCE ASSUMPTION WEAKNESS

In order to make it more clear that the independence assumption is not very appropriate even in the case of NELL where a significant amount of effort has been put into having the NELL classifiers make independent errors, we provide here a measure of that dependence. We compute the following quantity for each domain:

$$\frac{1}{Z} \sum_{i,j} \left| \frac{e_{\{i,j\}}}{e_{\{i\}}e_{\{j\}}} - 1 \right|, \quad (20)$$

where Z is the total number of terms in the sum, and we average over all domains. That gives us a measure of the average dependence of the functions error rates across all domains. If the functions make independent errors, then this quantity should be equal to 0. We computed this quantity for the NELL data set using the sample error rates, which are an estimate of the true error rates (a pretty accurate estimate since we have about 20,000 data samples per domain), and we obtained a value of 8.1770, which is indeed quite far from 0. That indicates why our methods, and especially the AR method, do so much better than the exact solution when assuming independent errors.

Figure 2 provides a plot of the estimated error rates for the AR method, along with the true error rates for five randomly selected NELL classification problems (plots for all regions are not included in this paper due to space constraints). This plot gives an idea of how good the AR estimates are, and helps to make sense of the reported MAD values. As is easily seen in this plot, irrespective of the exact error estimate *the ranking of the competing function approximations based on error rate is recovered exactly* by using the AR method. And that is in fact true for each of the 15 NELL target function classification problems we evaluated – not only for the five shown in this figure.

4.2 BRAIN DATA SET RESULTS

Table 3 presents results for the brain data set, obtained when using 4 of the 8 competing function approximations (randomly selected to be classifiers 1, 3, 4 and 5) and when using all 8 of them. It is clear from that table that the more competing classifiers used, the better the quality of the resulting estimates. When using all 8 classifiers the AR method performs significantly better than the other two

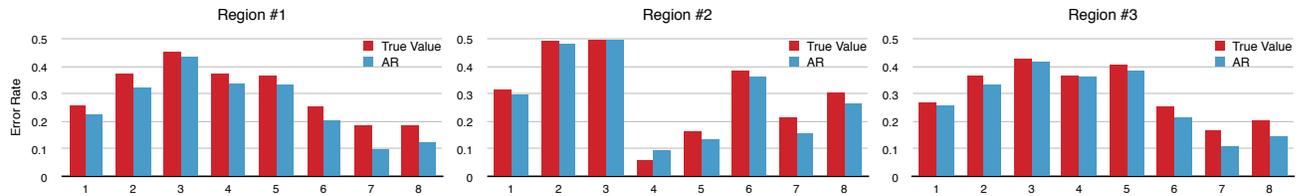

Figure 3: True errors (red bars) versus errors estimated from unlabeled data using AR method (blue bars), for eight competing function approximations (based on different story features), to three different target function domains (using neural activity from three different brain regions) using the brain data set. Note estimates from unlabeled data are quite close to true errors.

Table 3: Mean absolute error (MAE) of individual (Ind.), pairwise (Pair.) and all function error rates for the brain data set, for all three proposed methods and for the cases where we use 4 classifiers and 8 classifiers.

$\times 10^{-2}$	4 Classifiers			8 Classifiers		
	Ind.	Pair.	All	Ind.	Pair.	All
AR	10.97	6.60	6.50	4.36	4.14	2.01
MLE	10.60	8.34	7.64	32.02	12.33	4.50
MAP	9.61	18.19	11.16	27.95	18.60	7.26

methods. We have also included a plot of the estimated error rates for the AR method, along with the true error rates, for three randomly selected brain regions (i.e. domains), in figure 3 (it is clear from the figure that we can recover the ranking of the classifiers based on error rate, using the AR method, for this data set as well).

Note for this data set, for the case when we use 8 classifiers, the MLE method and the MAP method both perform poorly. This can probably be attributed to the optimization algorithm not being able to deal with those problems very well, due to their high dimensionality and non-convexity. These results could probably be improved by choosing a different optimization algorithm better suited for those problems. It is interesting to note that when we use only 4 classifiers the MLE and the MAP methods perform slightly better than the AR method in estimating the individual function error rates. However, they perform significantly worse when dealing with higher order error rates and so, overall, the AR method still dominates. Note that for this data set, for the MAP method, we also selected $\lambda = 10$ for the same reasons as for the NELL data set.

We also ran an experiment using the approximation described in section 3.3.3 and setting $M_e = 2$ (i.e. considering only pairwise agreement rates). The individual functions MAD in this case was 4.40×10^{-2} , the pairwise one was 4.06×10^{-2} and the overall one was 1.90×10^{-2} . These results are slightly better than the ones we obtained without using this approximation. This is important because it shows once again that this proposed approximation method is useful (there was a significant speedup as well - the code run 8 times faster). The better accuracy could possibly be attributed to two factors: (i) the problem is of much lower dimensionality and so the optimization algorithm might be

dealing better with it and (ii) the high order sample agreement rates might have been bad estimates of the true agreement rates due to insufficient data and so they might have affected our methods negatively.

5 CONCLUSION

We have introduced the concept of estimating the error rate of each of several approximations to the same function, based on their agreement rates over *unlabeled data* and we have provided three different analytical methods to do so: the AR method, the MLE method and the MAP method. Our experiments showed that the AR method performs significantly better than the other two methods for both data sets we considered. Our results are very encouraging and suggest that function agreement rates are indeed very useful in estimating function error rates. We consider this work to be a first step towards developing a *self-reflection framework* for autonomous learning systems.

There are several directions we would like to pursue to further improve upon the methods introduced here. Firstly, we wish to explore other interesting natural objectives one can aim to optimize, as described in section 3.1.2. It would also be very interesting to explore possible generalizations of our models to non-boolean, discrete-valued functions, or even to real-valued functions. Finally, apart from simply estimating function error rates, we want to explore how the obtained error rate estimates can be used to improve the learning ability of a system such as NELL, for example. In this context, we could try using our estimates in order to develop a more robust co-training framework. One very direct application of our methods would be to use the estimated error rates and their dependencies in order to combine the functions' outputs and obtain one final output.

Acknowledgements

We thank Leila Wehbe for providing us with the brain data set and Alan Ritter and Siddharth Varia for providing us with the NELL data set. Finally, we thank the previously mentioned people, Jayant Krishnamurthy and the anonymous reviewers for their helpful comments. This research has been supported in part by DARPA under contract number FA8750-13-2-0005 and in part by NSF grants IIS-1065251 and CCF-1116892.

Abstract

In this paper we study a general version of regression where each covariate itself is a functional data such as distributions or functions. In real applications, however, typically we do not have direct access to such data; instead only some noisy estimates of the true covariate functions/distributions are available to us. For example, when each covariate is a distribution, then we might not be able to directly observe these distributions, but it can be assumed that i.i.d. sample sets from these distributions are available. In this paper we present a general framework and a k -NN based estimator for this regression problem. We prove consistency of the estimator and derive its convergence rates. We further show that the proposed estimator can adapt to the local intrinsic dimension in our case and provide a simple approach for choosing k . Finally, we illustrate the applicability of our framework with numerical experiments.

1 INTRODUCTION

Machine learning has undergone a paradigm shift in the recent times. Traditional machine learning techniques focused on *simple* form of data such as features modeled as vectors in \mathbb{R}^p . However, with the advent of modern data collection methods datasets have not only become huge but also more complex, often involving objects like distributions, functions, and sets. Consider the example of brain connectivity mapping data. The brain contains billions of neurons with several trillion physical connections. Neuroimaging approaches like Diffusion Spectrum Imaging (DSI) attempt to visualize the underlying anatomical architecture of neural pathways by creating 3D probability distributions of water diffusion along nerve fiber bundles. In this ex-

ample the input data consists of distributions, instead of simple finite dimensional vectors. Likewise, there are many instances where the training data consists of functions. For example, whenever we encounter with time series data (e.g. time series of commodity's price, patient's health monitor, energy usage data), then we can always think of the instances as functions whose domain is the time.

Unfortunately, our understanding of algorithms for such complex data is still limited. Most of the existing machine learning and statistical techniques cannot handle such data, often resorting to ad-hoc approaches; thereby ignoring the underlying rich structure in the data. This necessitates the development of a different machine learning paradigm where the *true structure* in the complex data can be exploited. The goal of this paper is to further advance our knowledge of such algorithms.

One of the central issues working with complex functional data is that it is typically difficult to obtain the exact data (functions or distributions). Hence, our access to the data is often restricted to some noisy estimate of the data. For example, when the input variables are distributions, then it is more natural to assume that we only have finite samples from the distributions, but the true distributions (such as their pdf or cdf) are unknown to us. The empirical distribution can be viewed as a noisy estimate of the distribution. Similarly, in the case of function regression, we have the function values at some selected points rather than whole the function itself. We use the terms “measurement error” and “error in variable” to emphasize this issue of noise in the data.

Although, there have been a few attempts to tackle the issues of “error in variables” [3], most of the earlier works do not fully exploit the scenario where we have control over the measurement error. This is particularly relevant to the applications we are interested in such as distribution regression, where we can obtain more accurate measurements of the data by obtaining

more samples from the distribution.

While working with complex data, it is often desirable to have a simple yet powerful algorithms. One such algorithm often used in traditional machine learning is the k -Nearest Neighbor (k -NN) regression estimation. k -NN based algorithms are easy to use and robust. Furthermore, thanks to the extensive research on nearest neighbor search, there are many efficient algorithms for finding the nearest neighbors [1, 22, 5]. Additionally, k -NN estimators have the virtue of adapting to the local structure of the data [10]. Due to these factors, k -NN estimators are well-suited for complex data. However, very little is understood about these estimators in the context of functional data. To this end, we study the problem of k -NN regression on functional data with measurement error. We present our results in a rather broad framework since working within a general framework allows us to use the same tools across different settings and understand the underlying principles of k -NN estimators.

Main Contributions: Our contributions can be summarized as follows: (i) We provide a general framework for analysis of k -NN estimators for functional data. (ii) We prove consistency of the estimators under weak assumptions. (iii) We derive convergence rates for the estimators. (iv) We provide probabilistic bounds which exploit the local intrinsic structure of the probability measure. (v) We provide an adaptive procedure to select k by exploiting the local intrinsic structure. (vi) We apply the framework in two interesting settings, namely distribution regression and function regression. Due to space constraints, we relegate few longer proofs to the appendix.

2 RELATED WORK

Our work is related to functional data analysis, a new exciting field of statistics. We refer interested readers to [4, 17] for a comprehensive treatment of the topic. However, note that most of these works assume direct access to the covariates without any measurement error. This does not fit our framework for regression over distributions or functions.

One popular approach to deal with *distribution* covariates in ML tasks is to first embed the distributions into a reproducing kernel Hilbert space (RKHS) and then solve the learning problem using the standard machinery of kernel methods [20, 6, 18]. There are both parametric and non-parametric methods proposed along these lines. Parametric methods usually fit a parametric model to distributions for estimating inner products [9, 8, 12]. Few non-parametric methods for distributions also exist. For example, set kernels (since the samples from the distributions are repre-

sented by sets) or kernels over distributions may be used. In this context, it is worthwhile to note that the representer theorem was recently generalized for the space of probability distributions [13].

More recently, Póczos et al. [16] proposed a kernel regression approach for solving the regression problem with distribution covariates and real-valued responses. Convergence and sample complexity of the estimator were analyzed in the paper. Oliva et al. [14] provided a similar analysis for the case where the response is also a distribution. Function regression has also gained considerable interest recently. Oliva et al. [15] provided a functional analogue to the LASSO and studied the statistical properties of the estimator. The functional output case has been studied in [11]. None of these works, however, provide an adaptive algorithm which exploits the local structure of the data, such as the local intrinsic dimensionality. This is an important issue, because this dimension plays an important role in the convergence rate. To design efficient algorithms, it is important to be able to adapt to the local intrinsic dimensions. Another important difference between these algorithms and the estimator we propose here is that none of these algorithms are based on k -NN.

Our work is also related to the error in variables model [3]. However, unlike the latter case where the error is $O(1)$ and is not decreasing, we have control over the error and hence, can obtain very accurate (but expensive) measurements. This is true in the applications of our interest like distribution and function regression. As we will see later, we can exploit this additional flexibility to obtain faster rates of convergence.

There has been fairly extensive research on k -NN estimators for regression problem. Kpotufe et al. [10] study k -NN regression and show that it adapts to local intrinsic dimension. Furthermore, they also provide a simple method to choose k that nearly achieves the minimax rate. But these works do not address the problem of our concern, namely k -NN estimators for functional data with error in measurement.

Notation: The symbol $\mathbb{P}(E)$ is used to denote the probability of event E . We use $X \sim \mathbb{P}$ to denote that the random variable X has probability distribution \mathbb{P} . We use the $[n]$ and $i : j$ to denote the set $\{1, \dots, n\}$ and $\{i, \dots, j\}$ respectively. The symbol $\mathbb{E}(X)$ is used to denote the expectation of random variable X . We use $B(P, r)$ to denote a ball of radius r centered around P (where P is a point in some metric space).

3 PRELIMINARIES

We start this section with a formal discussion of k -NN based *regression* estimators. We denote by (\mathcal{P}, ρ) a

metric space \mathcal{P} with distance measure ρ . We assume that the space with this metric ρ is bounded, i.e., there exists a $\nu > 0$ such that $\rho(P, Q) \leq \nu$ for all $P, Q \in \mathcal{P}$. In a typical regression setting, we have m i.i.d samples $(\mathbf{P}, \mathbf{Y}) = \{(P_i, Y_i)\}_{i=1}^m$ from some unknown distribution over $(\mathcal{P} \times \mathbb{R})$, which is the space of input-output pairs. For example, many machine learning applications usually deal with finite dimensional Euclidean spaces, i.e., $\mathcal{P} = \mathbb{R}^p$ and ρ is the Euclidean distance. We assume that for our observations $\{Y_i\}$ it holds that

$$Y_i = f(P_i) + \gamma_i, \quad i \in [m],$$

where f is a regression function $f : \mathcal{P} \rightarrow \mathbb{R}$, and γ_i 's are noise variables with $\mathbb{E}[\gamma_i] = 0$ and variance $\mathbb{E}[\gamma_i^2] = \sigma^2$. We assume that the functional f is L -Lipschitz, i.e., $|f(P) - f(P')| \leq L\rho(P, P')$ for all $P, P' \in \mathcal{P}$. We use μ and μ_m to denote the marginal distribution and the empirical distribution on \mathcal{P} respectively. k -NN based regression is fairly well-understood when $\mathcal{P} = \mathbb{R}^p$ and ρ is the Euclidean distance [7].

In functional data analysis, as mentioned earlier, it is usually not possible to obtain the samples P_i exactly, and hence we have to deal with a *noisy* representation of P_i . Our goal, however, is still the same as in standard regression problems: to recover the function f . The type of representation generally depends on the application. For example, in the case of distribution regression (i.e., \mathcal{P} is the space of continuous distributions), we only have access to the samples from the distributions (and not the distributions themselves).

To formalize the notion of noisy representation of the input data, assume that we have m i.i.d. samples $(\hat{\mathbf{P}}, \mathbf{Y}) = \{(\hat{P}_i, Y_i)\}_{i=1}^m$ instead of (\mathbf{P}, \mathbf{Y}) . Here \hat{P}_i denotes the empirical estimation of distribution P_i .

In what follows, we will discuss the details of k -NN regression for functional data. We first look at the case of fixed k (given as an input). We will later investigate an approach to adaptively select k . The regression estimate at P (function or distribution) using $(\hat{\mathbf{P}}, \mathbf{Y})$ is defined as follows:

$$\hat{f}(P, \hat{P}_1, \dots, \hat{P}_m) = \sum_{j=1}^m Y_j W_j(P, \hat{P}_1, \dots, \hat{P}_m), \quad (1)$$

where

$$W_j(P, \hat{P}_1, \dots, \hat{P}_m) = \begin{cases} \frac{1}{k} & \text{if } \hat{P}_j \text{ is } k\text{-NN of } P \\ 0 & \text{otherwise.} \end{cases} \quad (2)$$

For the sake of brevity, we use $\hat{f}(P)$ and W_j to denote $\hat{f}(P, \hat{P}_1, \dots, \hat{P}_m)$ and $W_j(P, \hat{P}_1, \dots, \hat{P}_m)$ respectively. It should also be noted that more general approaches, such as the generalized version of k -NN with non-uniform weights can also be used through the means

of a kernel function [10]. For simplicity we only analyze the case of uniform weight in this paper, but all of our results can be extended to the aforementioned scenario.

Before we delve into the technical details of the regression estimator in Equation (1), we have to introduce the definition of doubling dimension, which will help us deriving upper bounds on the generalization error of the estimator. We just briefly describe the definition here, and refer interested readers to [10] for more details.

Definition 1. (*Doubling Dimension*) *The marginal distribution μ on \mathcal{P} has a doubling dimension at most d if there exists a constant C such that for all $P \in \mathcal{P}$ and $r \geq 0$, we have $\mu(B(P, r)) \leq C\epsilon^{-d}\mu(B(P, \epsilon r))$.*

To illustrate the concept, it is instructive to look at the simple case of Euclidean space \mathbb{R}^d and uniform measure over a closed ball. In this case, it is easy to see that the doubling dimension is d . While this describes a *global* notion of doubling dimension (since it holds uniformly over all region), we will also define and use a local notion in a later section. With this setting in mind, we now analyze the consistency and convergence rates of our estimator in a rather broad framework.

4 GENERAL FRAMEWORK FOR ANALYSIS OF k -NN ESTIMATORS

In this section, we first analyze consistency and convergence rates of the k -NN based estimator in Equation (1) within a general framework. We will investigate probabilistic bounds which depend on the local intrinsic structure of the measure μ on \mathcal{P} . Finally, we develop an approach which adapts to the local intrinsic dimension by carefully choosing k . Upper bounds on the convergence rates will also be derived for this estimator.

In this general framework, we assume certain application specific bounds on the estimation of \hat{P}_i . In particular, we assume the following:

- (i) $\mathbb{E}[\rho(P_i, \hat{P}_i)] \leq \Delta$.
- (ii) $\mathbb{P}(\rho(P_i, \hat{P}_i) - \mathbb{E}[\rho(P_i, \hat{P}_i)] > \epsilon) \leq \psi_i(\epsilon)$.

These bounds Δ and ψ_i will be instantiated for the cases of distribution and function regression in later sections. The first term provides an upper bound on how close P_i is to \hat{P}_i in expected sense, while the second term measures how far the random variable $\rho(P_i, \hat{P}_i)$ is from its expected value.

4.1 CONSISTENCY OF ESTIMATOR

In this section we analyze the L_2 -consistency of the k -NN estimator in Equation (1). In order to prove the consistency of our estimator, we assume that $k \rightarrow \infty$ but $k/m \rightarrow 0$ as $m \rightarrow \infty$. This assumption is typical in k -NN like estimators [7]. Additionally, we also assume that $\Delta \rightarrow 0$ as $m \rightarrow \infty$. Using these assumptions, we prove the following consistency result.

Theorem 1. *Suppose $k \rightarrow \infty$ and $\lim_{m \rightarrow \infty} k/m = 0$. Furthermore, we assume that $\Delta \rightarrow 0$ as $m \rightarrow \infty$. Then \hat{f} is consistent, i.e., $\lim_{m \rightarrow \infty} \mathbb{E}[|\hat{f}(P) - f(P)|^2] = 0$.*

Proof. The proof is in the appendix. \square

4.2 CONVERGENCE RATES

We now turn our attention towards the convergence rates of the estimator. In particular, we prove that if the measure μ has finite doubling dimension, then we can get a nonparametric convergence rate that depends on this dimension. We already know that $\mathbb{E}[\rho(\hat{P}_i, P_i)]$ is bounded by Δ . Lemma 5 in the Supplementary material provides a bound for uniform convergence.

Let $\Omega(\epsilon_0)$ denote the event that $\rho(\hat{P}_i, P_i) \leq \Delta + \epsilon_0$ for all $i \in [m]$. From Lemma 5, we know that this event occurs with at least probability $1 - \sum_i \psi_i(\epsilon_0)$. For feasibility, we assume that ϵ_0 is large enough such that $\sum_i \psi_i(\epsilon_0) < 1$.

Theorem 2. *Let $d \geq 3$, $m' = \lfloor \frac{m}{k} \rfloor$, and Δ, ϵ_0 be such that $\nu^{-d} \leq m' \leq (4(\Delta + \epsilon_0))^{-d}$ and $\sum_i \psi_i(\epsilon_0) \leq \frac{1}{m} \nu^{-d}$. Then the following holds:*

$$\mathbb{E}[|\hat{f}(P) - f(P)|^2] \leq \frac{\sigma^2}{k} + 2C'L^2m'^{-2/d} + 2L^2\Delta^2.$$

for some constant C' .

Proof. The proof is in the appendix. \square

4.3 LOCAL INTRINSIC BOUNDS FOR ESTIMATOR

We establish probabilistic convergence bounds for our estimators in this section, building on the work of [10]. Our rates exploit the local intrinsic dimension of the measure μ .

In order to obtain uniform bounds over \mathcal{P} , we assume additional structure in our problem setting. We assume that the VC-dimension of class \mathcal{B} of balls on (\mathcal{P}, ρ) is $\nu_{\mathcal{B}}$. To capture the notion of local intrinsic dimension, let us define the following.

Definition 2. (*Local Doubling Dimension*) *We say the measure μ has local doubling dimension d_l on $B(P, r)$ if we have $\mu(B(P, r')) \leq C\epsilon^{-d_l}\mu(B(P, \epsilon r'))$ for all $r' \leq r$ and $0 < \epsilon < 1$.*

Additionally, similar to [10], we assume a noise model that has uniformly bounded tails and variance. More formally, we have for all $\delta > 0$, there exists $t > 0$ such that $\sup_{P \in \mathcal{P}} \mathbb{P}_{Y|P}(|Y - f(P)| > t) \leq \delta$. Infimum amongst all such t is denoted by $T(\delta)$. Our goal is to obtain a probabilistic upper bound on $|\hat{f}(P) - f(P)|$.

The proof uses results from [10] with additional complexity arising due to the estimation error in the variables themselves. We capture the notion of local intrinsic dimension by the doubling dimension at the neighborhood of the point P . We have the following result for the consistency of the estimator:

Theorem 3. *Suppose μ has local doubling dimension d_l on $B(P, r)$. Let $\epsilon = (3Ck/m\mu(B(P, r)))^{1/d_l}$ and $\alpha_m = (\nu_{\mathcal{B}} \log(2m) + \log(16/\delta))/m$. Also, let $\delta' = \delta + \sum_i \psi_i(\epsilon_0)$. Suppose $\mu(B(P, \epsilon r)) \geq \epsilon^{d_l}\mu(B(P, r))/C \geq 3k/m$. Then the following holds with uniformly over all $P \in \mathcal{P}$ with probability at least $1 - \delta'$,*

$$|\hat{f}(P) - f(P)|^2 \leq \frac{2\nu_{\mathcal{B}}T^2(\delta/4m) \log(4m/\delta) + 16\sigma^2}{k} + 2L^2(r + 2(\Delta + \epsilon_0))^2 \left(\frac{3Ck}{m\mu(B(P, r))} \right)^{2/d_l}.$$

Proof. Let $\tilde{f}(P) = \sum_{i=1}^m W_i f(P_i)$. Using $\tilde{f}(P)$, we get the following:

$$|\hat{f}(P) - f(P)|^2 \leq 2 \underbrace{|\hat{f}(P) - \tilde{f}(P)|^2}_{\text{Variance}} + 2 \underbrace{|\tilde{f}(P) - f(P)|^2}_{\text{Bias}}$$

This is obtained by simple application of AM-GM inequality. We first derive an upper bound for the bias and then deal with the variance. We have:

$$\begin{aligned} |\tilde{f}(P) - f(P)| &= \left| \sum_{i=1}^m W_i (f(P_i) - f(P)) \right| \\ &\leq \sum_{i=1}^m W_i |f(P_i) - f(P)| \leq L \sum_{i=1}^m W_i \rho(P, P_i). \end{aligned}$$

The first step follows from the fact that $\sum_{i=1}^m W_i = 1$. The second and third steps follow from triangle inequality and Lipschitz continuity of f respectively. Consider the index set $\mathcal{J} = \{i_1, \dots, i_k\}$ which represents the nearest neighbors of P amongst $\{\hat{P}_1, \dots, \hat{P}_m\}$ where i_j is used to denote the index of the j^{th} nearest neighbor of P amongst $\{\hat{P}_1, \dots, \hat{P}_m\}$. Similarly, let us denote by i'_j and \mathcal{J}' , the index of j^{th} nearest neighbor of P amongst $\{P_1, \dots, P_m\}$ and corresponding index set respectively. Furthermore, we use r_k to

denote $\rho(P, P_{i'_k})$. In order to obtain an upper bound on the bias we need to analyze $\max_{j \in \mathcal{J}} \rho(P, P_j)$.

Let \mathcal{E} represent the event that $\max_i D(P_i, \hat{P}_i) \leq \Delta + \epsilon_0$ for all $i \in [m]$. We know that this event occurs with probability at least $1 - \sum_i \psi_i(\epsilon_0)$. Conditioned on the event \mathcal{E} , we have the following:

$$\rho(P, \hat{P}_i) \leq \rho(P, P_i) + \rho(P_i, \hat{P}_i) \leq \rho(P, P_i) + \Delta + \epsilon_0.$$

for all $i \in [m]$. This holds due to triangle inequality and the definition of the event \mathcal{E} . By similar argument, we also have $\rho(P, P_i) \leq \rho(P, \hat{P}_i) + \Delta + \epsilon_0$.

The rest of the argument is conditioned on the event \mathcal{E} . Using the above relation, we get the following: $\max_{i \in \mathcal{J}'} \rho(P, \hat{P}_i) \leq r_k + \Delta + \epsilon_0$. This is due to the fact that $\rho(P, \hat{P}_i) \leq \rho(P, P_i) + \Delta + \epsilon_0$ for all $i \in [m]$ and the definition of r_k . Using the above relation, we get the following inequality:

$$\max_{i \in \mathcal{J}} \rho(P, \hat{P}_i) \leq \max_{i \in \mathcal{J}'} \rho(P, \hat{P}_i) \leq r_k + \Delta + \epsilon_0.$$

The first step holds since \mathcal{J} are the indices for the k nearest neighbors of P amongst $\{\hat{P}_1, \dots, \hat{P}_m\}$. But we also have $\rho(P, P_i) \leq \rho(P, \hat{P}_i) + (\Delta + \epsilon_0)$ for all $i \in [m]$ (since we condition on \mathcal{E}). From above argument, the following holds:

$$\begin{aligned} \max_{i \in \mathcal{J}} \rho(P, P_i) &\leq \max_{i \in \mathcal{J}} \rho(P, \hat{P}_i) + (\Delta + \epsilon_0) \\ &\leq r_k + 2(\Delta + \epsilon_0). \end{aligned}$$

In order to complete our analysis for the bias, we need to bound the distance r_k . To this end, we appeal to the bound obtained in [10]. In particular, since $\mu(B(P, \epsilon r)) \geq 3k/m$, by invoking Lemma 10 we have $\mu_m(B(P, \epsilon r)) \geq k/m$. Therefore, with probability at least $1 - \delta$, we have $r_k \leq \epsilon r$. Finally, by using union bound over the event above and \mathcal{E} , we get the required bound on the bias.

To establish a bound on the variance, we resort to the bound from [10]. We derive the bounds here for the sake of completeness. We need to bound the term $|\hat{f}(P) - \tilde{f}(P)| = |\sum_{i=1}^m W_i (Y_i - f(P_i))|$. The key step is to utilize the classical VC-theory to obtain a bound on $|Y_i - f(P_i)|$.

More formally, let us first condition on the $\mathbf{P} = \{P_1, \dots, P_m\}$. By using the concept of VC-dimension and applying union bound, we can obtain the final result. We further restrict our attention to the event where $|Y_i - f(P_i)| < T(\delta_0)$ for all $i \in [m]$. Note that this event occurs with probability at least $1 - m\delta_0 > 0.5$. This is obtained by simple application of union bound. From Markov inequality, we have:

$$\begin{aligned} \mathbb{P}(\exists P \text{ s.t. } |\hat{f}(P) - \tilde{f}(P)| > 2\mathbb{E}(|\hat{f}(P) - \tilde{f}(P)|) + \epsilon) &\leq \\ \mathbb{P}(\exists P \text{ s.t. } |\hat{f}(P) - \tilde{f}(P)| > \mathbb{E}(|\hat{f}(P) - \tilde{f}(P)|) + \epsilon | \mathcal{E}) & \end{aligned}$$

Also note that,

$$\begin{aligned} \mathbb{P}(\exists P \text{ s.t. } |\hat{f}(P) - \tilde{f}(P)| > \mathbb{E}(|\hat{f}(P) - \tilde{f}(P)|) + \epsilon | \mathcal{E}) \\ \leq n^{\nu_B} \exp(-2k\epsilon^2/T^2(\delta_0)) \end{aligned}$$

This is due to the following facts: (i) changing any of the Y_i 's changes the function $|\hat{f}(P) - \tilde{f}(P)|$ by at most $T(\delta_0)/k$ and (ii) VC-dimension of the class of balls \mathcal{B} over \mathcal{P} is ν_B . Hence, using McDiarmid's inequality and union bound we get the above result. Let us take $\delta_0 = \delta/2m$. Now using a union bound over aforementioned events and rewriting the result using AM-GM inequality, we have with probability at least $1 - \delta$

$$\begin{aligned} |\hat{f}(P) - \tilde{f}(P)|^2 &< 8\mathbb{E}[|\hat{f}(P) - \tilde{f}(P)|^2] \\ &+ \frac{T^2(\delta/2m)}{k} (\nu_B \log(2m/\delta)) \end{aligned}$$

To complete the proof, we need to obtain an upper bound on the expected value $\mathbb{E}[|\hat{f}(P) - \tilde{f}(P)|^2]$. This is obtained in the following manner:

$$\begin{aligned} \mathbb{E}[|\hat{f}(P) - \tilde{f}(P)|^2] &= \mathbb{E}\left[\left|\sum_i (W_i Y_i - f(P_i))\right|^2\right] \\ &= \sum_i W_i^2 \mathbb{E}[|Y_i - f(P_i)|^2] \leq \sigma^2/k \end{aligned}$$

The second equality is obtained from the fact that $Y_i - f(P_i)$ are i.i.d random variables. The last inequality is obtained from the assumption that variance of $Y|P$ is bounded by σ^2 . Combining, the bounds obtained for the bias and variance, we get the required result. \square

Note the dependence of bounds on d_l , the local doubling dimension rather than d . When $d_l \ll d$, we have obtain much better rates of convergence locally.

4.4 SELECTION OF k AND ADAPTIVE CONVERGENCE RATES

In the previous section, we obtained convergence guarantees which depend on the local intrinsic dimension for k -NN estimators. A natural question to investigate is whether these bounds provide any principled approach to choose k . Intuitively, we can see that such an approach should respect the local structure at the query point P . We derive an approach to choose k by handling the bias-variance tradeoff. Here, Δ and

Algorithm 1 Adaptive Selection of k

- 1: Let $\theta \leq \log(4m/\delta)$, Δ and ϵ_0 be given.
 - 2: Let \hat{r}_i be i^{th} nearest neighbor amongst $\{\hat{P}_1, \dots, \hat{P}_m\}$.
 - 3: $k = \arg \min_i (\theta/i + \hat{r}_i^2 + 16(\Delta + \epsilon_0)^2 \hat{r}_i)$.
-

ϵ_0 are parameters to the algorithm. Δ can be obtained through upper bound on the error or through

estimation procedures. Intuitively, the above approach can be seen as choosing k which minimizes our upper bound. We make this intuition more formal by the following result.

Theorem 4. *Suppose μ has local doubling dimension d_l on $B(P, r)$. Suppose k is chosen according to Algorithm 1 for each $P \in \mathcal{P}$ and $\hat{f}(P)$ is the k -NN estimate. Assume $((\nu_{\mathcal{B}} \log(2m) + \log(16/\delta))/\theta < m^{4/(6+3d_l)})$. Let $\delta' = \delta + \sum_i \psi_i(\epsilon_0)$. Furthermore, let $r < R$ and $\mu(B(P, r)) > 6Cm^{-1/3}$. Then the following statement holds with probability at least $1 - \delta'$ simultaneously for all $P \in \mathcal{P}$.*

$$|\hat{f}(P) - f(P)|^2 \leq 2 \left(\frac{C}{\theta} + L^2 \right) \times \left((1 + 16R^2) \left(\frac{3C\theta}{m\mu(B(P, r))} \right)^{\frac{2}{2+d_l}} + 48(\Delta + \epsilon_0)^2 \right)$$

where $C = \nu_{\mathcal{B}} T^2 (\delta/4m) \log(4m/\delta) + 8\sigma^2$.

Proof. We have the following bound on $|\hat{f}(P) - f(P)|^2$ holds with probability at least $1 - \delta$:

$$\begin{aligned} |\hat{f}(P) - f(P)|^2 &\leq \frac{2C}{k} + 2L^2(r_k + 2(\Delta + \epsilon_0))^2 \\ &\leq \frac{2C}{k} + 2L^2(\hat{r}_k + 4(\Delta + \epsilon_0))^2 \\ &\leq \left(\frac{2C}{\theta} + 2L^2 \right) \left(\frac{\theta}{k} + (\hat{r}_k + 4(\Delta + \epsilon_0))^2 \right) \end{aligned}$$

The first and second inequalities holds from Theorem 3 and the fact that $|r_k - \hat{r}_k| \leq 2(\Delta + \epsilon_0)$ where r_k and \hat{r}_k denote the distance of k^{th} nearest neighbor of P amongst $\{P_1, \dots, P_m\}$ and $\{\hat{P}_1, \dots, \hat{P}_m\}$ respectively. Note that the procedure we use exactly minimizes $\frac{\theta}{k} + (\hat{r}_k + 4(\Delta + \epsilon_0))^2$. In order to complete the proof, we need to derive an upper bound for the estimator, we need to provide a bound on the minimum value of $\frac{\theta}{k} + (\hat{r}_k + 4(\Delta + \epsilon_0))^2$. To this end, we borrow ideas from [10] (Theorem 3), which provides a upper bound on the minimum value by explicitly constructing a k that has low objective value. We provide all the details here for sake of completeness.

Let $\tau = \theta^{d_l/(2+d_l)} \left(\frac{m\mu(B(P, r))}{3C} \right)^{2/(2+d_l)}$ Using our assumption on local doubling dimension, we have $\mu(B(P, r)) > 6C\theta m^{-d_l/(2+d_l)} \geq 6c\tau/m$. Let $\epsilon = \left(\frac{3C\tau}{m\mu(B(P, r))} \right)^{1/d_l}$. It is easy to see that from the above relationship that $\epsilon < 1$. Moreover, we have

$$\begin{aligned} \mu(B(P, \epsilon r)) &\geq \epsilon^{d_l} \mu(B(P, r))/C \geq 3\tau/m, \\ \alpha_m &= (\nu_{\mathcal{B}} \log(2m) + \log(8/\delta))/m \leq \frac{\theta}{m} m^{4/6+3d_l} \\ &\leq \frac{\theta}{m} m^{4/6+3d_l} \leq \frac{\tau}{m}. \end{aligned}$$

Therefore, using Lemma 10, we have $\mu_m(B(P, \epsilon r)) \geq \frac{\tau}{m}$ with probability at least $1 - \delta$. This in turn implies that $r_k \leq \epsilon r$ for all $k \leq \tau$.

The following argument shows a bound on r_k^2 . First, observe that if $k \leq \tau$, we have

$$r_k^2 \leq (\epsilon r)^2 \leq \left(\frac{3C\tau}{m\mu(B(P, r))} \right)^{2/d_l} R^2 = \frac{R^2\theta}{\tau} \leq \frac{R^2\theta}{k}.$$

The first and last inequalities holds since $k \leq \tau$. Let k_0 be the highest integer for which the above inequality holds. It can be proved that that either k_0 or $k_0 + 1$ is larger than τ . If $k_0 > \tau$, then the above statement is obviously true. For the case of $k_0 \leq \tau$, it is easy to see that $k_0 + 1 > \tau$ since k_0 is the highest integer for which $r_k^2 \leq \frac{R^2\theta}{k}$ and this holds for all $k \leq \tau$.

Suppose $k_0 \leq \tau$. Let $k_1 = k_0 + 1$ then $\theta/(k_1) < \epsilon^2$ since $\theta/k_1 < \theta/\tau = \epsilon^2$ when $k_1 > \tau$. Moreover, $r_{k_1} \leq 2^{1/d_l} \epsilon r$ since $\mu(B(P, 2^{1/d_l} \epsilon r)) \geq 6\tau/m$ which in turn implies $\mu_m(B(P, 2^{1/d_l} \epsilon r)) \geq 2\tau/m \geq k_1/m$ (by Lemma 10 and the fact that $k_1 \leq 2\tau$).

In the other case of $k_0 > \tau$, by similar argument, we can prove that $\theta/k_0 < \theta/\tau = \epsilon^2$ and $r_{k_0}^2 \leq R^2\epsilon^2$.

Therefore, either k_0 or k_1 , satisfy the following:

$$(\theta/k + 4r_k^2) \leq (1 + 16R^2)\epsilon^2 \quad (3)$$

Since k is chosen in such a way that it minimizes $(\theta/k + (\hat{r}_k + 4(\Delta + \epsilon_0))^2)$, we have the following bound:

$$\begin{aligned} |\hat{f}(P) - f(P)|^2 &\leq \left(\frac{2C}{\theta} + 2L^2 \right) \left(\frac{\theta}{k} + (\hat{r}_k + 4(\Delta + \epsilon_0))^2 \right) \\ &\leq \min_{k_0, k_1} \left(\frac{2C}{\theta} + 2L^2 \right) \left(\frac{\theta}{k} + (\hat{r}_k + 4(\Delta + \epsilon_0))^2 \right) \\ &\leq \min_{k_0, k_1} \left(\frac{2C}{\theta} + 2L^2 \right) \left(\frac{\theta}{k} + (2\hat{r}_k^2 + 32(\Delta + \epsilon_0)^2) \right) \\ &\leq \left(\frac{2C}{\theta} + 2L^2 \right) ((1 + 16R^2)\epsilon^2 + 48(\Delta + \epsilon_0)^2) \end{aligned}$$

The first and second inequalities follow from the fact that $|\hat{r}_k - r_k| \leq 2(\Delta + \epsilon_0)$ and the criteria of choosing k . The final inequality follows from Equation (3). This gives us the required result. \square

The above result shows adaptive convergence rates for the k -NN estimators. We now proceed towards applications of the general framework we just discussed.

5 APPLICATIONS

We discuss specific applications of the general framework introduced in the previous section. More specifically, we look at *distribution* regression and *function*

regression settings. We will see that by using appropriate instantiation of the bounds Δ and ψ_i in the general framework, the results for both these case follow in a straightforward manner.

5.1 DISTRIBUTION REGRESSION

We describe distribution regression problem in this section. We consider a regression problem where the input variables are from the space of continuous 1-Lipschitz probability distributions (i.e., $|P(x) - P(y)| \leq \|x - y\|$) on a compact subset $\mathcal{K} \subset \mathbb{R}^p$ (denoted by \mathcal{D}). In this case, $\mathcal{P} = \mathcal{D}$ and we assume ρ to the L_1 distance between distributions, i.e., $\rho(P, Q) = \|P - Q\|_1 = \int |P(x) - Q(x)| dx$. Note that $f : \mathcal{D} \rightarrow \mathbb{R}$. We assume that class of balls \mathcal{B} on \mathcal{D} have finite VC-dimension $\nu_{\mathcal{B}}$. Here, we have $Y_i = f(P_i) + \gamma_i$ for all $i \in [m]$.

The measurement error comes into play due to the fact that we do not have access to the probability distributions P_i directly; rather we observe samples $X_{i1}, \dots, X_{in_i} \sim P_i$. From these samples, we estimate the probability distributions through one of the several density estimation procedures like kernel density estimation, data clustering. Let $\hat{P}_1, \dots, \hat{P}_m$ be estimated probability distributions corresponding to P_1, \dots, P_m respectively. To summarize, we think of observations as $(\mathbf{P}, \mathbf{Y}) = \{(\hat{P}_i, Y_i)\}_{i=1}^m$ and our goal is to infer the function f . For ease of exposition, we assume that the number of samples observed for all the distributions, i.e., $n = n_i$ for all $i \in [m]$. To apply our framework, we need to instantiate the bounds Δ and ψ_i .

Bound Δ : We have the following bound on the expected error of estimation of the distributions.

Lemma 1. *Under above conditions, we have*

$$\mathbb{E}[\rho(\hat{P}_i, P_i)] \leq \tilde{C} n^{-1/(2+p)}$$

where \tilde{C} is a constant.

Using this result we can take $\Delta = \tilde{C} n^{-1/(2+p)}$. Refer [19] for details of the proof.

Bound ψ_i : We obtain the following bound ψ_i by using McDiarmid's inequality.

Lemma 2. *Under above conditions, we have*

$$\mathbb{P}(\rho(\hat{P}_i, P_i) > \mathbb{E}[\rho(\hat{P}_i, P_i)] + \epsilon) \leq e^{-\epsilon^2/2}$$

Therefore, $\psi_i(\epsilon) = \exp(-\epsilon^2/2)$ (see [2] for details).

By using the above bounds, we present the main results for distribution regression. Our first result is the consistency of the estimator \hat{f} . From Theorem 1, we have the following result. We set $\Delta = \tilde{C} n^{-1/(2+p)}$ and $\epsilon_0 = n^{-1/(2+p)}$.

Theorem 5. *(Consistency of Estimator) Suppose $k \rightarrow \infty$ and $\lim_{m \rightarrow \infty} k/m = 0$. Furthermore, we assume that $n = \Omega(\log^{(2+p)/p}(m))$. Then \hat{f} is consistent, i.e., $\lim_{m \rightarrow \infty} \mathbb{E}[|\hat{f}(P) - f(P)|^2] = 0$.*

The next result provides convergence rates for distribution regression by directly appealing to Theorem 2.

Theorem 6. *(Convergence Rate) Let $d \geq 3$ and $m' = \lfloor \frac{m}{k} \rfloor$. Assume $n \geq (2 \log(m) + 2d \log(\nu))^{(2+p)/p}$ and $d \log(1/\nu) \leq \log(m') \leq d \log(n)/(2+p) - d(\log(4 + 4\tilde{C}))$. Then the following holds:*

$$\mathbb{E}[|\hat{f}(P) - f(P)|^2] \leq \frac{\sigma^2}{k} + \frac{2C'L^2}{m'^{2/d}} + 2 \frac{\tilde{C}^2 L^2}{n^{2/(2+p)}}.$$

for some constant C' .

The following result shows that the convergence rates in fact depend on the local intrinsic dimension of the probability measure μ . This is obtain from Theorem 3 of the general framework.

Theorem 7. *(Adaptive Convergence Rates) Suppose μ has local doubling dimension d_l on $B(P, r)$. Let $\epsilon = (3Ck/m\mu(B(P, r)))^{1/d_l}$ and $\alpha_m = (\nu_{\mathcal{B}} \log(2m) + \log(16/\delta))/m$. Let $\delta' = \delta + m \exp(-n^{p/(p+2)}/2)$. Suppose $\mu(B(P, \epsilon r)) \geq \epsilon^{d_l} \mu(B(P, r))/C \geq 3k/m$. Then the following holds with uniformly over all $P \in \mathcal{P}$ with probability at least $1 - \delta'$,*

$$|\hat{f}(P) - f(P)|^2 \leq \frac{2\nu_{\mathcal{B}} T^2 (\delta/4m) \log(4m/\delta) + 16\sigma^2}{k} + 2L^2 \left(r + 2 \frac{(\tilde{C} + 1)}{n^{1/(2+p)}} \right)^2 \left(\frac{3Ck}{m\mu(B(P, r))} \right)^{2/d_l}.$$

The final result for distribution regression shows that by using Algorithm 1, we obtain reasonable adaptive convergence rates.

Theorem 8. *(k-Selection Convergence Rates) Suppose μ has local doubling dimension d_l on $B(P, r)$. Suppose k is chosen according to Algorithm 1 for each $P \in \mathcal{P}$ and $\hat{f}(P)$ is the k -NN estimate. Assume $((\nu_{\mathcal{B}} \log(2m) + \log(16/\delta))/\theta) < m^{4/(6+3d_l)}$. Let $\delta' = \delta + m \exp(-n^{p/(p+2)}/2)$. Furthermore, let $r < R$ and $\mu(B(P, r)) > 6Cm^{-1/3}$. Then the following statement holds with probability at least $1 - \delta'$ simultaneously for all $P \in \mathcal{P}$.*

$$|\hat{f}(P) - f(P)|^2 \leq 2 \left(\frac{C_0}{\theta} + L^2 \right) \times \left((1 + 16R^2) \left(\frac{3C\theta}{m\mu(B(P, r))} \right)^{\frac{2}{2+d_l}} + \frac{48(\tilde{C} + 1)^2}{n^{-2/(2+p)}} \right)$$

where $C_0 = \nu_{\mathcal{B}} T^2 (\delta/4m) \log(4m/\delta) + 8\sigma^2$.

5.2 FUNCTION REGRESSION

In this section, we describe another interesting application—function regression. Here, the input variables belong to the class of 1-Lipschitz (w.r.t Euclidean distance) functions on $[0, 1]$ (denoted by \mathcal{F}). For this case, we use $\rho(P, Q) = \|P - Q\|_2 = \sqrt{\int_0^1 (P(x) - Q(x))^2 dx}$ (norm in L^2 space of functions). We again focus only on the case when class of balls \mathcal{B} on $\mathcal{P} = \mathcal{F}$ have finite VC-dimension $\nu_{\mathcal{B}}$. The model is $Y_i = f(P_i) + \gamma_i$ for all $i \in [m]$ where P_i are functions. Similar to the distribution regression, we usually do not have access to the function themselves but only the ability to obtain noisy estimates of function value at certain points. For simplicity, we assume a deterministic design where we query at the points $\{X_{ij}\}_{j=1}^n$ where $X_{ij} = j/n$ for all $i \in [m]$ (see [21] for more details about deterministic design). Therefore, we have $Z_{ij} = P_i(X_{ij}) + \zeta_{ij}$ where ζ_{ij} is the noise variable with $\mathbb{E}[\zeta_{ij}] = 0$ and variance $\bar{\sigma}^2$.

We can intuitively think of function regression as 2-stage regression problem. We first estimate the functions themselves and then perform another regression on these functions to obtain the functional of interest f . From $\{(X_{ij}, Z_{ij})\}_{j=1}^n$, we can obtain estimated functions $\hat{P}_1, \dots, \hat{P}_m$ corresponding to P_1, \dots, P_m respectively. This model now fits our framework perfectly once we have appropriate bounds Δ and ψ_i . To obtain these bounds, we directly appeal to the following well-known bounds for regression.

Bound Δ : We have the following bound for Δ in the case of function regression.

Lemma 3. *Under the conditions mentioned above, we have*

$$\mathbb{E}[\rho(\hat{P}_i, P_i)] \leq \bar{C}n^{-1/3}$$

where \bar{C} is a constant.

Proof. From Jensen's inequality, we have

$$\mathbb{E}[\rho(\hat{P}_i, P_i)]^2 \leq \mathbb{E}[\rho^2(\hat{P}_i, P_i)] \leq \bar{C}^2 n^{-2/3}.$$

The last inequality follows from Corollary 1.2 of [21]. \square

Bound ψ_i : To obtain bound ψ_i , we resort to McDiarmid's inequality and obtain the following bound.

Lemma 4. *Under the conditions mentioned above, we have*

$$\mathbb{P}(\rho(\hat{P}_i, P_i) > \mathbb{E}[\rho(\hat{P}_i, P_i)] + \epsilon) \leq e^{-n\epsilon^2/2}$$

Proof. The result follows from simple application of McDiarmid's inequality. \square

We now state the main results for function regression by appealing to the general framework. We set $\Delta = \bar{C}n^{-1/3}$ and $\epsilon_0 = n^{-1/3}$. The following result shows consistency of estimator \hat{f} in case of function regression. This is obtained from Theorem 1.

Theorem 9. *(Consistency of Estimator) Suppose $k \rightarrow \infty$ and $\lim_{m \rightarrow \infty} k/m = 0$. Furthermore, we assume that $n = \Omega(\log^3(m))$. Then \hat{f} is consistent, i.e., $\lim_{m \rightarrow \infty} \mathbb{E}[|\hat{f}(P) - f(P)|^2] = 0$.*

The next result provides convergence rates for function regression by directly using Theorem 2.

Theorem 10. *(Convergence Rate) Let $d \geq 3$ and $m' = \lfloor \frac{m}{k} \rfloor$. Assume $n \geq (2 \log(m) + 2d \log(\nu))^3$ and $d \log(1/\nu) \leq \log(m') \leq d \log(n)/3 - d(\log(4 + 4\bar{C}))$. Then the following holds:*

$$\mathbb{E}[|\hat{f}(P) - f(P)|^2] \leq \frac{\sigma^2}{k} + \frac{2C'L^2}{m'^{2/d}} + \frac{2\bar{C}^2 L^2}{n^{2/3}}.$$

for some constant C' .

The following result shows that the convergence rates in fact depend on the local intrinsic dimension of the probability measure μ .

Theorem 11. *(Adaptive Convergence Rates) Suppose μ has local doubling dimension d_l on $B(P, r)$. Let $\epsilon = (3Ck/m\mu(B(P, r)))^{1/d_l}$ and $\alpha_m = (\nu_{\mathcal{B}} \log(2m) + \log(16/\delta))/m$. Let $\delta' = \delta + m \exp(-n^{1/3}/2)$. Suppose $\mu(B(P, \epsilon r)) \geq \epsilon^{d_l} \mu(B(P, r))/C \geq 3k/m$. Then the following holds uniformly over all $P \in \mathcal{P}$ with probability at least $1 - \delta'$,*

$$|\hat{f}(P) - f(P)|^2 \leq \frac{2\nu_{\mathcal{B}} T^2 (\delta/4m) \log(4m/\delta) + 16\sigma^2}{k} + 2L^2 \left(r + \frac{2(\bar{C} + 1)}{n^{1/3}} \right)^2 \left(\frac{3Ck}{m\mu(B(P, r))} \right)^{2/d_l}.$$

The final result for distribution regression shows that by using Algorithm 1, we obtain reasonable adaptive convergence rates.

Theorem 12. *(k-Selection Convergence Rates) Suppose μ has local doubling dimension d_l on $B(P, r)$. Suppose k is chosen according to Algorithm 1 for each $P \in \mathcal{P}$ and $\hat{f}(P)$ is the k -NN estimate. Assume $((\nu_{\mathcal{B}} \log(2m) + \log(16/\delta))/\theta) < m^{4/(6+3d_l)}$. Let $\delta' = \delta + m \exp(-n^{1/3}/2)$. Furthermore, let $r < R$ and $\mu(B(P, r)) > 6Cm^{-1/3}$. Then the following holds with probability at least $1 - \delta'$ simultaneously for all $P \in \mathcal{P}$.*

$$|\hat{f}(P) - f(P)|^2 \leq 2 \left(\frac{C_0}{\theta} + L^2 \right) \times \left((1 + 16R^2) \left(\frac{3C\theta}{m\mu(B(P, r))} \right)^{\frac{2}{2+d_l}} + \frac{48(\bar{C} + 1)^2}{n^{-2/3}} \right)$$

where $C_0 = \nu_{\mathcal{B}} T^2 (\delta/4m) \log(4m/\delta) + 8\sigma^2$.

Before ending our discussion of technical results, it is worthy to note two points: (i) Our rates are faster than the logarithmic rates that are sometimes obtained in measurement error nonparametric regression models as in [3]. As mentioned earlier, this is due to the fact that the measurement error corresponds to $\rho(\hat{P}_i, P_i)$ which is not Gaussian for finite n_i and which decreases when n_i increases. (ii) Typically, it is difficult to estimate the distance $\rho(P, Q)$ exactly. This presents additional level of complexity but it can be handled gracefully within our framework by viewing it as another measurement error.

6 EXPERIMENTS

Although the main contribution of our paper is to provide theoretical insights in k -NN based estimation for functional data, we also provide numerical evidence showing the empirical benefits of these estimators. We consider two distribution regression tasks: Beta distribution skewness and Gaussian distribution entropy estimation. In our experiments, we set all the n, n_1, \dots, n_m set sizes to the same values, which will be specified below. In the first experiment, we generated 325 sample sets from Beta($a, 3$) distributions where a was varied between $[3, 20]$ randomly. We constructed $m = 250$ sample sets for training, 25 for validation, and 50 for testing. Each sample set contained $n = 500$ i.i.d samples from Beta($a, 3$). Our task in this experiment was to learn the skewness of Beta(a, b) distributions, $f = \frac{2(b-a)\sqrt{a+b+1}}{(a+b+2)\sqrt{ab}}$. We considered the noiseless case, i.e., γ was set to zero. Our estimator is oblivious of the fact that the sample sets are coming from Beta distributions, and it does not know the skewness function values in the test sets either; its values are available only in the training and validation sets.

For obtaining the empirical probability distribution, we use kernel density estimation with Gaussian kernel. The optimal bandwidth of the kernel is obtained by cross validation. To estimate the L_2 distances between \hat{p}_i and p , we calculated their estimated values in 4096 points on a uniformly distributed grid between the min and max values in the sample sets, and then estimated the integral $\int (p(x) - \hat{p}_i(x))^2 d(x)$ with the rectangle method for numerical integration. To find the appropriate k , we selected the value from $\{1, \dots, 10\}$ that lead to minimum MSE on validation set. Figure 1(a) displays the predicted values for the 50 test sample sets, and we also show the true values of the skewness functions. As we can see the true and the estimated values are very close to each other.

In the next experiment, our task was to learn the entropy of Gaussian distributions. We chose a 2×2 covariance matrix $\Sigma = AA^T$, where $A \in \mathbb{R}^{2 \times 2}$, and A_{ij}

was randomly selected from the uniform distribution $U[0, 1]$. Just as in the previous experiments we constructed 325 sample sets from $\{\mathcal{N}(0, R(\alpha_i)\Sigma^{1/2})\}_{i=1}^{325}$. Where $R(\alpha_i)$ is a 2d rotation matrix with rotation angle $\alpha_i = i\pi/325$. From each $\mathcal{N}(0, R(\alpha_i)\Sigma^{1/2})$ distribution we sampled 500 2-dimensional i.i.d. points. Similarly to the previous experiment, 250 points was used for training, 25 for selecting appropriate bandwidth parameters, and 50 for training. Our goal was to learn the entropy of the first marginal distribution: $f = \frac{1}{2} \ln(2\pi e\sigma^2)$, where $\sigma^2 = M_{1,1}$ and $M = R(\alpha_i)\Sigma R^T(\alpha_i) \in \mathbb{R}^{2 \times 2}$. μ was zero in this experiment as well. Figure 1(b) displays the learned entropies of the 50 test sample sets. The true and the estimated values are close to each other in this experiment as well.

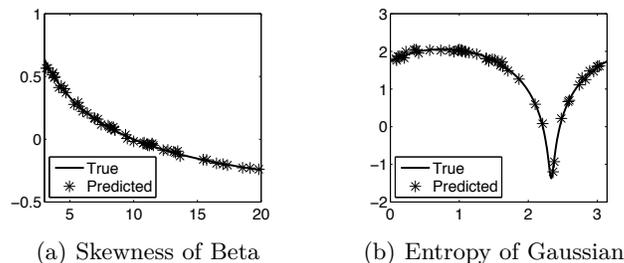

Figure 1: (a) Learned skewness of Beta($a, 3$) distribution. Axis x : parameter a in $[3, 20]$. Axis y : skewness of Beta($a, 3$). (b) Learned entropy of a 1d marginal distribution of a rotated 2d Gaussian distribution. Axes x : rotation angle in $[0, \pi]$. Axis y : entropy. The MSE in two cases are 7.1×10^{-3} and 8.6×10^{-2} respectively.

7 CONCLUSION

We presented a general framework for k -NN estimators for functional data with measurement error. We proved consistency of the estimator and derived upper bounds on the risk. We also analyzed probabilistic bounds capturing the local intrinsic dimension. Furthermore, we presented an algorithm for adaptively choosing k . Two interesting applications of our framework—distribution and function regression—were presented.

In future work, we would like to study lower bounds for the problem and compare our results with the minimax bounds. From practical point of view, it would also be interesting to use these estimators in conjunction with cover trees [1] to obtain fast k -NN estimators. Analyzing the empirical performance on large datasets is another interesting direction.

Abstract

We present new polynomial time algorithms for inference problems in Bayesian networks (BNs) when restricted to instances that satisfy the following two conditions: they have bounded treewidth and the conditional probability table (CPT) at each node is specified concisely using an *r-symmetric function* for some constant *r*. Our polynomial time algorithms work directly on the *unmoralized* graph. Our results significantly extend known results regarding inference problems on treewidth bounded BNs to a larger class of problem instances. We also show that relaxing either of the conditions used by our algorithms leads to computational intractability.

1 INTRODUCTION

Bayesian Networks (BNs) represent dependencies among a collection of probabilistic domain variables (Darwiche, 2009; Koller and Friedman, 2009; Pearl, 1988). Structurally, a BN $G(V, E)$ is a *directed acyclic graph* (dag) in which each node $v \in V$ represents a stochastic variable x_v ; a directed edge (u, v) in E indicates that variable x_v depends on x_u . Each node v is also associated with a table which gives the probability distribution of x_v conditioned on the variables on which x_v depends. Thus, a BN provides a simple graphical representation of the dependencies among domain variables.

BNs can be used to formulate and solve many problems in the context of stochastic decision support systems. For example, in the **inference problem**, the input is an observation (i.e., the observed values of a nonempty subset of variables) and the goal is to compute the conditional probability distribution for one specified variable. Such problems are useful in many application domains including medical diagnosis, weather forecasting, design of diagnosis-and-repair modules in computer systems, etc. (Darwiche, 2009; Koller and Friedman, 2009; Pearl, 1988).

Formal definitions of inference problems for BNs are provided in Section 2. In general, obtaining exact or approximate solutions to these problems is known to be computationally intractable (Abdelbar et al. (2000); Cooper (1990); Dagum and Luby (1993); Darwiche (2009); de Campos (2011)). Given the practical importance of these problems, researchers have tried to identify restricted versions of the problems which are useful in practice and which can be solved in polynomial time. An important development in this direction is the result of Lauritzen and Spiegelhalter (1988) who showed that for BNs of bounded treewidth, the inference problems can be solved in polynomial time using dynamic programming. Their approach uses the *moralized* form of the network, where for any node v , the parents of v are connected together as a clique. As a consequence, a moralized BN has bounded treewidth only when the maximum indegree in the unmoralized BN is also bounded.

Our Contributions: Our main result is a new dynamic programming approach that extends the class of BNs for which various inference problems can be solved in polynomial time. In particular, our approach does *not* use moralization. Instead, it works with the given BN and its tree decomposition. Thus, our algorithms are applicable to treewidth-bounded BNs, even when the indegrees of nodes are not bounded. Allowing nodes of unbounded indegree introduces a difficulty, namely that a fully specified CPT at a node may be exponentially large. To overcome this difficulty, we require the conditional probability tables at each node to be specified concisely using certain restricted classes of functions, called *r-symmetric functions* for some fixed integer *r*. As will be explained in Section 2, any CPT for a BN with maximum indegree *d* can be specified as a *d-symmetric function*. In other words, CPTs for BNs with bounded indegrees are a restricted form of *r-symmetric functions*. Thus, our approach identifies a larger class of BNs for which inference problems can be solved efficiently. Our results also extend the earlier results in (Bacchus et al., 2003; Courcelle et al., 2001; Fischer et al., 2008; Samer and Szeider, 2007) as discussed below. The results in (Courcelle et al., 2001; Fischer et al., 2008; Samer and Szeider, 2007) when combined with those of (Bacchus

et al., 2003) can be used to obtain polynomial time results for treewidth bounded BNs, with no a priori bound on indegree but whose CPTs are specified using certain threshold functions. As will be explained in Section 2.3, the class of r -symmetric functions is a strict superset of the class of threshold functions.

We also present hardness results that provide an indication of the tightness of our efficient solvability results. In particular, we show that if the conditional probability tables are not necessarily r -symmetric, then the inference problems remain computationally intractable (#P-hard) even when the BN is a directed tree (whose treewidth is 1). We also show that if the treewidth of the BN is not bounded, the inference problems remain computationally intractable even when each conditional probability table is expressed as a symmetric function. In other words, relaxing either of the assumptions (treewidth boundedness or r -symmetric functions) makes the problems computationally intractable. We note that the necessity of bounded treewidth for efficient inference in BNs was proven in Kwisthout et al. (2010) under a different assumption regarding complexity classes, namely, the Exponential Time Hypothesis (Impagliazzo and Paturi, 2001).

The remainder of this paper is organized as follows. Section 2 defines the necessary graph theoretic terms and presents formulations of several computations problems for BNs. It also discusses some related work on these problems. For space reasons, Section 3 presents our algorithm assuming that each CPT is a 1-symmetric function. Extensions of the result to other inference problems and r -symmetric functions (for any $r \geq 2$) are discussed in a longer version of this paper (Rosenkrantz et al., 2014). Section 4 mentions our hardness results whose proofs also appear in Rosenkrantz et al. (2014). Section 5 summarizes the paper and provides directions for future work.

2 DEFINITIONS AND PREVIOUS WORK

2.1 BAYESIAN NETWORKS

As mentioned earlier, a Bayesian network (BN) consists of a directed acyclic graph $G(V, E)$, where nodes represent stochastic domain variables and directed edges represent dependencies between variables. For simplicity, we will assume that each node represents a Boolean variable; the results in this paper can be extended to variables that assume values from a finite domain. Also, we do not distinguish between a node of the graph and the corresponding Boolean variable. When there is a directed edge $(u, v) \in E$, we say that u is a **parent** of v . The **indegree** of a node v is the number of parents of v .

At each node v , there is a **conditional probability table** (CPT) T_v which specifies the probability values for the variable v , conditioned on the parents of v . For a node v with indegree t , there are 2^t different combinations of

Boolean values for the parents of v . For each such combination, the table specifies the probability of v being 1 (or 0) conditioned on the parents assuming the given combination of values. Thus, the number of entries in T_v is 2^t . For a node v with indegree 0 (i.e., a node which does not have any parent), the table T_v specifies simply the probability of v assuming the value 1 (or 0).

Our formulation of the computational problems for BNs follows the presentation in (Bodlaender, 2004). For a node v , let $\mathcal{P}(v)$ denote the set of parents of v . Given a BN $G(V, E)$, a **configuration** c_V is an assignment of Boolean values to each variable in V . Given a subset $O \subseteq V$, a **partial configuration** c_O on O specifies a value for each variable in O . Given a configuration c_V (or a partial configuration c_O), we use $c_V(v)$ ($c_O(v)$) to denote the value of variable v in that configuration (partial configuration). With a slight abuse of notation, we also extend this notation to subsets of variables. Thus, given a configuration c_V (or a partial configuration c_O), and a subset $W \subseteq V$ ($W \subseteq O$), $c_V(W)$ ($c_O(W)$) denotes the combination of values assigned to the variables in W . Given a configuration c_V , its probability $\Pr\{c_V\}$ is given by

$$\Pr\{c_V\} = \prod_{v \in V} \Pr\{c_V(v) \mid c_V(\mathcal{P}(v))\}.$$

A configuration c_V is an **extension** of a partial configuration c_O if for each variable v that is assigned a value in c_O , $c_V(v) = c_O(v)$. Thus, an extension of a partial configuration c_O is obtained by specifying values for the variables that are not assigned a value in c_O .

We now provide formal definitions of two commonly considered problems in the context of BNs. In all these problems, we are given a partial configuration c_O (also called an **observation**) on a set of nodes $O \subseteq V$.

Definition 2.1 Let $G(V, E)$ denote the given BN.

1. **Inference Problem** (denoted by INF): Given an observation c_O and a variable v , find $\Pr\{v = 1 \mid c_O\}$, that is, the probability that v assumes the value 1 conditioned on the observation c_O .
2. **Most Probable Explanation Problem** (denoted by MPE): Given an observation c_O , find an extension of c_O which has the maximum probability among all the extensions of c_O .

For ease of exposition, we will also consider the following problem, which we call the **Probability Computation Problem** (denoted by PROB): Given an observation c_O , find the probability of c_O , that is, the sum of the probabilities of all configurations that are extensions of c_O . (Thus, when an observation does not specify a value for any variable, the answer to the PROB problem is 1.) The reasons for considering the PROB problem are twofold. First, the solution to INF problem for a node v and observation c_O can

be obtained using two calls to the PROB problem: compute $\Pr\{c_O\}$ and $\Pr\{v = 1 \wedge c_O\}$ using the algorithm for PROB and use the fact that

$$\Pr\{v = 1 \mid c_O\} = \frac{\Pr\{v = 1 \wedge c_O\}}{\Pr\{c_O\}}.$$

Second, an algorithm for the MPE problem can be devised along lines that are similar to that for the PROB problem. The main modification is that while the algorithm for the PROB problem computes sums of probability values at various steps, the algorithm for the MPE problem computes the maximum of the probability values.

2.2 TREE DECOMPOSITIONS

We now recall the standard definition of *tree decomposition* and *treewidth* from (Bodlaender, 1993), which will be used throughout this paper.

Definition 2.2 *Given a BN $G(V, E)$, a **tree decomposition** of G is a pair $(\{X_i \mid i \in I\}, T = (I, F))$, where $\{X_i \mid i \in I\}$ is a family of subsets of V and $T = (I, F)$ is an undirected tree with the following properties:*

1. $\bigcup_{i \in I} X_i = V$.
2. For every directed edge $e = (v, w) \in E$, there is a subset X_i , $i \in I$, with $v \in X_i$ and $w \in X_i$.
3. For all $i, j, k \in I$, if j lies on the path from i to k in T , then $X_i \cap X_k \subseteq X_j$.

The **treewidth** of a tree decomposition $(\{X_i \mid i \in I\}, T)$ is $\max_{i \in I} \{|X_i| - 1\}$. The **treewidth** of a graph is the minimum over the treewidths of all its tree decompositions.

A class of graphs is **treewidth bounded** if there is a constant k such that the treewidth of every graph in the class is at most k .

A number of problems that are NP-hard on general graphs can be solved efficiently when restricted to the class of treewidth-bounded graphs. A considerable amount of work has been done in this area (see for example (Bodlaender, 1997, 1993; Courcelle and Mosbah, 1993; Gottlob and Szeider, 2008; Robertson and Seymour, 1986) and the references therein).

As mentioned earlier, our approach works on the given (unmoralized) BN. To illustrate the effect of moralization on a BN, consider the class of directed star graphs defined as follows. For each $n \geq 2$, a directed star graph has n nodes and $n - 1$ directed edges; there is one center node and each of the other $n - 1$ nodes has just one outgoing edge to the center node. Thus, the center node has $n - 1$ parents and the moralized graph has a clique of size $n - 1$. Consequently, the moralized graph is not treewidth-bounded. On the other hand, it can be seen that according to Definition 2.2, this class of graphs has a treewidth of 1.

2.3 SPECIFYING CPTs CONCISELY

For a node v with q parents, the CPT T_v has 2^q entries. For BNs in which the maximum indegree is bounded, the CPTs can be given explicitly, since the size of each table is just a constant. However, when we consider BNs in which node indegrees may not be bounded, the size of a fully specified table may be exponential in the size of the BN. Thus, we need a method of specifying the CPTs concisely. We do this by identifying restricted classes of functions to specify the tables.

Consider a node v with q parents w_1, w_2, \dots, w_q . A CPT T_v for v specifies a probability value (i.e., the value $\Pr\{v = 1\}$) for each combination of values of the parents of v . Thus, T_v represents a function from $\{0, 1\}^q$ to the set of real values in $[0, 1]$. By restricting the class of functions, we can specify T_v concisely. We will now present some examples of such restrictions.

Definition 2.3 *Let q be an integer ≥ 1 . A function f from $\{0, 1\}^q$ to the set of real values in $[0, 1]$ is said to be **symmetric** if the value of f depends only on the number of inputs which are 1.*

Thus, a symmetric function f of q variables can be concisely described by specifying $q + 1$ probability values p_0, p_1, \dots, p_q , where p_i is the probability value when i of the inputs are 1, $0 \leq i \leq q$.

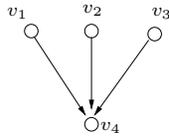

Example: Consider the BN shown in Figure 1. In that figure, nodes v_1, v_2 and v_3 don't have any parents. So, the probability values assigned to them can be thought of as symmetric functions where the only possible value for the number of parents is zero. Node v_4 has three parents. Hence, the CPT for v_4 shows the value of $\Pr\{v_4 = 1\}$ when 0, 1, 2 or 3 parents of v_4 are assigned the value 1. \square

For any integer $t \geq 0$, a **t -threshold** Boolean function on q inputs takes on the value 1 iff at least t of the inputs are 1. It is easy to see that each t -threshold function is a symmetric function. Thus, the class of symmetric functions contains all threshold functions.

One can define a further generalization of the class of symmetric functions as follows (Barrett et al., 2007b).

Definition 2.4 *Let $r \geq 1$ be a fixed integer. Let q be an integer ≥ 1 . A function f from $\{0, 1\}^q$ to the set of real values in $[0, 1]$ is said to be **r -symmetric** if the set of inputs can be partitioned into r classes such that the value of f depends only on the number of 1-valued inputs in each class.*

Note that any symmetric function is 1-symmetric. It can also be seen that for any $r \geq 1$, any r -symmetric function f of q variables can be concisely described by specifying $O(q^r)$ probability values. Since r is fixed, the size of the specification of any r -symmetric function is a polynomial in the size of the BN.

$$\Pr\{v_1 = 1\} = \Pr\{v_2 = 1\} = \Pr\{v_3 = 1\} = 1/2$$

CPT for node v_4 :

$ \mathcal{P}(v_4) $	$\Pr\{v_4 = 1 \mid \mathcal{P}(v_4)\}$
0	1/2
1	1/3
2	1/4
3	1/5

Figure 1: An Example of a BN where each CPT is a symmetric function. (Recall that $\mathcal{P}(v_4)$ denotes the set of parents of node v_4 .)

When a node has a bounded indegree, say d , the corresponding CPT can be thought of as a d -symmetric function, where each of the d classes contains exactly one input. Thus, the class of BNs in which each node has a bounded indegree is a special case of BNs in which each CPT is specified by an r -symmetric function for some fixed r .

2.4 OTHER RELATED WORK

Motivated by the practical importance of inference problems (Darwiche (2009); Koller and Friedman (2009); Pearl (1988)), research in this area has proceeded along two primary directions. The first direction focuses on the development of efficient heuristics that can be used to obtain fast solutions to problems that arise in practice (see for example (Chavira, 2007; Dechter, 1999) and the references cited therein). The second direction is the identification of restricted versions of inference problems that can be solved efficiently. As mentioned earlier, an important step in that direction is the work of Lauritzen and Spiegelhalter (1988) which provides an efficient algorithm for inference problems for treewidth bounded (moralized) BNs. Other references that consider inference problems for restricted versions of BNs include (Bacchus et al., 2003; Boutilier et al., 1996; Dechter, 1999; Jensen et al., 1990). The notion of causal independence used in Zhang and Poole (1996) relies on conditional probability tables that are essentially symmetric functions. We note that symmetric functions have also been used in the context of lifted inference (Jha et al., 2010; Milch et al., 2008).

Another approach, called **parent divorcing**, for dealing with nodes of large indegrees was introduced in Olesen et al. (1989). The basic idea of this approach is to modify a given BN in the following manner: when a node has a large indegree, the subgraph consisting of the node and its predecessors is replaced by a directed tree in which each node

has a small indegree. An example to illustrate this approach is shown in Figure 2. There are two main difficulties with this approach. The first is that the treewidth of the resulting BN can be much larger than that of the given BN. The second difficulty is that the size of domain from which newly added nodes take on values may become large. These two aspects can significantly increase the running time of the algorithms for the inference problems. Our algorithms can handle nodes with unbounded indegrees without modifying the given BN, provided all the CPTs are described by r -symmetric functions for some fixed integer r .

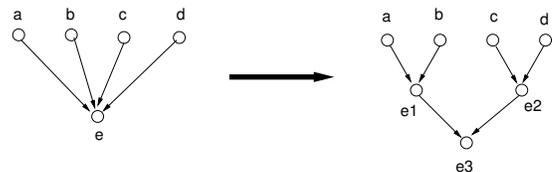

Figure 2: An Example for Parent Divorcing Approach

3 POLYNOMIAL TIME ALGORITHMS FOR TREewidth-BOUNDED BNs WITH SYMMETRIC CPTs

3.1 OVERVIEW

This section presents polynomial time algorithms for inference problems for treewidth-bounded BNs where each probability table is represented as symmetric function. We assume that a BN is given along with its tree decomposition of treewidth k , for some fixed integer $k \geq 1$. We will present the details of the algorithm for the PROB problem. The modifications needed to solve the INF and MPE problems and the extension of the algorithm to handle r -symmetric CPTs for any fixed $r \geq 1$ are presented in Rosenkrantz et al. (2014).

3.2 NOTES ON TREE DECOMPOSITION

This section mentions some known facts about tree decompositions and also reviews some related terminology.

We assume that one of the nodes of the tree decomposition is selected as the root so that the tree decomposition can be viewed as a rooted tree. When a graph G has bounded treewidth, it is well known that a tree decomposition $(\{X_i \mid i \in I\}, T = (I, F))$ of G can be constructed in time that is a polynomial in the size of G . Moreover, this can be done so that all of the following conditions hold (Barrett et al., 2007a,b; Bodlaender, 1997): (a) T is a binary tree; that is, each node of T has at most two children. (b) The number of nodes of T with fewer than two children is $\leq n$, the number of nodes in G . (c) The number of nodes of T with two children is $\leq n$. Our algorithm relies on this special form of tree decomposition.

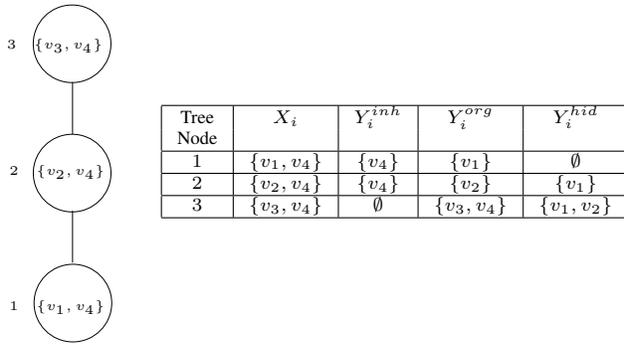

Figure 3: A Tree Decomposition for the BN shown in Figure 1. For each tree node i , X_i , Y_i^{inh} , Y_i^{org} and Y_i^{hid} denote respectively the set of explicit, inherited, originating and hidden nodes respectively, $1 \leq i \leq 3$.

The following terminology regarding nodes in tree decompositions is from (Barrett et al., 2007a,b). Let T be the given tree decomposition of a BN G . For a given node i of T , the nodes of G in X_i are called **explicit nodes** of i . If a given explicit node v of i is also an explicit node of the parent of i , then v is referred to as an **inherited node** of i ; and if v does not occur in the parent of i , then v is called an **originating node** of i .

We refer to the set of all explicit nodes occurring in the subtree of T rooted at i that are not explicit nodes of i as **hidden nodes** of i . (Thus, the hidden nodes of i are the union of the originating and hidden nodes of the children of i .) For any node i in T , we use Y_i^{inh} , Y_i^{org} and Y_i^{hid} to denote respectively the set of inherited nodes, the set of originating nodes and the set of hidden nodes of i .

Example: A tree decomposition for the BN of Figure 1 is shown in Figure 3. The tree decomposition has three nodes. For each tree node, the set of explicit nodes is shown. The table in Figure 3 also shows the explicit, inherited, originating and hidden sets for each tree node. \square

3.3 CONFIGURATIONS AND SIGNATURES

For all of the computational problems we consider, we are given a BN $G(V, E)$ and an observation c_O . As mentioned earlier, we also assume that each CPT is specified as a symmetric function.

Definition 3.1 (a) Let Y be a set of nodes of the given BN G . We refer to a partial configuration on Y as a **Y -configuration**.

(b) Let Y and W be not necessarily disjoint sets of nodes of the given BN G . We say that a given Y -configuration α and a given W -configuration β are **consistent** if for all nodes z in $Y \cap W$, $Y(z) = W(z)$.

(c) Given the observation (i.e., O -configuration) c_O , we

say that a given Y -configuration α is **valid** if for all nodes w assigned values in both c_O and α , $c_O(w) = \alpha(w)$, i.e., α and c_O are consistent.

(d) Γ_Y denotes the set of all valid Y -configurations.

(e) Let Y and W be sets of nodes of the given BN G such that $W \subseteq Y$. Let α be a Y -configuration. We define the **restriction** of α to W , denoted as $\alpha|_W$, to be the W -configuration obtained by restricting α to the members of W .

The concept of a signature, defined below for the case where each CPT is a symmetric function, plays an important role in our algorithm.

Definition 3.2 Let Y and W be not necessarily disjoint sets of nodes of the given BN G . (a) Let α be a Y -configuration. The **signature** of α with respect to W , denoted as $\text{sig}(\alpha, W)$, specifies for each $w \in W$, the number of parents of w that are set to 1 by α . We refer to such a signature as a (Y, W) -signature.

(b) Suppose Γ is a set of Y -configurations. The **signature** of Γ with respect to W is the union of the signature of each $\gamma \in \Gamma$ with respect to W .

(c) We say that a given (Y, W) -signature is **valid** if it is $\text{sig}(\alpha, W)$ for some valid Y -configuration α .

(d) $H_{Y,W}$ denotes the set of all valid (Y, W) -signatures.

Example: Consider the BN shown in Figure 1. Let $Y = \{v_2, v_3\}$ and $W = \{v_1, v_4\}$. Consider the Y -configuration γ which sets $v_2 = 0$ and $v_3 = 1$. It is easy to see that γ sets 0 of v_1 's parents to 1 and exactly one of v_4 's parents to 1. So $\text{sig}(\gamma, W)$, the signature of γ with respect to W , can be represented as $[v_1 : 0, v_4 : 1]$. Suppose that the given observation c_O does not specify the value of any node. Then Γ_Y contains four Y -configurations. By computing the union of the signatures of these four Y -configurations, it can be seen that $H_{Y,W}$ is the set $\{[v_1 : 0, v_4 : 0], [v_1 : 0, v_4 : 1], [v_1 : 0, v_4 : 2]\}$. \square

If σ is (Y, W) -signature, then for any $w \in W$, we use $\sigma(w)$ to denote the value specified by σ for w . Using this notation, we define some operations on signatures which produce new signatures. These operations are used by our algorithm.

Definition 3.3 Let G be a BN and let W be a subset of nodes of G .

(a) Let σ and σ' be two signatures with respect to a node set W . The **sum** of the two signatures is another signature denoted by $\sigma + \sigma'$, such that for each $w \in W$, $(\sigma + \sigma')(w) = \sigma(w) + \sigma'(w)$.

(b) Let σ be a signature with respect to a node set W and let Y be a subset of W . The **restriction** of σ to Y is another signature denoted by $\sigma|_Y$, such that for each $y \in Y$, $(\sigma|_Y)(y) = \sigma(y)$.

(c) Let σ be a signature with respect to a node set W and let X be a superset of W . The **extension** of σ to X is another signature denoted by $\text{ext}(g, X)$, which is defined as follows: for each $x \in X$, if $x \in W$, then $\text{ext}(\sigma, X)(x) = \sigma(x)$; otherwise, $\text{ext}(\sigma, X)(x) = 0$.

Suppose w is a node of G and η is a partial configuration that specifies a value (namely, $\eta(w)$) for w and for every parent of w . Given these values, the CPT for w specifies a probability value for $\eta(w)$, which will be denoted by $p_\eta(w)$. Suppose W is a subset of nodes of G and η is a partial configuration that specifies a value for every node $w \in W$ and for every parent of every node $w \in W$. Thus, for every node $w \in W$, the value $p_\eta(w)$ is defined. We define $p_\eta(W)$ by

$$p_\eta(W) = \prod_{w \in W} p_\eta(w). \quad (1)$$

We also need a slight extension of the definition given by Equation (1). Let X and Y be disjoint sets of nodes of G . Let η be a X -configuration, and σ be a (Y, X) -signature. Suppose that for a given node w in X , all the parents of w are in $X \cup Y$. Because the CPT for w is given by a symmetric function, given the values that η assigns to those parents of w that are in X , and the value that σ assigns to w , the CPT for w assigns a probability value to $\eta(w)$. We denote this probability value as $p_{\eta, \sigma}(w)$. Suppose that W is a subset of X , such that for every node w in W , all the parents of w are in $X \cup Y$. (Thus, for every node w in W , the value $p_{\eta, \sigma}(w)$ is defined.) Now, we define $p_{\eta, \sigma}(W)$ by

$$p_{\eta, \sigma}(W) = \prod_{w \in W} p_{\eta, \sigma}(w). \quad (2)$$

3.4 ALGORITHM FOR THE PROB PROBLEM

Recall that in the PROB problem, we are given a BN $G(V, E)$ and an observation c_O . The goal is to find the probability of c_O , that is, the sum of the probabilities of all (complete) configurations that are extensions of c_O . Let the constant k denote the treewidth of G . We assume that a tree decomposition $(\{X_i \mid i \in I\}, T = (I, F))$ of G satisfying all the conditions mentioned in Section 3.2 is also given and that each CPT is specified as a symmetric function.

3.4.1 Information Maintained by the Algorithm

Our algorithm solves the PROB problem for G by using bottom-up dynamic programming on the tree decomposition T . The algorithm maintains information for each node of T , as summarized in Table 1, and described below.

For each node i of T , the algorithm maintains the two sets of signatures $H_{Y_i^{hid}, X_i}$ and $H_{(Y_i^{hid} \cup Y_i^{org}), Y_i^{inh}}$, plus two tables of probability values, which we denote as Q^i and R^i . We now provide a description of these signature sets and tables for each tree node i .

- (a) $H_{Y_i^{hid}, X_i}$ is the set of all valid (Y_i^{hid}, X_i) -signatures. (Recall that Y_i^{hid} is the set of hidden nodes of i , and X_i is the set of explicit nodes of i .)
- (b) $H_{(Y_i^{hid} \cup Y_i^{org}), Y_i^{inh}}$ is the set of all valid $(Y_i^{hid} \cup Y_i^{org}, Y_i^{inh})$ -signatures. (Recall that Y_i^{inh} is the set of inherited nodes of i .)
- (c) Table Q^i contains a probability value for each pair in $\Gamma_{X_i} \times H_{Y_i^{hid}, X_i}$.

Consider a given element of table Q^i , say $Q^i[\alpha, \sigma]$, where α is a valid X_i -configuration and σ is a valid (Y_i^{hid}, X_i) -signature. The value of $Q^i[\alpha, \sigma]$ is defined by

$$Q^i[\alpha, \sigma] = \sum_{\beta} p_{\alpha \cup \beta}(Y_i^{hid}) \quad (3)$$

where the summation is over all β such that β is a valid Y_i^{hid} -configuration and $\text{sig}(\beta, X_i) = \sigma$.

Note that the definition of a tree decomposition ensures that every parent of a hidden node of i is either an explicit node or a hidden node of i , so each probability value occurring in Equation (3) is well defined.

- (d) Table R^i contains an entry for each pair in $\Gamma_{Y_i^{inh}} \times H_{(Y_i^{hid} \cup Y_i^{org}), Y_i^{inh}}$.

Consider a given element of table R^i , say $R^i[\psi, \theta]$, where ψ is a valid Y_i^{inh} -configuration and θ is a valid $(Y_i^{hid} \cup Y_i^{org}, Y_i^{inh})$ -signature. The value of $R^i[\psi, \theta]$ is defined by

$$R^i[\psi, \theta] = \sum_{\beta} p_{\psi \cup \beta}(Y_i^{hid} \cup Y_i^{org}) \quad (4)$$

where the summation is over all β such that β is a valid $(Y_i^{hid} \cup Y_i^{org})$ -configuration and $\text{sig}(\beta, Y_i^{inh}) = \theta$.

Note that the definition of a tree decomposition ensures that every parent of an hidden or originating node of i is either an explicit node or a hidden node of i , so each probability value occurring in Equation (4) is well defined.

Equation (3) represents the definition of each entry of Q^i . However, for a given α and σ , one *cannot* use the equation directly to efficiently compute the value of $Q^i[\alpha, \sigma]$, since the number of valid configurations to be considered may be exponential in the number of nodes of G . A similar comment applies to the computation of $R^i[\psi, \sigma]$ directly using Equation (4). How these values can be computed efficiently is discussed below.

3.4.2 Description of the Algorithm

Having described the information maintained by the algorithm, we can now describe the the bottom-up construction

Table 1: Notation used in Describing the Dynamic Programming Algorithm for the PROB Problem

Symbol	Explanation
X_i	The set of explicit nodes of tree node i .
Y_i^{inh}	The set of inherited nodes of tree node i .
Y_i^{org}	The set of originating nodes of tree node i .
Y_i^{hid}	The set of hidden nodes of tree node i .
Γ_{X_i}	The set of valid partial configurations on the explicit nodes of i
$\Gamma_{Y_i^{inh}}$	The set of valid partial configurations on the inherited nodes of i
$H_{Y_i^{hid}, X_i}$	The set of signatures of all valid partial configurations of the hidden nodes of i with respect to the explicit nodes of i .
$H_{(Y_i^{hid} \cup Y_i^{org}), Y_i^{inh}}$	The set of signatures of all valid partial configurations of the hidden and originating nodes of i with respect to the inherited nodes of i .
$Q^i[\Gamma_{X_i}, H_{Y_i^{hid}, X_i}]$	$Q^i[\alpha, \sigma]$ maps valid partial configuration α on the explicit nodes of i and signature $\sigma \in H_{Y_i^{hid}, X_i}$ to a probability value.
$R^i[\Gamma_{Y_i^{inh}}, H_{(Y_i^{hid} \cup Y_i^{org}), Y_i^{inh}}]$	$R^i[\psi, \theta]$ maps valid partial configuration ψ on the inherited nodes of i and signature $\theta \in H_{(Y_i^{hid} \cup Y_i^{org}), Y_i^{inh}}$ to a probability value.

of the signature sets and tables for each node of the tree decomposition. We present the construction in the following order.

1. First, we describe the computation of the set $H_{Y_i^{hid}, X_i}$ and the Q^i table for a *leaf* node i of the tree decomposition.
2. Next, we describe the computation of set $H_{(Y_i^{hid} \cup Y_i^{org}), Y_i^{inh}}$ and the R^i table for an *arbitrary* node i of the tree decomposition, given set $H_{Y_i^{hid}, X_i}$ and table Q^i .
3. Then we describe the computation of set $H_{Y_i^{hid}, X_i}$ and table Q^i for a *nonleaf* node i of the tree decomposition, given the $H_{(Y_i^{org} \cup Y_i^{hid}), Y_i^{inh}}$ sets and R tables for the children of node i in the tree decomposition.
4. Finally, we indicate how the solution for the PROB problem can be computed from the values computed for the root of the tree decomposition.

We now present the details for each of the four parts above. The operations on signatures defined in Section 3.3 are used in the following description.

Part 1: Consider a leaf node i of the tree decomposition. Note that leaf node i contains no hidden nodes. Consequently, $H_{Y_i^{hid}, X_i}$ consists of a single signature σ , which maps each node of X_i into the value 0.

For each valid X_i -configuration α , the table entry $Q^i[\alpha, \sigma]$ is given the value 1. Pseudocode for Part 1 is presented in Figure 4.

Part 2: For any node i of the tree decomposition, given set $H_{Y_i^{hid}, X_i}$ and table Q^i , set $H_{(Y_i^{hid} \cup Y_i^{org}), Y_i^{inh}}$ and table R^i can be constructed as follows.

1. $H_{Y_i^{hid}, X_i} = \{\sigma\}$, where σ is the signature that maps each node $x \in X_i$ into the value 0.
2. For each valid partial configuration α on X_i , $Q^i[\alpha, \sigma] = 1$.

Figure 4: Pseudocode for Part 1 of the Algorithm for the PROB Problem

Recall that $\Gamma_{Y_i^{org}}$ denotes the set of all valid Y_i^{org} -configurations, and that for any $\gamma \in \Gamma_{Y_i^{org}}$, $sig(\gamma, Y_i^{inh})$ denotes the signature of γ with respect to Y_i^{inh} .

Computation of $H_{(Y_i^{hid} \cup Y_i^{org}), Y_i^{inh}}$: This quantity is computed using the following equation

$$H_{(Y_i^{hid} \cup Y_i^{org}), Y_i^{inh}} = \bigcup_{\gamma, \sigma'} sig(\gamma, Y_i^{inh}) + (\sigma' | Y_i^{inh})$$

where the union is over each pair γ, σ' such that $\gamma \in \Gamma_{Y_i^{org}}$ and $\sigma' \in H_{Y_i^{hid}, X_i}$.

Computation of R^i : Consider an entry in the Q^i table, say $Q^i[\alpha, \sigma]$. The valid X_i -configuration α can be considered to be the disjoint union of the valid Y_i^{inh} -configuration $\psi = \alpha | Y_i^{inh}$ and the valid Y_i^{org} -configuration $\gamma = \alpha | Y_i^{org}$. Similarly, the (Y_i^{hid}, X_i) -signature σ can be considered to be the disjoint union of the (Y_i^{hid}, Y_i^{inh}) -signature $\sigma' = \sigma | Y_i^{inh}$ and the (Y_i^{hid}, Y_i^{org}) -signature $\sigma'' = \sigma | Y_i^{org}$. Let θ be the $(Y_i^{hid} \cup Y_i^{org}, Y_i^{inh})$ -signature $\sigma' + sig(\gamma, Y_i^{inh})$. The entry $Q^i[\alpha, \sigma]$ of the Q^i table contributes to the value of the entry $R^i[\psi, \theta]$ of the R^i table. The value of this contribution is the product $Q^i[\alpha, \sigma] * p_{\alpha, \sigma}(Y_i^{org})$.

The value $R^i[\psi, \theta]$ can be computed using the following equation.

$$R^i[\psi, \theta] = \sum Q^i[\alpha, \sigma] * p_{\alpha, \sigma}(Y_i^{org})$$

where the summation is over each $\alpha \in \Gamma_{X_i}$ and $\sigma \in H_{Y_i^{hid}, X_i}$ such that $(\psi = \alpha | Y_i^{inh}) \wedge (\theta = (\sigma | Y_i^{inh}) + sig(\alpha | Y_i^{org}, Y_i^{inh}))$.

Alternatively, the R^i table can be computed by first setting all the entries in the table to zero, and then scanning the Q^i table, adding the contribution of each entry in the Q^i table to the appropriate entry in the R^i table. Pseudocode for Part 2, using this approach to computing the R^i table, is shown in Figure 5.

Computation of $H_{(Y_i^{hid} \cup Y_i^{org}), Y_i^{inh}}$:

1. Initialization: $H_{(Y_i^{hid} \cup Y_i^{org}), Y_i^{inh}} = \emptyset$.
2. **for** each valid Y_i^{org} -configuration γ **do**
 - (i) Compute $\sigma' = sig(\gamma, Y_i^{inh})$, the signature of γ with respect to Y_i^{inh} .
 - (ii) **for** each signature $\sigma \in H_{Y_i^{hid}, X_i}$ **do**
 - (a) $\sigma'' = \sigma' + (\sigma | Y_i^{inh})$.
 - (b) $H_{(Y_i^{hid} \cup Y_i^{org}), Y_i^{inh}} = H_{(Y_i^{hid} \cup Y_i^{org}), Y_i^{inh}} \cup \{\sigma''\}$.

Computation of R^i :

for each valid Y_i^{inh} -configuration ψ **do**
for each signature $\theta \in H_{(Y_i^{hid} \cup Y_i^{org}), Y_i^{inh}}$ **do**
 $R^i[\psi, \theta] = 0$.

for each valid X_i -configuration α **do**

1. $\psi = \alpha | Y_i^{inh}$.
2. **for** each signature $\sigma \in H_{Y_i^{hid}, X_i}$ **do**
 - (a) Compute $\theta' = sig(\alpha | Y_i^{org}, Y_i^{inh})$, the signature of $\alpha | Y_i^{org}$ with respect to Y_i^{inh} .
 - (b) $\theta = (\sigma | Y_i^{inh}) + \theta'$.
 - (c) $R^i[\psi, \theta] = R^i[\psi, \theta] + Q^i[\alpha, \sigma] * p_{\alpha, \sigma}(Y_i^{org})$.

Figure 5: Pseudocode for Part 2 of the Algorithm for the PROB Problem

Part 3: We now consider computing set $H_{Y_i^{hid}, X_i}$ and table Q^i for a nonleaf node i of the tree decomposition.

Case 1: Nonleaf node i has only one child.

Let i_1 denote the child of i in the tree decomposition. We compute $H_{Y_i^{hid}, X_i}$ as

$$H_{Y_i^{hid}, X_i} = \{ext(\theta_1, X_i) \mid \theta_1 \text{ is in } H_{(Y_{i_1}^{hid} \cup Y_{i_1}^{org}), Y_{i_1}^{inh}}\}.$$

Given the table R^{i_1} for i_1 , the table Q^i is constructed as follows. Consider a given entry $Q^i[\alpha, \sigma]$, for X_i -

configuration α and (Y_i^{hid}, X_i) -signature σ . The value of this entry is set to the value of $R^{i_1}[\alpha | Y_{i_1}^{inh}, \sigma | Y_{i_1}^{inh}]$.

Case 2: Nonleaf node i has two children.

Let i_1 and i_2 denote the children of i in the tree decomposition. We compute $H_{Y_i^{hid}, X_i}$ as

$$H_{Y_i^{hid}, X_i} = \bigcup_{\theta_1, \theta_2} ext(\theta_1, X_i) + ext(\theta_2, X_i).$$

where the union is over all pairs θ_1 and θ_2 such that $\theta_1 \in H_{(Y_{i_1}^{hid} \cup Y_{i_1}^{org}), Y_{i_1}^{inh}}$ and $\theta_2 \in H_{(Y_{i_2}^{hid} \cup Y_{i_2}^{org}), Y_{i_2}^{inh}}$.

The tables R^{i_1} and R^{i_2} for tree nodes i_1 and i_2 are combined to produce table Q^i for tree node i as follows. For any $\theta_1 \in H_{(Y_{i_1}^{hid} \cup Y_{i_1}^{org}), Y_{i_1}^{inh}}$ and $\theta_2 \in H_{(Y_{i_2}^{hid} \cup Y_{i_2}^{org}), Y_{i_2}^{inh}}$, let

$$\sigma = ext(\theta_1, X_i) + ext(\theta_2, X_i).$$

For any valid X_i -configuration α , the table entries $R^{i_1}[\alpha | Y_{i_1}^{inh}, \theta_1]$ and $R^{i_2}[\alpha | Y_{i_2}^{inh}, \theta_2]$ together contribute to the value of $Q^i[\alpha, \sigma]$. The value of this contribution is $R^{i_1}[\alpha | Y_{i_1}^{inh}, \theta_1] * R^{i_2}[\alpha | Y_{i_2}^{inh}, \theta_2]$.

Consider a given a valid X_i -configuration α and signature σ in $H_{Y_i^{hid}, X_i}$. We can compute $Q^i[\alpha, \sigma]$ as a sum of products:

$$Q^i[\alpha, \sigma] = \sum_{\theta_1, \theta_2} R^{i_1}[\alpha | Y_{i_1}^{inh}, \theta_1] * R^{i_2}[\alpha | Y_{i_2}^{inh}, \theta_2]$$

where the summation is over all pairs θ_1 and θ_2 such that $\theta_1 \in H_{(Y_{i_1}^{hid} \cup Y_{i_1}^{org}), Y_{i_1}^{inh}}$, $\theta_2 \in H_{(Y_{i_2}^{hid} \cup Y_{i_2}^{org}), Y_{i_2}^{inh}}$ and $\sigma = ext(\theta_1, X_i) + ext(\theta_2, X_i)$.

Alternatively, the Q^i table can be computed by first setting all the entries in the table to zero, and then scanning the R^{i_1} and R^{i_2} tables, adding the contribution of each pair of entries in these tables to the appropriate entries in the R^i table. Pseudocode for Part 3, using this approach to computing the Q^i table, is shown in Figure 6.

Part 4: Let r be the root node of the tree decomposition. The root node has no inherited nodes, so $Y_r^{inh} = \emptyset$. Consequently, $\Gamma_{Y_r^{inh}}$ contains only the empty partial configuration, which we denote as ψ_\emptyset . Also, set $H_{(Y_r^{org} \cup Y_r^{hid}), Y_r^{inh}}$ contains only the empty signature, which we denote as σ_\emptyset . Table R^r consists of a single entry, $R^r[\psi_\emptyset, \sigma_\emptyset]$. The value of $R^r[\psi_\emptyset, \sigma_\emptyset]$ is the solution to the PROB problem.

3.4.3 Running Time Analysis

We now state a result that which gives the running time of the algorithm presented in the previous section. A proof of this result appears in Rosenkrantz et al. (2014).

Lemma 3.4 *The dynamic programming algorithm for the PROB problem runs in $O(n^{2k+3})$ time, where n is the number of nodes in the given Bayesian network G and k is the treewidth of G .*

Case 1: Node i has only one child i_1 in the tree decomposition.

Computation of $H_{Y_i^{hid}, X_i}$:

1. Initialization: $H_{Y_i^{hid}, X_i} = \emptyset$.
2. **for** each signature $\theta_1 \in H_{(Y_{i_1}^{hid} \cup Y_{i_1}^{org}), Y_{i_1}^{inh}}$ **do**
 $H_{Y_i^{hid}, X_i} = H_{Y_i^{hid}, X_i} \cup \{ext(\theta_1, X_i)\}$.

Computation of Q^i :

for each valid X_i -configuration α **do**
for each signature $\sigma \in H_{Y_i^{hid}, X_i}$ **do**
 $Q^i[\alpha, \sigma] = R^{i_1}[\alpha | Y_{i_1}^{inh}, \sigma | Y_{i_1}^{inh}]$.

Case 2: Node i has two children i_1 and i_2 in the tree decomposition.

Computation of $H_{Y_i^{hid}, X_i}$:

1. Initialization: $H_{Y_i^{hid}, X_i} = \emptyset$.
2. **for** each signature $\theta_1 \in H_{(Y_{i_1}^{hid} \cup Y_{i_1}^{org}), Y_{i_1}^{inh}}$ **do**
for each signature $\theta_2 \in H_{(Y_{i_2}^{hid} \cup Y_{i_2}^{org}), Y_{i_2}^{inh}}$ **do**
 - (a) $\sigma = ext(\theta_1, X_i) + ext(\theta_2, X_i)$.
 - (b) $H_{Y_i^{hid}, X_i} = H_{Y_i^{hid}, X_i} \cup \{\sigma\}$.

Computation of Q^i :

for each valid X_i -configuration α **do**
for each signature $\sigma \in H_{Y_i^{hid}, X_i}$ **do**
 $Q^i[\alpha, \sigma] = 0$.

for each signature $\theta_1 \in H_{(Y_{i_1}^{hid} \cup Y_{i_1}^{org}), Y_{i_1}^{inh}}$ **do**
for each signature $\theta_2 \in H_{(Y_{i_2}^{hid} \cup Y_{i_2}^{org}), Y_{i_2}^{inh}}$ **do**

- (a) $\sigma = ext(\theta_1, X_i) + ext(\theta_2, X_i)$.
- (b) **for** each valid X_i -configuration α **do**
 $Q^i[\alpha, \sigma] = Q^i[\alpha, \sigma] + R^{i_1}[\alpha | Y_{i_1}^{inh}, \theta_1] * R^{i_2}[\alpha | Y_{i_2}^{inh}, \theta_2]$.

Figure 6: Pseudocode for Part 3 of the Algorithm for the PROB Problem

Since k is fixed, our algorithm for the PROB problem runs in polynomial time. Thus, the following theorem summarizes the main result of Section 3.4.

Theorem 3.5 *The PROB problem can be solved efficiently for the class of treewidth-bounded BNs where each CPT is specified as a symmetric function.* ■

4 HARDNESS RESULTS

The results in the previous section show that inference problems for treewidth bounded BNs can be solved efficiently even when the indegrees of nodes are not bounded, provided each CPT is expressed as a symmetric function. The following result points out the tightness of these results; in particular, the result shows that the problems remain computationally intractable even if one of the conditions is violated. A proof of this result appears in Rosenkrantz et al. (2014).

Proposition 4.1 (a) *If CPTs are not required to be r -symmetric, then the PROB problem is #P-hard even when the BN is a directed tree (whose treewidth is 1).*

(b) *When the treewidth of the BN is not bounded, the PROB problem is #P-hard even when the CPT at each node is given by a symmetric function.*

5 CONCLUSIONS

We presented efficient algorithms for exact inference problems for BNs when the unmoralized graph is treewidth-bounded and each CPT is an r -symmetric function for a fixed r . We also observed that if either of these conditions is relaxed, the inference problems are computationally intractable.

We conclude by mentioning two general directions for further research. First, dynamic programming algorithms for treewidth-bounded BNs require memory that grows exponentially with the treewidth. It will be useful to develop practical techniques that can significantly reduce the amount of memory needed. Second, it is of interest to identify additional restrictions on BNs (based on problem instances that arise in practice) that can lead to practical algorithms for large problem instances.

Abstract

We study the problem of a user who has both public and private data, and wants to release the public data, e.g. to a recommendation service, yet simultaneously wants to protect his private data from being inferred via big data analytics. This problem has previously been formulated as a convex optimization problem with linear constraints where the objective is to minimize the mutual information between the private and released data. This attractive formulation faces a challenge in practice because when the underlying alphabet of the user profile is large, there are too many potential ways to distort the original profile. We address this fundamental scalability challenge. We propose to generate sparse privacy-preserving mappings by recasting the problem as a sequence of linear programs and solving each of these incrementally using an adaptation of Dantzig-Wolfe decomposition. We evaluate our approach on several datasets and demonstrate that nearly optimal privacy-preserving mappings can be learned quickly even at scale.

1 Introduction

Finding the right balance between privacy risks and big data rewards is one of the biggest challenges facing society today. Big data creates tremendous opportunity, especially for all of the services that offer personalized advice. Recommendation services are rampant today and offer advice on everything including movies, TV shows, restaurants, music, sleep, exercise, vacation, entertainment, shopping, and even friends. On one hand, people are willing to part with some of their personal data (e.g. movie watching history) for the sake of these services. On the other hand, many users have some data about themselves they would prefer to keep private (e.g. their political affiliation, salary, pregnancy status, religion). Most individuals have both public and private data and hence they need to maintain a boundary between these different ele-

ments of their personal information. This is an enormous challenge because inference analysis on publicly released data can often uncover private data [27, 6, 21].

A number of research efforts have explored the idea of distorting the released data [29, 26, 17, 7, 11, 3] to preserve user’s privacy. In some of these prior efforts, distortion aims at creating some confusion around user data by making its value hard to distinguish from other possible values; in other efforts, distortion is designed to counter a particular inference threat (i.e. a specific classifier or analysis). Recently [7] proposed a new framework for data distortion, based on information theory, that captures privacy leakage in terms of mutual information. Minimizing the mutual information between a user’s private data and released data is attractive because it reduces the correlation between the private data and the publicly released data, and thus any inference analysis that tries to learn the private data from the public data is rendered weak, if not useless. In other words, this approach is agnostic to the type of inference analysis used in a given threat.

This promising framework, while theoretically sound, faces some challenges in terms of bridging the gap between theory and practicality. Distorting data, in the context of recommendation systems, means altering a user’s profile. The framework casts this privacy problem as a convex optimization problem with linear constraints, where the number of variables grows quadratically with the size of the underlying alphabet that describes user’s profiles. In real world systems, the alphabet can be huge, thus the enormous number of options for distorting user profiles presents a scalability challenge, that we address in this paper.

We make two contributions to handle scalability. First, by studying small scale problems, both analytically and empirically, we identify that mappings to distort profiles are in fact naturally sparse. We leverage this observation to develop sparse privacy-preserving mappings (SPPM). Second, we propose an algorithm, called SPPM that handles scalability through two insights. Although the underlying optimization problem has linear constraints, its objective function is non-linear. We use the Frank-Wolfe algorithm that approximates the objective via a sequence of linear approximations that can be solved quickly. To do this, we

adapt the Dantzig-Wolfe decomposition to the structure of our problem. Overall we reduce the number of variables from quadratic to linear in the number of user profiles. To the best of our knowledge, this work is the first to apply large scale linear programming optimization techniques to privacy problems.

A salient feature of our novel approach is that the distortion applied to each user is personalized, meaning that it is tailored for that user. Our solution does not require applying distortion to profiles in a uniform way, nor requires any monotonic behavior such as mapping a profile to a far neighbor with decreasing likelihood (such as in [19]). We will see that the flexibility our system allows for a better use of the distortion budget where it is needed, and avoids wasting this budget on unnecessary distortions.

Our third contribution is a detailed evaluation on three datasets, in which we compare our solution to an optimal one (when feasible) and to a state-of-the-art solution based on differential privacy (called the Exponential Mechanism [19]). We find that our solutions are close to optimal, and consistently outperform the exponential mechanism (ExpMec) approach in that we achieve more privacy with less distortion. We show that our methods scale well with respect to the number of user profiles and their underlying alphabet.

Related Work. We consider the framework for privacy against statistical inference in [7, 18, 24]. In [24], a method based on quantization was proposed to reduce the number of optimization variables. It was shown that the reduction in complexity does not affect the privacy levels that can be achieved, but comes at the expense of additional distortion. In [18], privacy mappings in the class of parametric additive noise were considered, which allow the number of optimization variables to be reduced to the number of noise parameters. However, this suboptimal solution is not suitable for perfect privacy, as it requires a high distortion. In this paper, we propose to exploit the structure of the optimization to achieve computational speed-ups that will allow scalability. To the best of our knowledge, this is the first paper that evaluates the privacy-utility framework in [7] on such a large scale.

Our use of the information theoretic framework [7] relies on a *local privacy* setting, where users do not trust the entity collecting data, thus each user holds his data locally, and passes it through a privacy-preserving mechanism before releasing it to the untrusted entity. Local privacy dates back to randomized response in surveys [28], and has been considered in privacy for data mining and statistics [2, 12, 20, 16, 4, 7, 18, 9]. Information theoretic privacy metrics have also been considered in [23, 29, 12, 22, 25]. Finally, differential privacy [10] is currently the prevalent notion of privacy in privacy research. In particular, the expo-

nential mechanism, to which we compare our privacy mapping in Section 4.3, was introduced in [19].

The general problem of minimizing a convex function under convex constraints has been studied extensively, and is of crucial importance in many machine learning tasks. The idea of a sparse approximate solutions to those problems has also been studied in the literature and is often called *Sparse Greedy Approximation* [8, 15, 14, 13, 30]. This type of algorithm has been used with success in many applications such as Neural Network [15], Matrix Factorization [14], SVM [13], Boosting [30], etc. We apply this approach to a new problem and adapt it to efficiently handle our scalability challenges. Another common approach to minimizing a convex function is stochastic gradient descent [31]. This approach is preferable when the feasible set has a simple form and is easy to project to. In our case, the feasible set is defined by many constraints, thus we opted for the Frank-Wolfe algorithm.

2 Problem Statement and Challenges

Privacy-Utility Framework: We consider the setting described in [7], where a user has two kinds of data: a vector of personal data $A \in \mathcal{A}$ that he would like to remain private, e.g. his income level, his political views, and a vector of data $B \in \mathcal{B}$ that he is willing to release publicly in order to receive a useful service (such as releasing his media preferences to a recommender service to receive content recommendations). \mathcal{A} and \mathcal{B} are the sets from which A and B can assume values. We assume that the user private attributes A are linked to his data B by the joint probability distribution $p_{A,B}$. Thus, an adversary who would observe B could infer some information about A . To reduce this inference threat, instead of releasing B , the user releases a *distorted version* of B , denoted $\hat{B} \in \hat{\mathcal{B}}$, generated according to a conditional probabilistic mapping $p_{\hat{B}|B}$, called the *privacy-preserving mapping*. Note that the set $\hat{\mathcal{B}}$ may differ from \mathcal{B} . This setting is reminiscent of the *local privacy* setting (e.g. randomized response, input perturbation) [28], where users do not trust the entity collecting data, thus each user holds his data locally, and passes it through a privacy-preserving mechanism before releasing it. The privacy mapping $p_{\hat{B}|B}$ is designed to render any statistical inference of A based on the observation of \hat{B} harder, while preserving some utility to the released data \hat{B} , by limiting the distortion caused by the mapping. Following the framework for privacy-utility against statistical inference in [7], the inference threat is modeled by the mutual information $I(A; \hat{B})$ between the private attributes A and the publicly released data \hat{B} , while the utility requirement is modeled by a constraint on the average distortion $E_{B, \hat{B}}[d(B, \hat{B})] \leq \Delta$, for some distortion metric $d : \mathcal{B} \times \hat{\mathcal{B}} \rightarrow \mathbb{R}^+$, and $\Delta \geq 0$.

In the case of perfect privacy ($I(A; \hat{B}) = 0$), the privacy mapping $p_{\hat{B}|B}$ renders the released data \hat{B} statistically independent from the private data A .

In general, a system that provides privacy protection does not know in advance the inference algorithm that the adversary will run on released data. This framework is appealing because it works regardless of the inference algorithm used by an adversary. In addition, this framework allows for the use of any distortion metric, either generic metrics such as Hamming, l_p , or weighted norms, or specific utility metrics tailored to a given learning algorithm that will run on the released user data. The use of a generic distance in the utility constraint is relevant in several cases. First, the learning algorithm that will run on the released data may not be known in advance to the system providing privacy protection, as it may be proprietary information that belongs to the service provider. Second, the released user data may be used by numerous analyses tasks based on multiple different ML algorithms, in which case the utility constraint should not be limited to one specific distortion metric.

Both the mutual information $I(A; \hat{B})$ and the average distortion $E_{B, \hat{B}}[d(B, \hat{B})]$ depend on both the prior distribution $p_{A,B}$ and the privacy mapping $p_{\hat{B}|B}$, since $A \rightarrow B \rightarrow \hat{B}$ form a Markov chain. To stress these dependencies, we will denote $I(A; \hat{B}) = J(p_{A,B}, p_{\hat{B}|B})$. Consequently, given a prior $p_{A,B}$ linking the private attributes A and the data B , the privacy mapping $p_{\hat{B}|B}$ minimizing the inference threat subject to a distortion constraint is obtained as the solution to the following convex optimization problem [7]¹

$$\begin{aligned} & \underset{p_{\hat{B}|B} \in \text{Simplex}}{\text{minimize}} && J(p_{A,B}, p_{\hat{B}|B}) \\ & \text{s.t.} && \mathbb{E}_{p_{B, \hat{B}}} [d(B, \hat{B})] \leq \Delta, \end{aligned} \quad (1)$$

where Simplex denotes the probability simplex ($\sum_x p(x) = 1$, $p(x) \geq 0 \forall x$).

Sparsity of the privacy mapping: When applying the aforementioned privacy-accuracy framework to large data, we encounter a challenge of scalability. Designing the privacy mapping requires characterizing the value of $p_{\hat{B}|B}(\hat{b}|b)$ for all possible pairs $(b, \hat{b}) \in \mathcal{B} \times \hat{\mathcal{B}}$, i.e. solving the convex optimization problem over $|\mathcal{B}||\hat{\mathcal{B}}|$ variables. When $\hat{\mathcal{B}} = \mathcal{B}$, and the size of the alphabet $|\mathcal{B}|$ is large, solving the optimization over $|\mathcal{B}|^2$ variables may become intractable.

¹Solving Optimization (1) for different values of Δ allows to generate the whole privacy-utility curve, as in Fig. 2. Any point on or above this curve is achievable. Using this curve, one can efficiently solve the related problem of maximizing utility given a constraint on privacy: for a given privacy requirement, the curve gives the operating point corresponding to the smallest loss in utility.

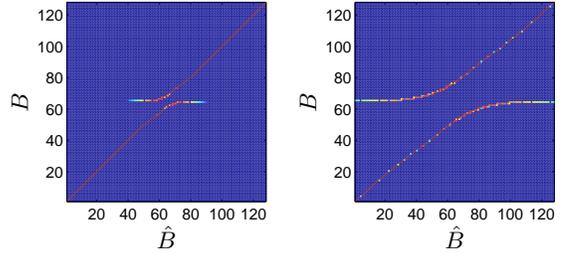

Figure 1: Optimal mappings for Toy example

A natural question is whether $\hat{\mathcal{B}} = \mathcal{B}$ is a necessary assumption to achieve the optimal privacy-utility trade-off. In other words, does Optimization (1) need to be solved over $|\mathcal{B}|^2$ variables to achieve optimality? The following theoretical toy example motivates a sparser approach to the design of the privacy mapping.

Example: Let $A \in \{0, 1\}$, and $B \in \{1, 2, \dots, 2^m\}$, and define the joint distribution $p_{A,B}$ such that $p(A = 0) = p(A = 1) = \frac{1}{2}$, and for $i \in \{1, 2, \dots, 2^m\}$, let $p(B = i|A = 0) = \frac{1}{2^{m-1}}$ if $i \leq 2^{m-1}$, 0 otherwise, and let $p(B = i|A = 1) = \frac{1}{2^{m-1}}$ if $i > 2^{m-1}$, 0 otherwise. For this example, the privacy threat is the worse it could be, as observing B determines deterministically the value of the private random variable A (equivalently, $I(A; B) = H(A) = 1$). In Fig. 2, we consider an l_2 distortion measure $d(B; \hat{B}) = (B - \hat{B})^2$ and illustrate the optimal mappings solving Problem ((1)) for different distortion values. For small distortions, the red diagonal in Figure 2 shows that most points $B = b$ are only mapped to themselves $\hat{B} = b$. As we increase the distortion level, each point $B = b$ gets mapped to a larger number of points $\hat{B} = \hat{b}$.

This theoretical example, as well as experiments on real world datasets such as the census data have shown that the optimal privacy preserving mapping may turn out to be sparse, in the sense that the support of $p_{\hat{B}|B}(\hat{b}|b)$ may be of much smaller size than \mathcal{B} , and may differ for different values of $B = b$. We propose to exploit sparsity properties of the privacy mapping to speed up the computation, by picking the support of $p_{\hat{B}|B}(\hat{b}|b)$, i.e. the set of points $\hat{B} = \hat{b}$ to which $B = b$ can be mapped with a non-zero probability, in an iterative greedy way. Although we a priori motivate the sparse approach using one theoretical example, and limited empirical evidence from some datasets, our experimental results demonstrate, a posteriori, that the sparse approach performs close to optimally on other datasets, and thus justifies empirically its relevance.

3 Sparse and Greedy Algorithm

Before we describe our algorithm, we rewrite Optimization (1) compactly. Let \mathbf{X} be a $n \times n$ matrix of optimized variables, whose entries are defined as

$x_{i,j} = p_{\hat{B}|B}(\hat{b}_i | b_j)$, and let \mathbf{x}_j be the j -th column of \mathbf{X} . To highlight the optimization aspect of our problem, we write the objective function $J(p_{A,B}, p_{\hat{B}|B})$ as a function $f(\mathbf{X})$, with the understanding that f depends on $p_{A,B}$, which is not optimized, and on \mathbf{X} , which is optimized. Similarly the distortion constraint can be written as $\sum_{j=1}^n \mathbf{d}_j^\top \mathbf{x}_j \leq \Delta$, where each $\mathbf{d}_j = p_B(b_j)(d(\hat{b}_1, b_j), d(\hat{b}_2, b_j), \dots, d(\hat{b}_n, b_j))^\top$ is a vector of length n that represents the distortion metric scaled by the probability of the corresponding symbol b_j . The marginal of B is computed as $p_B(b_j) = \sum_a p_{A,B}(a, b_j)$. Finally, the simplex constraint can be written as $\mathbf{1}_n \mathbf{x}_j = 1$ for all j , where $\mathbf{1}_n$ is an all-ones vector of length n . Given the new notation, our original problem (1) can be written compactly as:

$$\begin{aligned} & \underset{\mathbf{X}}{\text{minimize}} && f(\mathbf{X}) \\ & \text{subject to} && \sum_{j=1}^n \mathbf{d}_j^\top \mathbf{x}_j \leq \Delta \\ & && \mathbf{1}_n^\top \mathbf{x}_j = 1 \quad \forall j = 1, \dots, n \\ & && \mathbf{X} \geq 0 \end{aligned} \quad (2)$$

where $\mathbf{X} \geq 0$ is an entry-wise inequality.

3.1 Franke-Wolfe Linearization

The optimization problem (1) has linear constraints but its objective function is non-linear. In this paper, we solve the problem as a sequence of linear programs, also known as the *Franke-Wolfe method*. Each iteration ℓ of the method consists of three major steps. First, we compute the gradient $\nabla_{\mathbf{X}} f(\mathbf{X}_{\ell-1})$ at the solution from the previous step $\mathbf{X}_{\ell-1}$. The gradient is a $n \times n$ matrix \mathbf{C} , where $c_{i,j} = \frac{\partial}{\partial x_{i,j}} f(\mathbf{X}_{\ell-1})$ is a partial derivative of the objective function with respect to the variable $x_{i,j}$. Second, we find a feasible solution \mathbf{X}' in the direction of the gradient. This problem is solved as a linear program with the same constraint as the original problem:

$$\begin{aligned} & \underset{\mathbf{X}}{\text{minimize}} && \sum_{j=1}^n \mathbf{c}_j^\top \mathbf{x}_j \\ & \text{subject to} && \sum_{j=1}^n \mathbf{d}_j^\top \mathbf{x}_j \leq \Delta \\ & && \mathbf{1}_n^\top \mathbf{x}_j = 1 \quad \forall j = 1, \dots, n \\ & && \mathbf{X} \geq 0 \end{aligned} \quad (3)$$

where \mathbf{c}_j is the j -th column of \mathbf{C} . Finally, we find the minimum of f between $\mathbf{X}_{\ell-1}$ and \mathbf{X}' , \mathbf{X}_ℓ , and make it the current solution. Since f is convex, this minimum can be found efficiently by ternary search. The minimum is also feasible because the feasible region is convex, and both \mathbf{X}' and $\mathbf{X}_{\ell-1}$ are feasible.

Algorithm 1 SPPM: Sparse privacy preserving maps

Input: Starting point \mathbf{X}_0 , number of steps L

for all $\ell = 1, 2, \dots, L$ **do**

$\mathbf{C} \leftarrow \nabla_{\mathbf{X}} f(\mathbf{X}_{\ell-1})$

$\mathcal{V} \leftarrow \text{DWD}$

Find a feasible solution \mathbf{X}' in the direction of the gradient \mathbf{C} :

$$\begin{aligned} & \underset{\mathbf{X}}{\text{minimize}} && \sum_{j=1}^n \mathbf{c}_j^\top \mathbf{x}_j \\ & \text{subject to} && \sum_{j=1}^n \mathbf{d}_j^\top \mathbf{x}_j \leq \Delta \\ & && \mathbf{1}_n^\top \mathbf{x}_j = 1 \quad \forall j = 1, \dots, n \\ & && \mathbf{X} \geq 0 \\ & && x_{i,j} = 0 \quad \forall (i,j) \notin \mathcal{V} \end{aligned} \quad (4)$$

Find the minimum of f between $\mathbf{X}_{\ell-1}$ and \mathbf{X}' :

$$\gamma^* \leftarrow \arg \min_{\gamma \in [0,1]} f((1-\gamma)\mathbf{X}_{\ell-1} + \gamma\mathbf{X}') \quad (5)$$

$\mathbf{X}_\ell \leftarrow (1-\gamma^*)\mathbf{X}_{\ell-1} + \gamma^*\mathbf{X}'$

Output: Suboptimal feasible solution \mathbf{X}_L

3.2 Sparse Approximation

The linear program (3) has n^2 variables and therefore is hard to solve when n is large. In this section, we propose an incremental solution to this problem, which is defined only on a subset of *active variables* $\mathcal{V} \subseteq \{1, 2, \dots, n\} \times \{1, 2, \dots, n\}$. The active variables are the non-zero variables in the solution to the problem (3). Therefore, solving (3) on active variables \mathcal{V} is equivalent to restricting all inactive variables to zero. The corresponding linear program is shown in (4) in Algorithm 1. This linear program has only $|\mathcal{V}|$ variables. Now the challenge is in finding a good set of active variables \mathcal{V} . This set should be small, and such that the solutions of (3) and (4) are close.

We grow the set \mathcal{V} greedily using the dual linear program of (4). In particular, we incrementally solve the dual by adding most violated constraints, which corresponds to adding most beneficial variables in the primal. The dual of (4) is (6) in Algorithm 2, where $\lambda \in \mathbb{R}$ is a variable associated with the distortion constraint and $\mu \in \mathbb{R}^n$ is vector of n variables associated with the simplex constraints. Given a solution (λ^*, μ^*) to the dual, the most violated constraint for a given j is the one that minimizes:

$$c_{i,j} - \lambda^* d_{i,j} - \mu_j^*. \quad (8)$$

This quantity, called the *reduced cost*, has an intuitive interpretation. We choose an example i in the direc-

Algorithm 2 DWD: Dantzig-Wolfe decomposition

Initialize the set of active variables:

$$\mathcal{V} \leftarrow \{(1, 1), (2, 2), \dots, (n, n)\}$$

while the set \mathcal{V} grows **do**Solve the master problem for λ^* and μ^* :

$$\underset{\lambda, \mu}{\text{maximize}} \quad \lambda \Delta + \sum_{j=1}^n \mu_j \quad (6)$$

subject to $\lambda \leq 0$

$$\lambda d_{i,j} + \mu_j \leq c_{i,j} \quad \forall (i, j) \in \mathcal{V}$$

for all $j = 1, 2, \dots, n$ **do**Find the most violated constraint in the master problem for fixed j :

$$i^* = \arg \min_i [c_{i,j} - \lambda d_{i,j} - \mu_j] \quad (7)$$

if $(c_{i^*,j} - \lambda d_{i^*,j} - \mu_j < 0)$ **then**

$$\mathcal{V} \leftarrow \mathcal{V} \cup \{(i^*, j)\}$$

Output: Active variables \mathcal{V}

tion of the steepest gradient of $f(\mathbf{X})$, so $c_{i,j}$ is small; which is close to j , so $d_{i,j}$ is close to zero (as $\lambda^* \leq 0$). The search for the most violated constraint leverages the problem structure. Therefore, our approach can be viewed as an instance of *Dantzig-Wolfe decomposition*.

The pseudocode of our search procedure is in Algorithm 2. This is an iterative algorithm, where each iteration consists of three steps. First, we solve the reduced dual linear program (6) on active variables. Second, for each point j , we identify a point i^* that minimize the reduced cost. Finally, if the pair (i^*, j) corresponds to a violated constraint, we add it to the set of active variables \mathcal{V} .

The pseudocode of our final solution is in Algorithm 1. We refer to Algorithm 1 as *Sparse Privacy Preserving Mappings (SPPM)*, because of the mappings learned by the algorithm. Algorithm 2 is a subroutine of Algorithm 1, which identifies the set of active variables \mathcal{V} . SPPM is parameterized by the number of iterations L .

3.3 Convergence

Algorithm SPPM is a gradient descent method. In each iteration ℓ , we find a solution \mathbf{X}' in the direction of the gradient at the current solution $\mathbf{X}_{\ell-1}$. Then we find the minimum of f between $\mathbf{X}_{\ell-1}$ and \mathbf{X}' , and make it the next solution \mathbf{X}_ℓ . By assumption, the initial solution \mathbf{X}_0 is feasible in the original problem (1). The solution \mathbf{X}' to the LP (4) is always feasible in (1), because it satisfies all constraints in (1), and some additional constraints $x_{i,j} = 0$ on inactive variables. After the first iteration of SPPM, \mathbf{X}_1 is a convex combina-

tion of \mathbf{X}_0 and \mathbf{X}' . Since the feasible region is convex, and both \mathbf{X}_0 and \mathbf{X}' are feasible, \mathbf{X}_1 is also feasible. By induction, all solutions \mathbf{X}_ℓ are feasible.

The value of $f(X_\ell)$ is guaranteed to monotonically decrease with ℓ . When the method converges, $f(X_\ell) = f(X_{\ell-1})$. The convergence rate of the Frank-Wolfe algorithm is $O(1/L)$ in the worst case [5].

3.4 Computational Efficiency

The computation time of our method is dominated by the search for n^2 violated constraints in Algorithm 2. To search efficiently, we implement the following speedup in the computation of the gradients $c_{i,j}$. The marginal and conditional distributions:

$$p_{\hat{B}}(\hat{b}) = \sum_{a,b} p_{A,B}(a,b) p_{\hat{B}|B}(\hat{b} | b)$$

$$p_{\hat{B}|A}(\hat{b} | a) = \frac{\sum_b p_{A,B}(a,b) p_{\hat{B}|B}(\hat{b} | b)}{\sum_b p_{A,B}(a,b)}$$

are precomputed, because these terms are common for all elements of \mathbf{C} . Then each gradient is computed as:

$$\frac{\partial}{\partial p(\hat{b}_i | b_j)} J(p_{a,b}, p_{\hat{b}|b}) = \sum_a p(a, b_j) \log \frac{p(\hat{b}_i | a)}{p(\hat{b}_i)}$$

$$+ \sum_a p(a, \hat{b}) \left(\frac{p(b_j | a)}{p(\hat{b}_i | a)} - \frac{p(a, b_j)}{p(\hat{b}_i)} \right).$$

Since all marginals and conditionals are precomputed, each gradient can be computed in $O(|A|)$ time.

The space complexity of our method is $O(|\mathcal{V}|)$, because we operate only on active variables \mathcal{V} .

We point out that the complexity of the algorithm is closely linked to the sparsity of the optimal solution, which itself is related to the value of the distortion constraint Δ . This means that some distortion regimes may not be achievable with a given computational budget. Therefore one has to reduce Δ in order to have a sparser solution. In practice however, we did not run into problems, and were able to generate mappings efficiently even when high distortion was needed to drive the mutual information close to 0.

4 Evaluation

4.1 Datasets

Census Dataset: The *Census* dataset is a sample of the United States population from 1994, and contains both categorical and numerical features. Each entry in the dataset contains features such as age, workclass, education, gender, and native country, as well as income category (smaller or larger than 50k per year). For our purposes, we consider the information to be

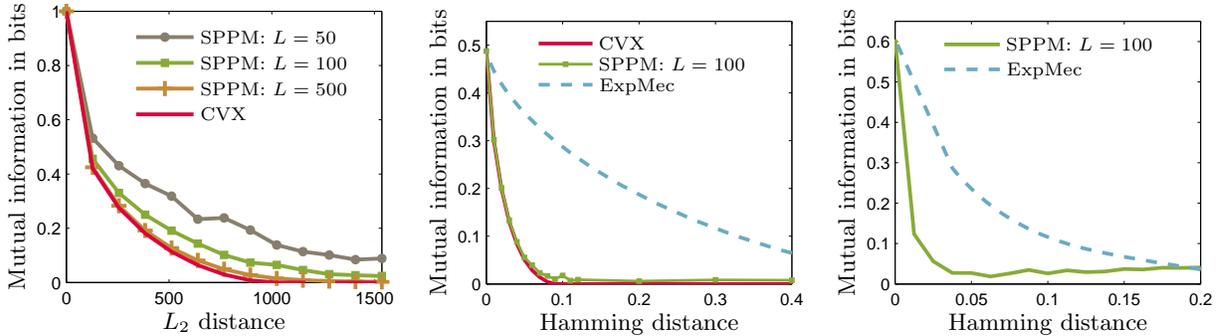

Figure 2: **Left.** Effect of parameters on privacy-distortion tradeoff. Synthetic data. **Middle.** Privacy distortion tradeoff. Census data. **Right.** Privacy distortion tradeoff. Movie data.

released publicly as the seven attributes shown in Table 1, while the income category is the private information to be protected. In this dataset, roughly 76% of the people have an income smaller than 50k. Due to the categorical nature of these features, a natural distortion metric for this data is the Hamming distance, and thus we use this metric in our experiments on this data. Fig. 3 shows that the user profile consisting of these 7 attributes can be a threat to income; the ROC curve illustrates the success rate of a simple classifier that tries to guess a user’s income category when there is no privacy protection.

Movie Dataset: The well known *MovieLens* dataset [1] consists of 1M ratings of 6K users on 4K movies. Each movie comes annotated with metadata indicating its genre. In *MovieLens*, there are 19 genres, that we expanded as follows. We gathered the more extended set of 300 genre tags from Netflix. From these, we select those that appear in at least 5% of movies, yielding 31 genres. For user j , we compute the preference for genre i as the probability that the user chooses a movie from the genre times the reciprocal of the number of movies in that genre. We capture the user profile using a binary vector of length 31; the bits corresponding to the six most preferred genres are set to one. We treat the preference vector as public but the gender of the user as private. The fact that this profile can be a threat to gender is illustrated in Fig. 4 which shows the success of a classifier that tries to guess gender when there is no privacy protection. Once more, as the features are categorical, we use the Hamming distance for our evaluations on this dataset.

Synthetic Dataset: We consider synthetic data as well since this allows us to freely vary the problem size. The input distribution is specified in our example in Sec. 2, namely the private attribute is a binary variable $A \in \{0, 1\}$, and the public attribute B is perfectly correlated with A . By varying the parameter m as defined in the example, we modify the size of the alphabet of B , which allow us to asses the scalability.

The distortion metric is the squared l_2 distance.

4.2 Benchmarks

Optimal mapping: The optimal mapping is the solution to (1); for small scale problems we were able to compute this using CVX without running out of memory. On our server, we could solve optimally (1) with alphabet size up to $|\mathcal{B}| = 2^{12} = 4096$.

Exponential Mechanism: The differential privacy metric is most commonly used in a database privacy setting, in which an analyst asks a query on a private database of size n containing data from n users. The privacy-preserving mechanism, which computes and releases the answer to the query, is designed to satisfy differential privacy under a given notion of neighboring databases. In the strong setting of *local* differential privacy [16], users do not trust the entity collecting the data in a database, thus each user holds his data locally, and passes it through a differentially private mechanism before releasing it to the untrusted entity. In this case, the privacy-preserving mechanism works on a database of size $n = 1$, and all possible databases are considered to be neighbors. This local differential privacy setting, based on input perturbation at the user end, is comparable to our local privacy setting, where user data is distorted before its release, but it differs from our setting by the privacy metric that the privacy mechanism is required to satisfy. More precisely, the local differential privacy setting considers a database of size 1 which contains the vector b of a user. The local differentially private mechanism p^{DP} satisfies $p^{DP}(\hat{b}|b) \leq e^\epsilon p^{DP}(\hat{b}|b'), \forall b, b' \in \mathcal{B}$ and $\forall \hat{b} \in \hat{\mathcal{B}}$.

As the non-private data in our 3 datasets is categorical, we focus on the *exponential mechanism* [19], a well-known mechanism that preserves differential privacy for non-numeric valued queries. More precisely, in our experiments, we use the exponential mechanism $p^{DP}(\hat{b}|b)$ that maps b to \hat{b} with a probability that decreases exponentially with the distance $d(\hat{b}, b)$

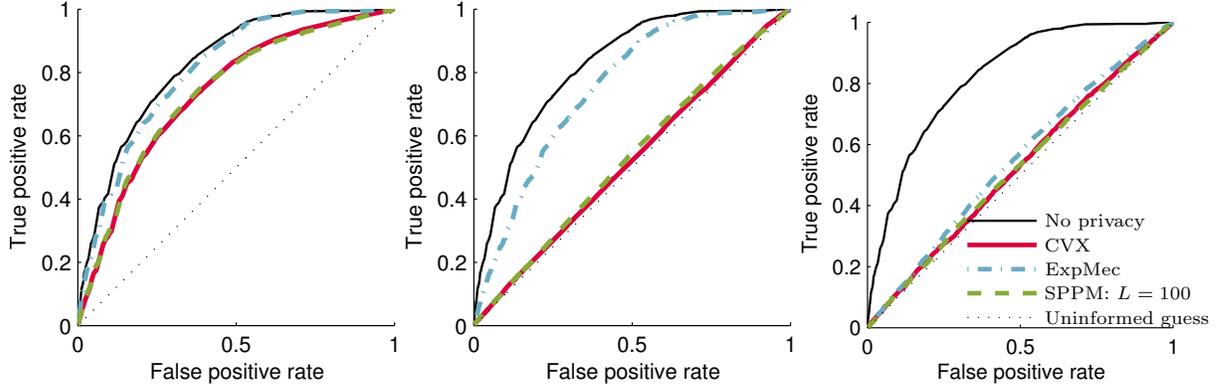

Figure 3: ROC for Naive Bayes Classifier with $\Delta = 0.02$ (Left), 0.14 (Middle) and 0.44 (Right). Census Data.

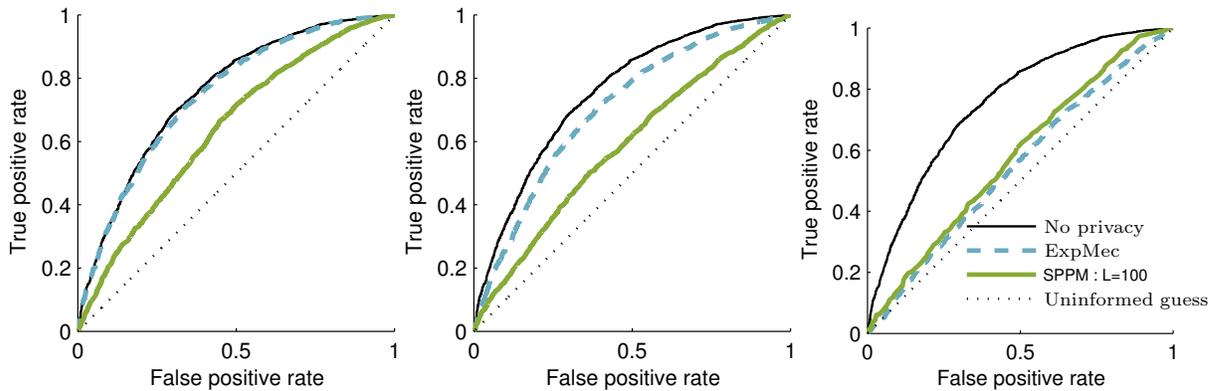

Figure 4: ROC for Logistic Regression with $\Delta = 0.04$ (Left), 0.13 (Middle) and 0.22 (Right). Movie Data.

$p^{DP}(\hat{b}|b) \propto \exp(-\beta d(\hat{b}, b))$, where $\beta \geq 0$. Let $d_{\max} = \sup_{\hat{b}, b \in \mathcal{B}} d(\hat{b}, b)$. This exponential mechanism satisfies $(2\beta d_{\max})$ -local differential privacy. Intuitively, the distance $d(\hat{b}, b)$ represents how appealing substituting \hat{b} for b is: the larger the distance $d(\hat{b}, b)$, the less appealing the substitution. To make a fair comparison between the exponential mechanism and SSPM, the distance $d(\hat{b}, b)$ used to define the exponential mechanism will be the same as the distance used in the distortion constraint of the optimization problem (1). In Section 4.3, $d(\hat{b}, b)$ will be the Hamming distance for experiments on the census and the movie datasets, and the squared l_2 distance for the synthetic datasets.

In [7], it was shown that in general, differential privacy with some neighboring database notion, does not guarantee low information leakage $I(A; \hat{B})$, for all priors $p_{A,B}$. However, it was also shown in [18], that *strong* ϵ -differential privacy, i.e. ϵ -differential privacy under the neighboring notion that all databases are neighbors, implies that $I(A; \hat{B}) \leq \epsilon$. Local differential privacy is a particular case of strong differential privacy. Consequently, the mutual information between private A and the distorted \hat{B}^{DP} resulting from the exponential mechanism p^{DP} will be upperbounded as

$I(A; \hat{B}^{DP}) \leq 2\beta d_{\max}$. We acknowledge that differential privacy was not defined with the goal of minimizing mutual information. However, regardless of the mechanism, mutual information is a relevant privacy metric [7, 18, 24, 25, 22, 12], thus we can compare these 2 algorithms with respect to this metric.

4.3 Results

Parameter Choices. Using synthetic data, we explore the privacy distortion tradeoff curve (in Fig. 2 **Left**) for different values of our algorithm's parameter L . First we observe that for small values of distortions, the difference between the various curves is insignificant, which suggests that in this regime the optimal mapping is indeed sparse. Second, as we increase L accuracy improves as we approach the optimal solution. Since the gain of using $L = 500$ compared to $L = 100$ seems small, and using 100 rather than 500 approximations is clearly much faster, we elect to use $L = 100$ for further experiments.

Privacy Performance. We provide two ways of comparing SSPM and our benchmarks on two datasets. We first compare them in Fig. 2 terms of tradeoff between privacy leakage, as measured by $I(A; \hat{B})$, and

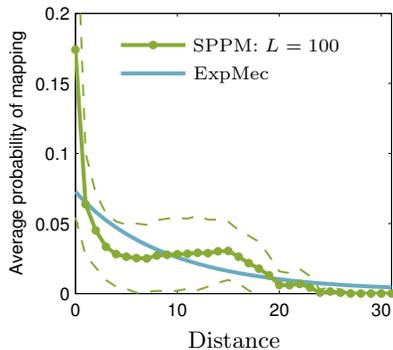

Figure 5: Behavior of SPPM and ExpMec. Synthetic data.

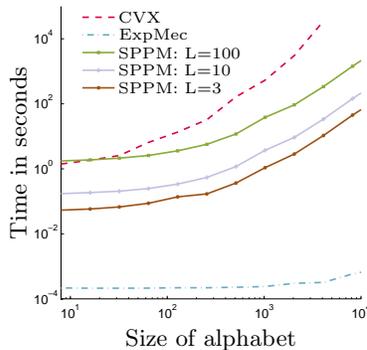

Figure 6: Time complexity and parameter sensitivity. Synthetic data.

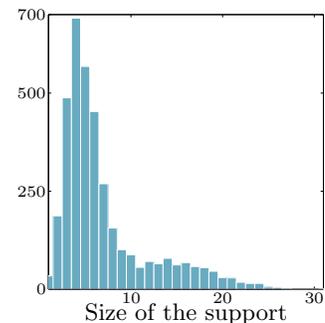

Figure 7: Histogram on size of support for mapping. Movie data, initial alphabet size 3717.

distortion. Then we draw another more general, meaningful, and fair comparison, in Fig. 3 and Fig. 4, by comparing the ability of SSPM and our benchmarks to defeat two different inference algorithms that would try to infer private data by using the privatized data $\hat{\mathcal{B}}$. ROC curves are agnostic and meaningful measures privacy that do not a priori favor a privacy metric (differential privacy or mutual information).

We start by illustrating the privacy versus distortion tradeoff for SPPM and our benchmarks, on the Census dataset, in which each user is represented by a vector of 7 attributes. We do not consider all possible values of this vector, as it would be prohibitive for an exact solver and prevent us from comparing to an optimal solution. Instead, we restrict the alphabet $|\mathcal{B}|$ to the 300 most probable vectors of 7 attributes, since we are mainly focused on a relative comparison. In Fig. 2(Middle) we see that SPPM is nearly indistinguishable from the optimal solution whereas the exponential mechanism (ExpMec) is much further away. To bring the mutual information down from 0.5 to 0.07, SPPM needs 0.05 distortion to achieve perfect privacy, while ExpMec needs more than 8 times as much. Note that for a given level of distortion, e.g. 0.1, 0.2, SPPM achieves much better privacy than ExpMec as the mutual information is significantly lower.

Next we consider the Movie dataset which is one order of magnitude larger than the Census dataset. The results in Fig. 2(Right) mirror what we observed with the Census data, namely that a given level of privacy can be achieved with less distortion using SPPM as opposed to ExpMec. For example, to reduce our privacy leakage metric from 0.6 to 0.05, SPPM requires roughly 0.03 distortion whereas ExpMec needs approximately 0.17, nearly 6 times as much. For both the Census and Movie datasets, SPPM can achieve perfect or near-perfect privacy with a small distortion.

Differential privacy does not aim to minimize mutual

information, which explains why ExpMec does not perform as well as SSPM in Fig. 2. Another metric to gage the success of our privacy mapping is to consider its impact on a classifier attempting to infer the private attribute. Recall that the goal of our mapping is to weaken any classifier that threatens to infer the private attribute. First, we consider a simple Naive Bayes classifier that analyzes the Census data to infer each user’s income category. We quantify the classifier’s success, in terms of true positives and false negatives (in an ROC curve) in Fig. 3. Recall that in an ROC curve, the $y = x$ line corresponds to a blind classifier that is no better than an uninformed guess. The weaker a classifier the closer it is to this line, and it becomes useless when it matches this line. We consider three bounds on distortion that allow us to explore the extremes of nearly no distortion ($\Delta = 0.02$ in Fig. 3(a)), a large amount of distortion ($\Delta = 0.44$ in Fig. 3(c)), and something in between ($\Delta = 0.14$ in Fig. 3(b)). In the case of small distortion, all algorithms make modest improvements over the no privacy case. However even in this scenario, SPPM performs close to optimal, unlike ExpMec that only slightly outperforms the no privacy case. With only a very small amount of distortion, not even the optimal solution can render the classifier completely useless (i.e. equivalent to the blind uninformed guess). On the other hand, when a large distortion is permitted, then all algorithms do naturally well (Fig. 3(c)). For a value of Δ between these extremes, SPPM is close to optimal, while ExpMec can only weaken the classifier a little.

In a second scenario, we study a logistic regression classifier that analyzes the movie dataset to infer gender. We focus on logistic regression for movie data because it has been shown to be an effective classifier for inferring gender [27]. Again we see in Fig. 4 that the findings essentially mimic those of the previous case. We thus conclude that, for a given distortion budget, SPPM is more successful against inference

threats because it can diminish the success of a classifier more than the exponential mechanism. In other words, SPPM can provide more privacy than the exponential mechanism for the same level of distortion.

Why is it that SPPM consistently outperforms ExpMec? Fig. 5 illustrates how these mappings work. We plot the average probability of being mapped to the k th closest point, together with the standard error that measures the variability among points. In ExpMec, the probability of mapping one point to another decreases exponentially with distance and the same mapping is applied to all points (in other words the standard deviation is null). With SPPM, many points are mapped to themselves. This means that the privacy of these points cannot be improved within the distortion constraint. This can happen if a given profile is already very private, or if there is no hope of providing privacy. In both cases, the distortion budget should not be wasted on such profiles, and SPPM is able to detect these cases and save its budget for other cases. ExpMec *wastes* some distortion on those points which are forced to be mapped to close neighbours. The key difference between SPPM and ExpMec is that SPPM is not required to apply the same mapping to each user, and can thus personalize the distortion, or adapt it as needed. This flexibility leads to a fair bit of variance as seen in Fig. 5. Because the probability of mapping to another point does not decrease with the distance from that point, we see a non-monotonically decreasing curve with distance: some points are better off being mapped to far neighbors rather than close ones; e.g. users whose profile is hard to disguise.

To further understand the effect of the mappings that SPPM proposes, we examine which features in a user profile are impacted most by our distortions. In Tab. 1 we list the mutual information between a single public feature (e.g., Education) and the private attribute we wish to hide (e.g., income category). We see that $I(A; F)$ is largest for Education, Marital status and Occupation, indicating these features are the most correlated with the private attribute. This is intuitive as, for example, more highly educated people tend to make larger salaries. The table shows that these 3 features experience the largest reduction in mutual information after distortion, indicating that SPPM spent its distortion budget on the biggest threats. This intuitive property shows that the mappings learned depend on the underlying prior distribution in a *smart* way, such that with limited distortion budget the priority is on the biggest privacy threats. Another point can be easily seen in the movie data in Tab. ??; here the single features mutual information are rather low, whereas the mutual information of the full vector of features is significant. This means that a big part of the privacy threat comes from co-occurrence of features rather than individual features. This explains

Feature F	Examples	$I(A; F)$	
		before	after
Age	10-20, 20-30,...	0.1064	0.0408
Education	Bachelor, PhD,...	0.1502	0.0702
Marital status	Divorced, Married,...	0.1241	0.0440
Occupation	Manager, Scientist,...	0.1126	0.0367
Race	Black, White,...	0.0192	0.0084
Gender	Female, Male	0.0123	0.0082
Country	Mexico, USA,...	0.0470	0.0203

Table 1: Mutual information between private attribute A and public attributes F before and after SPPM on Census dataset.

why it is not enough to simply reduce the mutual information of a single feature to obtain good privacy.

Scalability. Having established good privacy performance, we now assess how the runtime performance scales in terms of the size of the problem, shown in Fig. 6. We fix the distortion constraint to be proportional to the size of the problem, in order to keep a similar difficulty as we grow the size. As stated in Sec. 3.1, the time complexity is linear in L . This trend is evident as we observe the gaps between the lines for $L = 3, 10$, and 100 . Importantly, we see that our method scales with problem size better than the optimal solution. We observe that the computation speed of the exponential mechanism is very quick, and note that indeed this is one of the salient properties of this mechanism. Overall, this figure shows that our method is indeed tractable and can compute the distortion maps within a few minutes for problems whose alphabet size is on the order of tens of thousands.

Recall that we designed for computation efficiency by smartly selecting a limited number of alternate user profiles to map each original profile to. This corresponds to the support size of $p(\hat{B}|b_i)$ for all b_i . In Fig. 7 we show the histogram of the support sizes for our SPPM mapping on the movie data. Although the initial alphabet size is very large (above 3500), for most users we don't consider more than 10 alternate profiles, and in the worst case we consider up to 30. This amounts to huge savings in computation and memory, without sacrificing privacy.

5 Conclusion

In this paper, for the first time, we apply large scale LP optimization techniques to the problem of data distortion for privacy. We show that our privacy-preserving mappings can be close to optimal, and consistently outperform a state of the art technique called the Exponential Mechanism. Our solution achieves better privacy with less distortion than existing solutions, when privacy leakage is measured by a mutual information metric. We demonstrated that our method can scale, even for systems with many users and a large underlying alphabet that describes their profiles.

Abstract

We consider the problem of recovering sparse correlated data on networks. To improve accuracy and reduce costs, it is strongly desirable to take the potentially useful side-information of network structure into consideration. In this paper we present a novel correlated compressive sensing method called `CorrCS` for networked data. By naturally extending Bayesian compressive sensing, we extract correlations from network topology and encode them into a graphical model as prior. Then we derive posterior inference algorithms for the recovery of jointly sparse and correlated networked data. First, we design algorithms to recover the data based on pairwise correlations between neighboring nodes in the network. Next, we generalize this model through a diffusion process to capture higher-order correlations. Both real-valued and binary data are considered. Our models are extensively tested on several real datasets from social and sensor networks and are shown to outperform baseline compressive sensing models in terms of recovery performance.

1 INTRODUCTION

Networked data, from domains such as social network of friends, hyper-linked networks of webpages and distributed network of sensors, are becoming increasingly pervasive and important in modern signal processing and machine learning. Recent research has demonstrated compelling approaches to extract useful information from these networked data, including latent structure of social links (Kemp et al., 2004), community detection (Fortunato, 2010), etc. However, with the massive amount of data generated at an exploding rate, conventional ways of collecting networked data are being challenged, particularly when measurements are expensive and/or data are redundant.

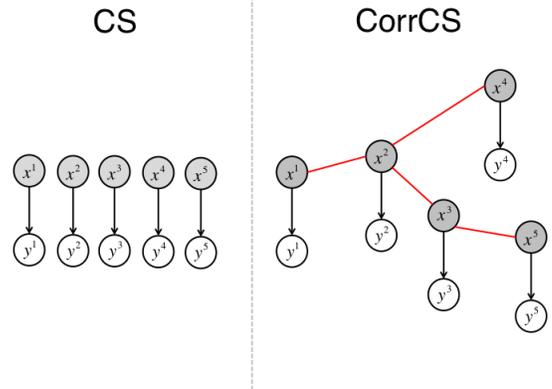

Figure 1: A graphical illustration of Compressive Sensing (CS) and Correlated Compressive Sensing (CorrCS) on networked data. In CS, each sparse signal x^i is recovered independently as y^i ; in CorrCS, they are recovered jointly with the network structure.

A significant finding of a large class of high-dimensional data over the last two decades is their inherent sparsity (Candès and Wakin, 2008). As a robust tool to leverage the sparsity, Compressive Sensing (CS) (Donoho, 2006) has been developed to collect high-dimensional sparse data from their low-dimensional projections. With sufficiently sparse signals, compressive sensing is guaranteed to recover the original signal from fewer samples required by Shannon-Nyquist limit (Candès, 2006). Compressive sensing has therefore been successfully applied to attack various problems of data collection in a wide range of fields, such as medical imaging (Lustig et al., 2008), low-level vision (Yang et al., 2008), etc.

Successful attempts have been made to apply compressive sensing to collect and analyze sparse networked data. For example, in studying large-scale sensor networks, the pioneering work by Luo et al. (2009) shows a successful scheme to efficiently gather spatially sparse sensor readings. For social networks, Compressive Network Anal-

ysis (Jiang et al., 2011) proposes a novel framework for clique detection. These approaches typically require finding a proper basis over the network topology so that data could be sparsely represented.

In many cases, however, it is unclear how the network topology could imply the sparse structure of the data, and therefore difficult to identify the sparse basis. Take the social network for example. It has been known that social influence and correlation exist at a large statistical level (Backstrom et al., 2006), but it turns out hard to directly model due to unobserved latent factors (Anagnostopoulos et al., 2008). An interesting question would be, under uncertainty about correlation of sparse data across the network, is it possible to seriously incorporate the network structure into compressive sensing and hopefully to improve recover performance?

In this paper, we present Correlated Compressive Sensing (CORRCS) to solve this problem. In particular, the setting in Figure 1 is considered. Each node i is equipped with a sensor, and we aim to recover the original high-dimensional data \mathbf{x}^i from its low-dimensional measurements \mathbf{y}^i . Instead of independently recover sparse signals, CORRCS incorporates side-information of the network structure and build correlation into signal modeling jointly with the inherent sparsity. By adopting a probabilistic approach, we show that it is possible to exploit the flexibility of graphical models to improve compressive sensing. Our approach is extensively tested on several real datasets, including product review data from social trust networks, social polling data and Air Quality Index from distributed sensors. The results show that CORRCS outperforms CS in terms of recover performance and demonstrates the usefulness of correlation in sensing networked data.

2 PRELIMINARY

In a typical sensing problem, the data of interest is regarded as a signal, which is a vector \mathbf{x} in a high-dimensional space \mathbb{R}^r . A measurement of \mathbf{x} is a low-dimensional vector $\mathbf{y} \in \mathbb{R}^m$ ($m \leq r$) from which the information of \mathbf{x} can be extracted. From a Bayesian point of view, this corresponds to inferring $p(\mathbf{x} | \mathbf{y}) \propto p(\mathbf{y} | \mathbf{x})p(\mathbf{x})$. The likelihood term $p(\mathbf{y} | \mathbf{x})$ describes a sensing model, which is the noisy measurement process, and the term $p(\mathbf{x})$ corresponds to a signal model, which represents the prior knowledge.

2.1 THE SENSING MODEL

A large body of sensing methods focus on the linear system

$$\mathbf{y} = V\mathbf{x} \quad (1)$$

with the goal to recover \mathbf{x} from \mathbf{y} accurately. However, since $r \gg m$, the inversion problem is highly ill-posed due to the undetermined solutions. One way to deal with the

uncertainty is to adopt a Gaussian generative model for \mathbf{y} as follows,

$$\mathbf{y} | \mathbf{x} \sim \mathcal{N}(V\mathbf{x}, \beta), \quad (2)$$

where β is the variance controlling the precision of measurement.

2.2 THE SIGNAL MODEL

Many natural signals $\mathbf{x} \in \mathbb{R}^r$ can be sparsely represented under some basis $\Phi = [\phi_1, \phi_2, \dots, \phi_K]$ as

$$\mathbf{x} = \Phi\mathbf{z} \quad (3)$$

where \mathbf{z} is the sparse coefficients such that $\|\mathbf{z}\|_0 = S \ll K$. Compressive sensing (Donoho, 2006; Candès and Wakin, 2008) shows that if the signal \mathbf{x} is sufficiently sparse, one can recover it effectively through minimizing the number of non-zero components in \mathbf{z} :

$$\begin{aligned} \min \quad & \|\mathbf{z}\|_0 \\ \text{s.t.} \quad & \mathbf{y} = M\mathbf{z} \end{aligned} \quad (4)$$

where $M = V\Phi$. In practice, it is often hard to solve the non-convex objective in (4) exactly, and a ℓ_1 relaxation is usually adopted, which corresponds to the basis pursuit (BP) algorithm (Chen et al., 1998). Candès et al. (2006) have proved that, under certain isometry properties, one can recover \mathbf{x} perfectly from $m = \Omega(S \log r)$ observations \mathbf{y} through BP.

To allow extra flexibility that we would exploit later, the framework of CS could be reformulated approximately as a Bayesian inference problem (Ji et al., 2008), and its goal is to design a signal model $p(\mathbf{z}; \Gamma)$ with some parameter Γ so that \mathbf{z} is controlled to be sufficiently sparse. Below we describe two common sparse signal models in social and sensor networks.

ℓ_1 prior for real-valued \mathbf{z} . Using sparsity-favoring Laplace priors on the coefficients (Babacan et al., 2010), one could use the following signal model:

$$p(\mathbf{z}; \lambda) = \frac{\lambda^{K/2}}{2^K} \exp\left(-\sqrt{\lambda}\|\mathbf{z}\|_1\right) \quad (5)$$

In practice, it is often inconvenient that the Laplace prior is not conjugate to the Gaussian signal model. However, one can show that (5) is equivalent to a hierarchical conjugate model parametrized by $\Gamma = (\{\gamma_k\}_{k=1}^K, \lambda)$ (Seeger and Nickisch, 2008).

$$\begin{aligned} p(\mathbf{z}; \Gamma) &= \prod_{k=1}^K \mathcal{N}(z_k; 0, \gamma_k) \\ p(\Gamma) &= \text{Gamma}(\gamma_k; 1, \frac{\lambda}{2}) \end{aligned} \quad (6)$$

The inference of \mathbf{z} for (6) can be efficient via the EM algorithm (Dempster et al., 1977).

Beta process for binary \mathbf{z} . An efficient way to characterize the sparsity of binary-valued coefficients is the Beta process (Paisley and Carin, 2009). In practice, a finite truncation of the process is used and leads to the following hierarchical conjugate model:

$$p(\mathbf{z}; \mathbf{\Gamma}) = \prod_{k=1}^K \text{Bernoulli}(z_k; \pi_k) \quad (7)$$

$$p(\mathbf{\Gamma}) = \prod_{k=1}^K \text{Beta}(\pi_k; \frac{a}{K}, b(1 - \frac{1}{K}))$$

where $\mathbf{\Gamma} = (\{\pi_k\}_{k=1}^K, a, b)$ and a, b are hyper-prior affecting sparsity. The exact posterior inference of (7) is intractable, but can be approximated through MCMC (Mohamed et al., 2011) or mean-field variational inference (Paisley and Carin, 2009).

3 CORRELATED COMPRESSIVE SENSING

Now, consider the problem of collecting data distributed on a network of n nodes. When the network structure is known, it can be described by a graph $G(V, E)$, where the edges have weight

$$E_{ij} = \begin{cases} w_{ij}, & \text{node } i \text{ and } j \text{ are adjacent} \\ 0, & \text{otherwise} \end{cases}, \quad (8)$$

where w_{ij} encodes the side-information about the correlation between the node i and j . In practice, such weight can either be collected directly from network or be computed through some metrics such as Pearson correlation and some function of geographic distance. When this weight is not exactly available, it is convenient to set $w_{ij} = 1$ for all edges uniformly. Let $(\mathbf{Z}, \mathbf{X}, \mathbf{Y}) = \{\mathbf{z}^i, \mathbf{x}^i, \mathbf{y}^i\}_{i=1}^n$, the Bayesian formulation of sensing is generalized as the following principle

$$p(\mathbf{Z}|\mathbf{Y}) \propto p(\mathbf{Z}) \prod_{i=1}^N \mathcal{N}(M^i \mathbf{z}^i, \beta). \quad (9)$$

Instead of applying compressive sensing independently to each node (i.e. $p(\mathbf{Z}) = \prod_i p(\mathbf{z}^i)$), Correlated Compressive Sensing (CORRCS) fuses the network structure G into recovery as side-information. To fulfill this goal, a joint distribution $p(\mathbf{Z})$ is explored in this section to capture the notion of joint sparsity and correlation.

3.1 PAIRWISE CORRELATION

The simplest form of correlation among networked data is pairwise according to the edge connecting neighboring nodes. Inspired by graphical models, we consider a range of pairwise Correlated Compressive Sensing

(CORRCS-PAIR) that can be formulated as the Gibbs distribution

$$p(\mathbf{Z} | \mathbf{\Gamma}) \propto \exp \left(- \sum_i \mathcal{S}^i - c \sum_{(i,j) \in E} \mathcal{C}^{ij}(\mathbf{z}^i, \mathbf{z}^j) \right). \quad (10)$$

where \mathcal{S}^i is the sparsity of individual node \mathbf{z}^i controlled by hyper-parameter $\mathbf{\Gamma}$ and \mathcal{C}_{ij} models the pairwise correlation between two neighboring signal coefficients $\mathbf{z}_i, \mathbf{z}_j$. The parameter c controls prior on the strength of correlation.

Notice when $c = 0$, equation (10) reduces to independently applying BCS to each node. And the bigger c is, more correlation between neighboring nodes is favored over sparsity. On networked data with inherent correlation, we would expectedly improve the recovery performance with proper choice of positive c . However, if $c \rightarrow \infty$, the model would totally neglect sparsity, and therefore be undesirable. This variation of the recovery performance happens in actual experiments, as will be discussed later.

Below we consider two specific forms of CORRCS for real-valued and binary networked data. We discuss their inference algorithm in section 3.3.

Laplace-GRF Model. Assume $\mathbf{Z} = \mathbb{R}^{k \times n}$. Often we have the prior knowledge that neighboring sparse coefficient $\mathbf{z}^i, \mathbf{z}^j$ are close. This intuition leads to combining Laplace prior and Gaussian Random Field (GRF). Let

$$\mathcal{S}^i = \|\mathbf{z}^i\|_1$$

$$\mathcal{C}^{ij} = w_{ij} \|\mathbf{z}^i - \mathbf{z}^j\|^2.$$

The distribution $p(\mathbf{Z}; \mathbf{\Gamma})$ is jointly Gaussian.

Beta-Ising Model. Assume $\mathbf{Z} = \{0, 1\}^{k \times n}$. This case is appealing for potential social network applications. For example, z_{ij} could be a latent feature indicating whether user i likes the product j . The Beta process (7) enforces the sparsity of binary coefficients. And based on similar idea of closeness, the Ising model shows a way to incorporate pairwise correlation into the model:

$$\mathcal{C}^{ij} = \sum_{k=1}^K w_{ij} (2z_{ik} - 1)(2z_{jk} - 1). \quad (11)$$

3.2 DIFFUSION PROCESS

We show that the pairwise correlation for real-valued signals can be generalized through a Diffusion Process (DP) on the graph G . The Correlated Compressive Sensing with Diffusion Process (CORRCS-DP) characterizes the covariant structure of the latent signals with a generative model, whose zeroth-order approximation is compressive sensing, and first-order approximation is pairwise CORRCS.

Diffusion Process. For any graph $G(V, E)$, a value function $f : V \rightarrow \mathbb{R}$ can be defined. Diffusion Process (DP)

is a natural class of stochastic processes on graphs that yields covariance structure of the function f (Kondor and Lafferty, 2002). First, we extend our value function as a function of time t : define $\mathbf{f}[t]$ be the snapshot vector of $[f(v_1), f(v_2), \dots, f(v_n)]$ at time t . Next, a diffusion generator H is defined as a Laplacian matrix of graph G as:

$$H_{ij} = \begin{cases} w_{ij} & \text{for } i \neq j \text{ and } j \in \mathcal{A}(i) \\ -\sum_{i'} w_{ii'} & \text{for } i=j \\ 0 & \text{otherwise.} \end{cases} \quad (12)$$

Then H is applied to the value function in the following way

$$\frac{\partial \mathbf{f}[t]}{\partial t} = \alpha H \mathbf{f}[t]. \quad (13)$$

Solving (13), we obtain

$$\mathbf{f}[t] = K \mathbf{f}[0], \quad (14)$$

where $K = \exp(\alpha t H)$ is the *Diffusion Kernel*. Notice that heat kernel is always invertible, which means given $\mathbf{f}[t]$ at any time t it is easy to compute $\mathbf{f}[0] = \exp(-\alpha t H) \mathbf{f}[t]$. Notice that when $t = 0$, $K = I$; when t is small, we have the first-order approximation $K = I - \alpha t H$.

Correlation via Diffusion. In CORRCS, we can define $f_k : V \rightarrow \mathbb{R}$ for each dimension of the features as $f_k^i = z_{ik}^i$, so the snapshot \mathbf{f}_k is a vector. By studying the statistical characteristics of f_k , $k = 1, 2, \dots, K$, we can then build a correlated sparse signal model $p(\mathbf{Z})$, which is the core of CORRCS-DP.

Imagine that \mathbf{f}_k is generated through the following process: Initially $\mathbf{f}_k[0]$ is sparse. This means each entry $f_k^i[0]$ is distributed i.i.d as

$$f_k^i[0] \sim \mathcal{N}\left(0, \gamma_k^i\right), \quad \forall v_i \in V \quad (15)$$

Hyper-parameters γ_k^i control the sparsity of each entry. They are both drawn from hyper-priors according to equation (6).

A diffusion process is then run on the graph $G(V, E)$ and stops at some time t producing $\mathbf{f}_k[t] = K \mathbf{f}_k[0]$. Using the diffusion-based generative model, the inference problem (9) for real-valued signals becomes

$$p(\mathbf{Z} | \mathbf{Y}; \Gamma) \propto \Pr(\Gamma) \exp\left(-\frac{1}{2} \sum_k (\mathbf{f}^k)^\top (K^{-1})^\top D_k K^{-1} \mathbf{f}^k - \frac{1}{2} \beta \sum_i (\mathbf{y}_i - M_i \mathbf{x}_i)^\top (\mathbf{y}_i - M_i \mathbf{x}_i)\right) \quad (16)$$

where $D_k = \text{diag}(\gamma_k^i)^{-1}$. Notice that in this formulation, we no longer need constant c to control the extent of correlation, since it is directly induced by the prior uncertainty γ_k^i . A few observations can be made about the connection of CORRCS-DP to other compressive sensing methods summarized as follows.

Proposition 3.1. *Using zeroth-order approximation $K := I$, where I is the identity matrix, CORRCS-DP subsumes BCS.*

Proof. Straightforward. By replacing $K := I$ in (16), the posterior $p(\mathbf{X} | \mathbf{Y})$ is exactly the same as BCS. \square

Proposition 3.2. *Using first-order approximation $K := I - \alpha t H$, CORRCS-DP reduces to Laplace-GRF model.*

Proof. This claim is induced by the general property of Laplacian H that $\mathbf{f}_k^\top H \mathbf{f}_k = \sum_{ij} w_{ij} (f_k^i - f_k^j)^2$. Using the first order approximation, we have

$$-\log p(\mathbf{Z} | \mathbf{Y}; \Gamma) = \frac{1}{2} \sum_{ik} \left(\frac{\mathbf{f}_i^k}{\gamma_i^k}\right)^2 - \alpha t \sum_k (\mathbf{f}^k)^\top D_k H \mathbf{f}^k + \text{Const} \quad (17)$$

Let $d_i^k = 1/(\gamma_i^k)^2$. Notice H is a Laplacian matrix,

$$\begin{aligned} -(\mathbf{f}^k)^\top D_k^H \mathbf{f}^k &= \sum_{ij} w_{ij} \left(d_i^k (f_i^k)^2 + d_j^k (f_j^k)^2 \right. \\ &\quad \left. - (d_i^k + d_j^k) f_i^k f_j^k \right) \\ &= \sum_{ij} w_{ij} \left(\frac{d_i^k + d_j^k}{2} \right) (f_i^k - f_j^k)^2 \\ &\quad - \frac{\alpha t}{2} \sum_i (H \mathbf{d}^k)_i \end{aligned}$$

Let

$$\mathcal{S} = \frac{1}{2} \sum_{ik} (f_i^k)^2 \left((I - \frac{\alpha t}{2}) d_i^k \right)_i$$

and

$$\mathcal{C}_{ij} = w_{ij} \left(\frac{d_i^k + d_j^k}{2} \right) (f_i^k - f_j^k)^2,$$

then $p(\mathbf{X} | \mathbf{Y}; \Gamma) \propto \exp(-\mathcal{S} - \sum_{ij} \mathcal{C}_{ij})$ shows that CORRCS-DP reduces to a pairwise correlation model. \square

3.3 INFERENCE ALGORITHM

The exact inference of CORRCS is largely intractable due to two reasons. First, the signal model and the sensing model is not in same conjugate family. Second, even if $p(\mathbf{X}; \Gamma)$ is jointly Gaussian, in real applications either the number of nodes or the dimension of features is big.

Instead, we resort to approximation methods and develop the posterior inference based on Variational Bayes EM (Bernardo et al., 2003). In particular, we use the mean-field approximation $p(\mathbf{X} | \mathbf{Y}; \Gamma) = \prod_{ik} q(z_{ik}; \Gamma)$ and perform the following two-step scheme. In the E-step, we propagate information across nodes to spread correlation, which can be related to a message-passing process (Donoho et al., 2009); in the M-step, we update Γ to enforce sparsity. The details are outlined in Algorithm 1.

Algorithm 1 Correlated Compressive Sensing

- 1: **Input:** Network $G(V, E)$, $\mathbf{Y} = [\mathbf{y}_1, \mathbf{y}_2, \dots, \mathbf{y}_n]$, basis Φ , measurement matrices V^i and iter .
 - 2: **for** $i = 1 \rightarrow n$ **do**
 - 3: compute $M^i = V^i \Phi$ for all $i = 1, 2, \dots, n$.
 - 4: initialize $\mathbf{z}^i = (M^i)^\top \mathbf{y}_i$.
 - 5: **end for**
 - 6: **for** $j = 1 \rightarrow \text{iter}$ **do**
 - 7: **for** $i = 1 \rightarrow n$ **do**
 - 8: **for** $k = 1 \rightarrow k$ **do**
 - 9: Update factor $q_k^i(\mathbf{z}_k^i)$ using equation (19), (20), (21).
 - 10: **end for**
 - 11: **end for**
 - 12: **for** $i = 1 \rightarrow n$ **do**
 - 13: For binary case, use equation (22) to update π^i ;
 for real-valued case, use equation (24) to update γ^i .
 - 14: **end for**
 - 15: **end for**
-

E-Step: Spread Correlation.

In the pairwise case, the update algorithm in general is

$$q_i(\mathbf{z}_k^i) \propto \exp\left(\mathbb{E}_{q(\mathbf{z}_{-k}^i)}\left[\frac{1}{2}\beta\|\mathbf{y}^i - M_i \mathbf{z}_i\|^2 + \mathcal{S}_i\right] + c \sum_{j \in \mathcal{A}(i)} \mathbb{E}_{q_j(\mathbf{z}^j)}[C_{ij} + C_{ji}]\right). \quad (18)$$

where \mathbf{z}_{-k}^i denotes all variables in \mathbf{z}^i except \mathbf{z}_k^i . Intuitively, the first expectation in (18) propagates information across dimensions of \mathbf{z}^i , while the second expectation in (18) spreads correlation among different nodes on the graph via the edges in between. Notice that for directed networks $w_{ij} \neq w_{ji}$, the information propagates forward and backward the edge in the same way, due to the symmetry of $C_{ij} + C_{ji}$.

Specifically, for Beta-Ising model,

$$\begin{aligned} q(\mathbf{z}_k^i = 1) &\propto \pi_k^i \exp\left(-\frac{1}{2}\beta(M_k^i)^\top(M_k^i) - 2(M_k^i)^\top(\mathbf{y}^i - M_{-k}^i \mathbb{E}[\mathbf{z}_{-k}^i])\right. \\ &\quad \left.+ c \sum_{j \in \mathcal{A}(i)} (w_{ij} + w_{ji})(2z_k^i - 1)\right) \quad (19) \\ q(\mathbf{z}_k^i = 0) &\propto 1 - \pi_k^i. \end{aligned}$$

Similarly for Laplace-GRF model, the mean-field update for each factor is $q_k^i(\mathbf{z}_k^i) = \mathcal{N}(\mu_k^i, \sigma_k^i)$, where

$$\begin{aligned} \sigma_k^i &= (\beta(M_k^i)^\top M_k^i + 1/\gamma_k^i)^{-1} \\ \mu_k^i &= \sigma_k^i \cdot \left(\beta(M_k^i)^\top(\mathbf{y}^i - M_{-k}^i \mu_{-k}^i) + c \sum_{j \in \mathcal{A}(i)} (w_{ij} + w_{ji})\mu_k^j\right). \quad (20) \end{aligned}$$

where μ_{-k}^i denotes all entries in μ^i except μ_k^i . For the extension of Laplace-GRF model, CorrCS-DP contains long-range interaction among the node, so all other nodes contribute to the distribution of the current node being updated. As in Laplace-GRF, we still have $q_k^i(\mathbf{z}_k^i) = \mathcal{N}(\mu_k^i, \sigma_k^i)$, but instead

$$\begin{aligned} \sigma_k^i &= \left(\beta(M_k^i)^\top M_k^i + U_{ii}^k\right)^{-1} \\ \mu_k^i &= \sigma_k^i \cdot \left(\beta(M_k^i)^\top(\mathbf{y}^i - M_{-k}^i \mu_{-k}^i) + \sum_{j \in V} (U_{-i}^k + (U^k)_{-i}^\top)^\top \mathbf{u}_k^j\right). \quad (21) \end{aligned}$$

where $U^k = K^{-T} D_k K^{-1}$ and $\mathbf{u}_k = [\mu_k^1, \mu_k^2, \dots, \mu_k^n]$.

Iteratively updating the factors according to equation (20), (19) and (21) guarantees convergence (Wainwright and Jordan, 2008).

M-Step: Update hyper-parameters. With the expectation of current belief about the signal to recover, we can further update the hyper-parameters Γ to enforce sparsity based on EM algorithm (Dempster et al., 1977). For Beta-Ising, we update the parameters of the Bernoulli prior π_k^i as follows

$$\pi_k^i \sim \frac{a/K + \mathbb{E}[z_k] - 1}{a/K + b(1 - 1/K) - 1}. \quad (22)$$

For Laplace-GRF, we update the global parameters

$$\gamma_k^i = -\frac{1}{2\lambda^2} + \sqrt{\frac{1}{4\lambda^2} + \frac{(\sigma_k^i + (\mu_k^i)^2)}{\lambda}}. \quad (23)$$

The update of γ_k^i in CorrCS-DP is similar to Laplace-GRF. Specifically, let Q^k be a diagonal matrix at time t such that $Q_{ii}^k = \sigma_k^i$, compute $\tilde{Q}^k = K^{-1} Q^k K^{-\top}$, which can be regarded as the uncertainty about $\mathbf{f}_k[0]$. Then we modify (24) as

$$\gamma_k^i = -\frac{1}{2\lambda^2} + \sqrt{\frac{1}{4\lambda^2} + \frac{\tilde{Q}_{ii}^k}{\lambda}}. \quad (24)$$

Combining E-step and M-step, we can jointly optimize Γ and infer \mathbf{Z} , which eventually recovers the networked data on the graph G .

4 EXPERIMENT

We evaluate Correlated Compressive Sensing (CorrCS) empirically on real datasets from social and sensor networks with pairwise or Diffusion-like correlation.

4.1 SOCIAL NETWORK DATA WITH PAIRWISE CORRELATION

Using compressive sensing with pairwise correlation, we test the two recovery models Laplace-GRF and Beta-Ising on two datasets: product review on Epinion¹ and consumer polling data in Michigan.

4.1.1 Performance on different datasets

Michigan Polling Data. The social polling data is collected from a survey of consumers in Michigan with 500 monthly telephone calls from January, 1978 to December 2012. The data is real-valued aggregation of four hundred economic indices. It has been known that pairwise correlation exists in these indices. Using half of the dataset as past history, this pairwise correlation is computed through Pearson correlation and taken as the weight w_{ij} . Therefore, we establish a graph of features representing their inherent correlation. Furthermore, the data is continuous real values and to sparsify it, we use online sparse matrix factorization (Mairal et al., 2010) to find a set of sparse basis.

We test Laplace-GRF model on the Michigan polling data with $a = 1, b = 0.1$ and $c = 1$. As measurements, we randomly select a fraction of the polling data for each feature. We refer to the dimension of the selected data versus the dimension of the original data as measurement ratio. The performance is evaluated via Mean Squared Error (MSE) of the recover signal with respect to the original one. The MSE is normalized by the 2-norm of the original signal. For independent compressive sensing, we include two popular choices – Bayesian Compressive Sensing (Ji et al., 2008)(BCS) and Orthogonal Matching Pursuit (Tropp and Gilbert, 2007)(OMP) – as baseline algorithms. Notice that some baseline implementations of compressive sensing, such as Basis Pursuit (Chen et al., 1998)(BP), are too slow and impractical for networked data.

The result is reported in Figure 2. As we can see, Laplace-GRF outperforms BCS and OMP largely for small measurement ratios (less than 0.6). When the measurement ratio is large (exceed 0.6), Laplace-GRF will have a performance similar to BCS, and it still outperform OMP to a big extent. Correlation is less useful for large measurement ratios, mainly because the numbers of observations are already sufficient for sparse recovery. However, since in practice, people usually use a measure ratio in the rang $[0.2, 0.5]$, and rarely measure more than 60% of the data for recovering. Hence, this will not have strong influence on Laplace-GRF’s practical use.

To measure the superiority of Laplace-GRF for small measurement ratio, we could compare the minimum measurement ratio that is needed to achieve a fixed accuracy level (i.e. MSE level) for different models. Like in this

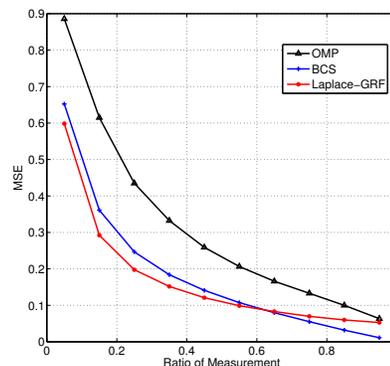

Figure 2: Performance of Laplace-GRF model versus the BCS model and OMP on the polling data.

dataset, we compare the minimum measurement ratio for different models to achieve a MSE not more than 0.2: our Laplace-GRF needs a measurement ratio of 0.23, BCS needs 0.32, while the most common baseline algorithm OMP needs 0.56. We could see that, to achieve this same recovery effect, Laplace-GRF needs 21% less measurements than BCS, and 59% less measurements than OMP. This result may imply that Laplace-GRF model could have valuable practical use since we could use a small number of measurements to recover a polling result, which is very close to the original ones. And by considering the inherent correlation between these indices, we could reduce the number of measurements by a ratio of 21% to recover a result with MSE 0.2 on this data, which means we could save a great deal of costs for this poll.

Epinion Data. The Epinion data is derived from the social product review network Epinions with 17,022 customers and 139,738 products. The graph G is built from the trust-list of all users: $w_{ij} = 1$ if and only if user i trusts user j , and therefore it is directed. To reduce the dimensionality of features, we select a subset of the most 100 popular products. Then z_{ij} represents whether customer i liked product j . The data Z is inherently sparse with only 5 to 10 nonzero per column, because the fraction of products rated by each customer is small. As measurements, each column z^i is projected to a low-dimensional space.

We test Beta-Ising model on the Epinion dataset against Bayesian Compressive Sensing (BCS) with beta prior. We choose $\lambda = 1, c = 0.3$. For the binary Epinion data, MSE is not a good choice because the data is zero almost everywhere. Instead, we regard the recovery as predicting label z_{ij} and use F1 score from classifier evaluations, which is the harmonic mean of precision (ratio of number of correct 1’s we recover over the total number of 1’s in our recovery result) and recall (ratio of number of correct 1’s we recover over the total number of 1’s in the ground truth).

¹Available at trustlet.org.

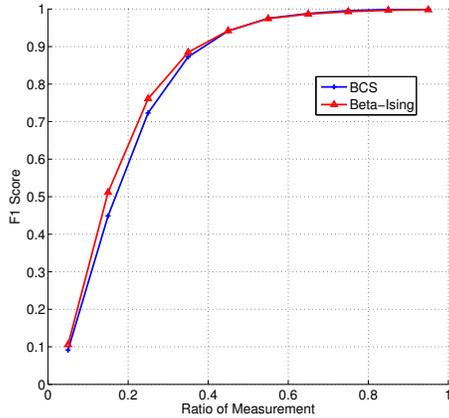

Figure 3: Performance of Beta-Ising model versus the Bayesian-Compressive Sensing on the Epinion data.

Figure 3 shows the result under F1 score. It can be seen that with correlation, the performance of BCS can be improved with a varying number of measurement ratios.

In our experiment, Beta-Ising model takes approximately the same amount of time for one iteration as BCS does, which indicates that it is a feasible and practical method for recovering binary networked data.

4.1.2 Sensitivity evaluation

Impact of parameters. In these two datasets, all parameters we could set are the parameter of the hierarchical conjugate prior a, b, λ and weight c . As has been discussed in BCS (Ji et al., 2008), our models are not sensitive the parameters a, b, λ . So in this paper, we focus on the impact of the weight parameter c on the performance of the `CorrCS` models.

The choice of c is the key to `CorrCS`, which can be viewed as a regularization parameter controlling the tradeoff with sparsity. To evaluate the impact of the c on the performance, we test the variation of the behavior of the `CorrCS` model on different scenario. For example, consider the Beta-Ising model on the Epinion data, we compare the variation of the recovery F1 score corresponding to the change of c when some reasonable measurement ratios are selected (15%, 25% and 35%). Figure 4 shows that among all these 3 measurement ratios, the performance of this model will be improved when c starts to grow from 0, and will be demoted when c pass some specific values. This result accords with our discussion about c in Section 3.1. This kind of variation of the performance according to c 's variation is reasonable since different values of c imply different extents that we care about the inherent correlation between nodes in the network structure. This experiment show us that the performance will have the same trends of

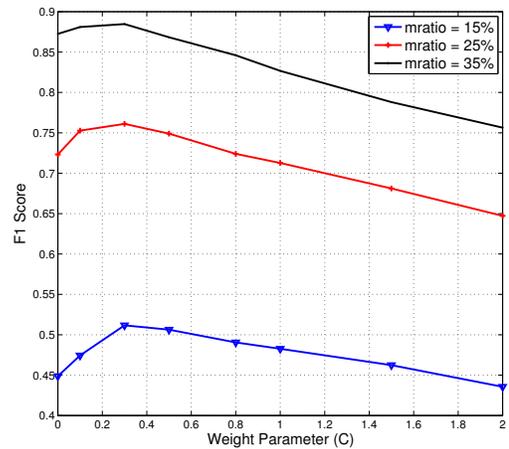

Figure 4: Relationship between the performance of the Beta-Ising model and the parameter c on different measure ratios.

variation on different measurement ratios when c is changing.

It is worth noting that among the 3 reasonable measurement ratios, the best c 's that will induce an optimal performance are very close. As shown in Figure 4, the model will possess an optimal performance when c is some value among 0.3. If $c = 0.3$, then the model will always have a nearly optimal recovery result as long as the measurement ratio is in a reasonable range. Therefore, in this model, we could choose an optimal choice of c that works well on all reasonable cases.

Impact of noise on the measured data. To test the robustness of these two models, we test the performance of our model on the two datasets when noises are added. More precisely, we add a Gaussian noise at each dimension of the observation \mathbf{y} , where the standard deviation of this noise at each dimension is κ times the original value of this dimension, where κ is Signal-to-Noise Ratio. We test the performance of the two models as κ increases from 0 to 0.5 on different scenarios (i.e. different measure ratios and weight parameters). As can be seen in Figure 5, this two models possess strong robustness on the two datasets since even if κ goes to 0.5 the recovery result will not vary too much. The Beta-Ising model on the Epinion dataset has a slightly better robustness than that of the Laplace-GRF model on the polling dataset since it deals with binary variables, whose robust recovery turns out to be easier.

4.2 POLLUTION DATA FROM SENSOR NETWORK

The Beijing pollution data includes a network of 22 monitoring stations collecting data in the same time window

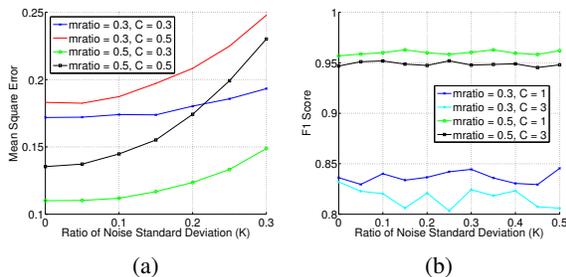

Figure 5: Robustness of `CorrCS` on the 2 datasets when some noise is added to the measure. **(a)**. Robustness of the Laplace-GRF model on the Polling dataset. **(b)**. Robustness of the Beta-Ising model on the Epinion dataset

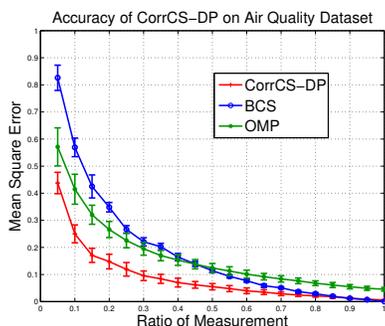

Figure 6: Performance of `CorrCS-DP` on Air Quality Dataset. Recovery accuracy of `CorrCS-DP` compared with `BCS` and `OMP`.

from Feb. 8th 2013 to Dec. 17 2013. The Air Quality Indexes (AQI) PM2.5 is recorded at an interval of 1 hour. The geography information of the sensors are available as GPS coordinates (g_i, l_i) , which we use to compute the edge weight of the sensor network through their euclidean distance $e_{ij} = \exp(-\theta\sqrt{(g_i - g_j)^2 + (l_i - l_j)^2})$.

The time sequence data is divided into 22 chunks, with 2 weeks of pollution data each chunk. The data is then split into two parts. Then we use 11 chunks to train a set of sparse basis using online sparse matrix factorization (Mairal et al., 2010), and also as cross-validation to find the best choice of diffusion time $t = 0.1$ and $c = 5$. The rest 11 chunks are used to test `CorrCS` and its counterparts. To simulate a real setting of measurement, we randomly select a portion of the samples as measurement and try to recover the rest. To test recovery accuracy in various situations, we change the ratio of measurement from 0 to 1 and compute the mean square error of the recovered signals.

Figure 6 and 7 shows the recovery accuracy and convergence rate of `CorrCS-DP` on the pollution dataset with comparison to the compressive sensing counterparts. The

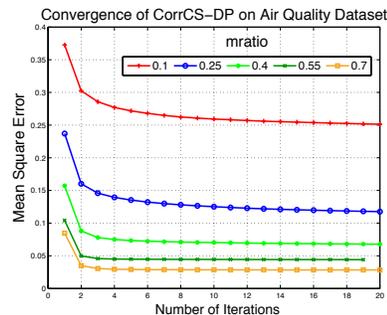

Figure 7: Convergence of recovery accuracy with number of iterations.

Objective MSE	<code>CorrCS-DP</code>	<code>OMP</code>	<code>BCS</code>
0.1	0.30	0.60	0.54
0.15	0.18	0.41	0.43
0.2	0.13	0.29	0.35

Table 1: Minimum measurement ratio to reach some particular values of MSE on the AQI dataset on different models

results are averaged over 10 independent runs. From Figure 6 we can see that `CorrCS` largely improves the recovery accuracy for various ratio of measurement, due to exploiting the correlation among different nodes. To measure the improvement of `CorrCS-DP` comparing to the other two models precisely, we could again compare the necessary minimum measurement ratio to reach some particular values of MSE on this data set on different models. As shown in Table 1, to reach the same MSE, `CorrCS-DP` could measure at least 40% less data than the other two models. Furthermore, as shown in Figure 7, `CorrCS` converges in about 3-4 steps. The convergence is faster than both `OMP` and `BCS`, and therefore demonstrates `CorrCS-DP` to be an efficacious and pragmatic correlated-recovery model.

5 RELATED WORK

Last two decades have witnessed significant advances in the theory and application of sensing sparse signals. Compressive sensing exploited the fact that natural signals are sparse and compressive under proper basis and designed sampling algorithms beyond the Nyquist-Shannon limit (Candès and Wakin, 2008). The theory of compressive sensing was developed by Candès et al. (2006) to explain this novel recovery performance. This theory was further improved by Candès and Tao (2006) to account for noisy measurements. The underlying property empowering sparse recovery is Restricted Isometry Property (RIP) of measurement matrices (Candès, 2008). On the algorithmic side, the first attempts to solve compressive sensing problems rely on ℓ_1 minimization under linear programming (Chen et al., 1998; Candès and Tao, 2005). Instead of optimizing with a large number of constraints, Orthog-

onal Matching Pursuit (Tropp and Gilbert, 2007) used a greedy heuristic to find solutions close to ℓ_0 optimum. To facilitate large-scale applications, Donoho et al. (2009) borrowed ideas from graphical models and derived a message passing algorithm for compressive sensing.

The Bayesian formulation of compressive sensing (BCS) is first proposed by Ji et al. (2008), which used a tractable conjugate Gamma prior on signal precision to enforce sparsity. It was shown that Bayesian compressive sensing allows uncertainty estimate and adaptive sampling. Based on BCS, Ji et al. (2009) developed a multi-tasking compressive sensing algorithm that allows simultaneously data collection from multiple sensors. Babacan et al. (2010) showed that stronger sparsity can be achieved for BCS with an conjugate prior on signal variance that is equivalent to the Laplace prior. As a counterpart of Laplace prior, beta prior is also commonly used (Paisley and Carin, 2009), with an additional latent variable controlling the support of signals. By comparing Laplace and Beta priors for sparse representation, Mohamed et al. (2011) concluded that Beta prior enforced stronger sparsity than the Laplace prior.

Real data is typically not sparse and therefore one must take effort in finding the appropriate basis. With a data-drive approach, dictionary learning for sparse basis originated from efforts in reproducing V1-like visual neurons through sparse coding (Olshausen and Field, 1997). Aharon et al. (2006) generalized the K-means clustering algorithm, and computed sparse decomposition by iteratively updating sparse coefficients and dictionary items. Mairal et al. (2009) proposed online dictionary learning methods, which leads to efficient computation of sparse coding.

Compressed sensing has find great applications in sensor networks. It was first successfully applied to network monitoring for optical and all-IP networks (Coates et al., 2007). In terms of data gathering, Luo et al. (2009) constructed a sensor network with a sink collecting compressed measurements, which is equivalent to a random matrix projection. Xu et al. (2013) considered more general compressed sparse functions for sparse representation of signals over graphs. Other than collecting data, compressive sensing was also used as a network analysis tool to identify social community on graphs (Jiang et al., 2011).

The topic of correlation in compressive sensing has been explored preliminarily in various ways. Shahrabi et al. (2011) used belief propagation to handle time-correlated signals with compressive sensing. Arildsen and Larsen (2014) explores the correlation of signal and measurement noise. In terms of networked data, Feizi et al. (2010) considers a distributed setting and a joint recovery model. As far as we know, our work is the first to explicitly incorporate graph structure as a hint of correlation.

Diffusion process has long been used as a general tool to capture correlation among data (Kondor and Lafferty,

2002). Ma et al. (2008) used diffusion process to model marketing candidate selection in social networks. The diffusion process may also be utilized to produce an representing wavelet basis on graphs and manifolds (Bremer et al., 2006). Using diffusion wavelets, it is possible to sparsify signals on different graph topologies and allow compressive sensing (Haupt et al., 2008). However, our correlated compressive sensing does not rely on the strong assumption that data on the network should be sparse under some basis, but rather weakly correlated.

6 CONCLUSIONS AND FUTURE WORK

In this paper, we present Correlated Compressive Sensing (CorrCS) to leverage correlation among networked data and to empower better sparse recovery. Using a Bayesian approach, CorrCS allows flexible representation of prior knowledge about correlation via a graphical model. Two common types of correlation of networked data are considered: pairwise and diffusion-based. We have shown the diffusion-based formulation subsumes the pairwise case via a low-order approximation. Through extensive empirical evaluation on real data on social and sensor networks, we have demonstrated the advantage of correlated compressive sensing over its counterparts.

As future work, we are interested in showing bounds in its recovery performance to better understand its properties. Also we are interested in developing nonparametric extensions of the current approach to allow adaptive inference of key parameters and the basis for sparse representation.

Abstract

The existing work on densification of one permutation hashing [24] reduces the query processing cost of the (K, L) -parameterized Locality Sensitive Hashing (LSH) algorithm with minwise hashing, from $O(dKL)$ to merely $O(d + KL)$, where d is the number of nonzeros of the data vector, K is the number of hashes in each hash table, and L is the number of hash tables. While that is a substantial improvement, our analysis reveals that the existing densification scheme in [24] is sub-optimal. In particular, there is not enough randomness in that procedure, which affects its accuracy on very sparse datasets.

In this paper, we provide a new densification procedure which is provably better than the existing scheme [24]. This improvement is more significant for very sparse datasets which are common over the web. The improved technique has the same cost of $O(d + KL)$ for query processing, thereby making it strictly preferable over the existing procedure. Experimental evaluations on public datasets, in the task of hashing based near neighbor search, support our theoretical findings.

1 Introduction

Binary representations are common for high dimensional sparse data over the web [8, 25, 26, 1], especially for text data represented by high-order n -grams [4, 12]. Binary vectors can also be equivalently viewed as sets, over the universe of all the features, containing only locations of the non-zero entries. Given two sets $S_1, S_2 \subseteq \Omega = \{1, 2, \dots, D\}$, a popular measure of similarity between sets (or binary vectors) is the *resemblance* R , defined as

$$R = \frac{|S_1 \cap S_2|}{|S_1 \cup S_2|} = \frac{a}{f_1 + f_2 - a}, \quad (1)$$

where $f_1 = |S_1|$, $f_2 = |S_2|$, and $a = |S_1 \cap S_2|$.

It is well-known that minwise hashing belongs to the *Locality Sensitive Hashing (LSH)* family [5, 9]. The method

applies a random permutation $\pi : \Omega \rightarrow \Omega$, on the given set S , and stores the minimum value after the permutation mapping. Formally,

$$h_\pi(S) = \min(\pi(S)). \quad (2)$$

Given sets S_1 and S_2 , it can be shown by elementary probability arguments that

$$Pr(h_\pi(S_1) = h_\pi(S_2)) = \frac{|S_1 \cap S_2|}{|S_1 \cup S_2|} = R. \quad (3)$$

The probability of collision (equality of hash values), under minwise hashing, is equal to the similarity of interest R . This property, also known as the *LSH property* [14, 9], makes minwise hash functions h_π suitable for creating hash buckets, which leads to sublinear algorithms for similarity search. Because of this same LSH property, minwise hashing is a popular indexing technique for a variety of large-scale data processing applications, which include duplicate detection [4, 13], all-pair similarity [3], fast linear learning [19], temporal correlation [10], 3-way similarity & retrieval [17, 23], graph algorithms [6, 11, 21], and more.

Querying with a standard (K, L) -parameterized LSH algorithm [14], for fast similarity search, requires computing $K \times L$ min-hash values per query, where K is the number of hashes in each hash table and L is the number of hash tables. In theory, the value of KL grows with the data size [14]. In practice, typically, this number ranges from a few hundreds to a few thousands. Thus, processing a single query, for near-neighbor search, requires evaluating hundreds or thousands of independent permutations π (or cheaper universal approximations to permutations [7, 22, 20]) over the given data vector. If d denotes the number of non-zeros in the query vector, then the query preprocessing cost is $O(dKL)$ which is also the bottleneck step in the LSH algorithm [14]. Query time (latency) is crucial in many user-facing applications, such as search.

Linear learning with b -bit minwise hashing [19], requires multiple evaluations (say k) of h_π for a given data vector. Computing k different min-hashes of the test data costs $O(dk)$, while after processing, classifying this data vector

(with SVM or logistic regression) only requires a single inner product with the weight vector which is $O(k)$. Again, the bottleneck step during testing prediction is the evaluation of k min-hashes. Testing time directly translates into the latency of on-line classification systems.

The idea of storing k contiguous minimum values after one single permutation [4, 15, 16] leads to hash values which do not satisfy the LSH property because the hashes are not properly aligned. The estimators are also not linear, and therefore they do not lead to feature representation for linear learning with resemblance. This is a serious limitation.

Recently it was shown that a “rotation” technique [24] for densifying sparse sketches from one permutation hashing [18] solves the problem of costly processing with min-wise hashing (See Sec. 2). The scheme only requires a single permutation and generates k different hash values, satisfying the LSH property (i.e., Eq.(3)), in linear time $O(d + k)$, thereby reducing a factor d in the processing cost compared to the original minwise hashing.

Our Contributions: In this paper, we argue that the existing densification scheme [24] is not the optimal way of densifying the sparse sketches of one permutation hashing at the given processing cost. In particular, we provide a provably better densification scheme for generating k hashes with the same processing cost of $O(d + k)$. Our contributions can be summarized as follows.

- Our detailed variance analysis of the hashes obtained from the existing densification scheme [24] reveals that there is not enough randomness in that procedure which leads to high variance in very sparse datasets.
- We provide a new densification scheme for one permutation hashing with provably smaller variance than the scheme in [24]. The improvement becomes more significant for very sparse datasets which are common in practice. The improved scheme retains the computational complexity of $O(d + k)$ for computing k different hash evaluations of a given vector.
- We provide experimental evidences on publicly available datasets, which demonstrate the superiority of the improved densification procedure over the existing scheme, in the task of resemblance estimation and as well as the task of near neighbor retrieval with LSH.

2 Background

2.1 One Permutation Hashing

As illustrated in Figure 1, instead of conducting k independent permutations, *one permutation hashing* [18] uses only one permutation and partitions the (permuted) feature space into k bins. In other words, a single permutation π is used to first shuffle the given binary vector, and then the shuffled vector is binned into k evenly spaced bins. The

k minimums, computed for each bin separately, are the k different hash values. Obviously, empty bins are possible.

	Bin 0	Bin 1	Bin 2	Bin 3	Bin 4	Bin 5
$\pi(\Omega)$	0 1 2 3	4 5 6 7	8 9 10 11	12 13 14 15	16 17 18 19	20 21 22 23
	0 1 2 3					
$\pi(S_1)$	0 0 0 0	0 <u>1</u> 0 1	0 0 0 0	0 0 <u>1</u> 1	<u>1</u> 0 1 0	0 <u>1</u> 1 0
$\pi(S_2)$	0 0 0 0	0 <u>1</u> 1 1	0 0 0 0	<u>1</u> 0 1 0	<u>1</u> 1 0 0	0 0 0 0
OPH(S_1)	E	1	E	2	0	1
OPH(S_2)	E	1	E	0	0	E

Figure 1: One permutation hashes [18] for vectors S_1 and S_2 using a single permutation π . For bins not containing any non-zeros, we use special symbol “E”.

For example, in Figure 1, $\pi(S_1)$ and $\pi(S_2)$ denote the state of the binary vectors S_1 and S_2 after applying permutation π . These shuffled vectors are then divided into 6 bins of length 4 each. We start the numbering from 0. We look into each bin and store the corresponding minimum non-zero index. For bins not containing any non-zeros, we use a special symbol “E” to denote empty bins. We also denote

$$M_j(\pi(S)) = \left\{ \pi(S) \cap \left[\frac{Dj}{k}, \frac{D(j+1)}{k} \right) \right\} \quad (4)$$

We assume for the rest of the paper that D is divisible by k , otherwise we can always pad extra dummy features. We define OPH_j (“OPH” for one permutation hashing) as

$$OPH_j(\pi(S)) = \begin{cases} E, & \text{if } \pi(S) \cap \left[\frac{Dj}{k}, \frac{D(j+1)}{k} \right) = \phi \\ M_j(\pi(S)) \bmod \frac{D}{k}, & \text{otherwise} \end{cases} \quad (5)$$

i.e., $OPH_j(\pi(S))$ denotes the minimum value in Bin j , under permutation mapping π , as shown in the example in Figure 1. If this intersection is null, i.e., $\pi(S) \cap \left[\frac{Dj}{k}, \frac{D(j+1)}{k} \right) = \phi$, then $OPH_j(\pi(S)) = E$.

Consider the events of “simultaneously empty bin” $I_{emp}^j = 1$ and “simultaneously non-empty bin” $I_{emp}^j = 0$, between given vectors S_1 and S_2 , defined as:

$$I_{emp}^j = \begin{cases} 1, & \text{if } OPH_j(\pi(S_1)) = OPH_j(\pi(S_2)) = E \\ 0 & \text{otherwise} \end{cases} \quad (6)$$

Simultaneously empty bins are only defined with respect to two sets S_1 and S_2 . In Figure 1, $I_{emp}^0 = 1$ and $I_{emp}^2 = 1$, while $I_{emp}^1 = I_{emp}^3 = I_{emp}^4 = I_{emp}^5 = 0$. Bin 5 is only empty for S_2 and not for S_1 , so $I_{emp}^5 = 0$.

Given a bin number j , if it is not simultaneously empty

($I_{emp}^j = 0$) for both the vectors S_1 and S_2 , [18] showed

$$\Pr \left(OPH_j(\pi(S_1)) = OPH_j(\pi(S_2)) \mid I_{emp}^j = 0 \right) = R \quad (7)$$

On the other hand, when $I_{emp}^j = 1$, no such guarantee exists. When $I_{emp}^j = 1$ collision does not have enough information about the similarity R . Since the event $I_{emp}^j = 1$ can only be determined given the two vectors S_1 and S_2 and the materialization of π , one permutation hashing cannot be directly used for indexing, especially when the data are very sparse. In particular, $OPH_j(\pi(S))$ does not lead to a valid LSH hash function because of the coupled event $I_{emp}^j = 1$ in (7). The simple strategy of ignoring empty bins leads to biased estimators of resemblance and shows poor performance [24]. Because of this same reason, one permutation hashing cannot be directly used to extract random features for linear learning with resemblance kernel.

2.2 Densifying One Permutation Hashing for Indexing and Linear Learning

[24] proposed a “rotation” scheme that assigns new values to all the empty bins, generated from one permutation hashing, in an unbiased fashion. The rotation scheme for filling the empty bins from Figure 1 is shown in Figure 2. The idea is that for every empty bin, the scheme borrows the value of the closest non-empty bin in the clockwise direction (circular right hand side) added with offset C .

	Bin 0	Bin 1	Bin 2	Bin 3	Bin 4	Bin 5
$\mathcal{H}(S_1)$	1+C	1	2+C	2	0	1
$\mathcal{H}(S_2)$	1+C	1	0+C	0	0	1+2C

Figure 2: Densification by “rotation” for filling empty bins generated from one permutation hashing [24]. Every empty bin is assigned the value of the closest non-empty bin, towards right (circular), with an offset C . For the configuration shown in Figure 1, the above figure shows the new assigned values (in red) of empty bins after densification.

Given the configuration in Figure 1, for Bin 2 corresponding to S_1 , we borrow the value 2 from Bin 3 along with an additional offset of C . Interesting is the case of Bin 5 for S_2 , the circular right is Bin 0 which was empty. Bin 0 borrows from Bin 1 acquiring value $1 + C$, Bin 5 borrows this value with another offset C . The value of Bin 5 finally becomes $1 + 2C$. The value of $C = \frac{D}{k} + 1$ enforces proper alignment and ensures no unexpected collisions. Without this offset C , Bin 5, which was not simultaneously empty, after reassignment, will have value 1 for both S_1 and S_2 . This would be an error as initially there was no collision (note $I_{emp}^5 = 0$). Multiplication by the distance of the non-empty bin, from where the value was borrowed, ensures

that the new values of simultaneous empty bins ($I_{emp}^j = 1$), at any location j for S_1 and S_2 , never match if their new values come from different bin numbers.

Formally the hashing scheme with “rotation”, denoted by \mathcal{H} , is defined as:

$$\mathcal{H}_j(S) = \begin{cases} OPH_j(\pi(S)) & \text{if } OPH_j(\pi(S)) \neq E \\ OPH_{(j+t) \bmod k}(\pi(S)) + tC & \text{otherwise} \end{cases} \quad (8)$$

$$t = \min z, \quad \text{s.t.} \quad OPH_{(j+z) \bmod k}(\pi(S)) \neq E \quad (9)$$

Here $C = \frac{D}{k} + 1$ is a constant.

This densification scheme ensures that whenever $I_{emp}^j = 0$, i.e., Bin j is simultaneously empty for any two S_1 and S_2 under considerations, the newly assigned value mimics the collision probability of the nearest simultaneously non-empty bin towards right (circular) hand side making the final collision probability equal to R , irrespective of whether $I_{emp}^j = 0$ or $I_{emp}^j = 1$. [24] proved this fact as a theorem.

Theorem 1 [24]

$$\Pr(\mathcal{H}_j(S_1) = \mathcal{H}_j(S_2)) = R \quad (10)$$

Theorem 1 implies that \mathcal{H} satisfies the LSH property and hence it is suitable for indexing based sublinear similarity search. Generating KL different hash values of \mathcal{H} only requires $O(d + KL)$, which saves a factor of d in the query processing cost compared to the cost of $O(dKL)$ with traditional minwise hashing. For fast linear learning [19] with k different hash values the new scheme only needs $O(d+k)$ testing (or prediction) time compared to standard b -bit minwise hashing which requires $O(dk)$ time for testing.

3 Variance Analysis of Existing Scheme

We first provide the variance analysis of the existing scheme [24]. Theorem 1 leads to an unbiased estimator of R between S_1 and S_2 defined as:

$$\hat{R} = \frac{1}{k} \sum_{j=0}^{k-1} \mathbf{1}\{\mathcal{H}_j(S_1) = \mathcal{H}_j(S_2)\}. \quad (11)$$

Denote the number of simultaneously empty bins by

$$N_{emp} = \sum_{j=0}^{k-1} \mathbf{1}\{I_{emp}^j = 1\}, \quad (12)$$

where $\mathbf{1}$ is the indicator function. We partition the event $(\mathcal{H}_j(S_1) = \mathcal{H}_j(S_2))$ into two cases depending on I_{emp}^j . Let M_j^N (*Non-empty Match at j*) and M_j^E (*Empty Match at j*) be the events defined as:

$$M_j^N = \mathbf{1}\{I_{emp}^j = 0 \text{ and } \mathcal{H}_j(S_1) = \mathcal{H}_j(S_2)\} \quad (13)$$

$$M_j^E = \mathbf{1}\{I_{emp}^j = 1 \text{ and } \mathcal{H}_j(S_1) = \mathcal{H}_j(S_2)\} \quad (14)$$

Note that, $M_j^N = 1 \implies M_j^E = 0$ and $M_j^E = 1 \implies M_j^N = 0$. This combined with Theorem 1 implies,

$$\begin{aligned} \mathbb{E}(M_j^N | I_{emp}^j = 0) &= \mathbb{E}(M_j^E | I_{emp}^j = 1) \\ &= \mathbb{E}(M_j^E + M_j^N) = R \quad \forall j \end{aligned} \quad (15)$$

It is not difficult to show that,

$$\mathbb{E}(M_j^N M_i^N | i \neq j, I_{emp}^j = 0 \text{ and } I_{emp}^i = 0) = R\tilde{R},$$

where $\tilde{R} = \frac{a-1}{f_1+f_2-a-1}$. Using these new events, we have

$$\hat{R} = \frac{1}{k} \sum_{j=0}^{k-1} [M_j^E + M_j^N] \quad (16)$$

We are interested in computing

$$Var(\hat{R}) = \mathbb{E} \left(\left(\frac{1}{k} \sum_{j=0}^{k-1} [M_j^E + M_j^N] \right)^2 \right) - R^2 \quad (17)$$

For notational convenience we will use m to denote the event $k - N_{emp} = m$, i.e., the expression $\mathbb{E}(\cdot | m)$ means $\mathbb{E}(\cdot | k - N_{emp} = m)$. To simplify the analysis, we will first compute the conditional expectation

$$f(m) = \mathbb{E} \left(\left(\frac{1}{k} \sum_{j=0}^{k-1} [M_j^E + M_j^N] \right)^2 \middle| m \right) \quad (18)$$

By expansion and linearity of expectation, we obtain

$$\begin{aligned} k^2 f(m) &= \mathbb{E} \left[\sum_{i \neq j} M_i^N M_j^N \middle| m \right] + \mathbb{E} \left[\sum_{i \neq j} M_i^E M_j^E \middle| m \right] \\ &+ \mathbb{E} \left[\sum_{i \neq j} M_i^E M_j^E \middle| m \right] + \mathbb{E} \left[\sum_{i=1}^k [(M_j^N)^2 + (M_j^E)^2] \middle| m \right] \end{aligned}$$

$M_j^N = (M_j^N)^2$ and $M_j^E = (M_j^E)^2$ as they are indicator functions and can only take values 0 and 1. Hence,

$$\mathbb{E} \left[\sum_{j=0}^{k-1} [(M_j^N)^2 + (M_j^E)^2] \middle| m \right] = kR \quad (19)$$

The values of the remaining three terms are given by the following 3 Lemmas; See the proofs in the Appendix.

Lemma 1

$$\mathbb{E} \left[\sum_{i \neq j} M_i^N M_j^N \middle| m \right] = m(m-1)R\tilde{R} \quad (20)$$

Lemma 2

$$\mathbb{E} \left[\sum_{i \neq j} M_i^E M_j^E \middle| m \right] = 2m(k-m) \left[\frac{R}{m} + \frac{(m-1)R\tilde{R}}{m} \right] \quad (21)$$

Lemma 3

$$\begin{aligned} \mathbb{E} \left[\sum_{i \neq j} M_i^E M_j^E \middle| m \right] &= (k-m)(k-m-1) \\ &\times \left[\frac{2R}{m+1} + \frac{(m-1)R\tilde{R}}{m+1} \right] \end{aligned} \quad (22)$$

Combining the expressions from the above 3 Lemmas and Eq.(19), we can compute $f(m)$. Taking a further expectation over values of m to remove the conditional dependency, the variance of \hat{R} can be shown in the next Theorem.

Theorem 2

$$\begin{aligned} Var(\hat{R}) &= \frac{R}{k} + A \frac{R}{k} + B \frac{R\tilde{R}}{k} - R^2 \quad (23) \\ A &= 2\mathbb{E} \left[\frac{N_{emp}}{k - N_{emp} + 1} \right] \\ B &= (k+1)\mathbb{E} \left[\frac{k - N_{emp} - 1}{k - N_{emp} + 1} \right] \end{aligned}$$

The theoretical values of A and B can be computed using the probability of the event $Pr(N_{emp} = i)$, denoted by P_i , which is given by Theorem 3 in [18].

$$P_i = \sum_{s=0}^{k-i} \frac{(-1)^s k!}{i!s!(k-i-s)!} \prod_{t=0}^{f_1+f_2-a-1} \frac{D(1 - \frac{i+s}{k}) - t}{D-t}$$

4 Intuition for the Improved Scheme

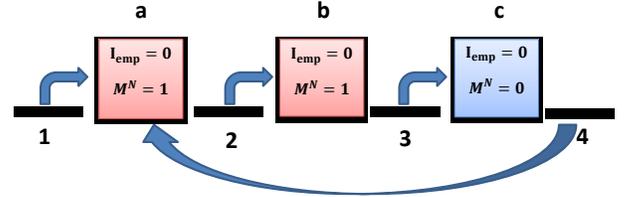

Figure 3: Illustration of the existing densification scheme [24]. The 3 boxes indicate 3 simultaneously non-empty bins. Any simultaneously empty bin has 4 possible positions shown by blank spaces. Arrow indicates the choice of simultaneous non-empty bins picked by simultaneously empty bins occurring in the corresponding positions. A simultaneously empty bin occurring in position 3 uses the information from Bin c . The randomness is in the position number of these bins which depends on π .

Consider a situation in Figure 3, where there are 3 simultaneously non-empty bins ($I_{emp} = 0$) for given S_1 and S_2 . The actual position numbers of these simultaneously non-empty bins are random. The simultaneously empty bins ($I_{emp} = 1$) can occur in any order in the 4 blank spaces. The arrows in the figure show the simultaneously

non-empty bins which are being picked by the simultaneously empty bins ($I_{emp} = 1$) located in the shown blank spaces. The randomness in the system is in the ordering of simultaneously empty and simultaneously non-empty bins.

Given a simultaneously non-empty Bin t ($I_{emp}^t = 0$), the probability that it is picked by a given simultaneously empty Bin i ($I_{emp}^i = 1$) is exactly $\frac{1}{m}$. This is because the permutation π is perfectly random and given m , any ordering of m simultaneously non-empty bins and $k - m$ simultaneously empty bins are equally likely. Hence, we obtain the term $\left[\frac{R}{m} + \frac{(m-1)R\tilde{R}}{m} \right]$ in Lemma 2.

On the other hand, under the given scheme, the probability that two simultaneously empty bins, i and j , (i.e., $I_{emp}^i = 1$, $I_{emp}^j = 1$), both pick the same simultaneous non-empty Bin t ($I_{emp}^t = 0$) is given by (see proof of Lemma 3)

$$p = \frac{2}{m+1} \quad (24)$$

The value of p is high because there is not enough randomness in the selection procedure. Since $R \leq 1$ and $R \leq R\tilde{R}$, if we can reduce this probability p then we reduce the value of $[pR + (1-p)R\tilde{R}]$. This directly reduces the value of $(k-m)(k-m-1) \left[\frac{2R}{m+1} + \frac{(m-1)R\tilde{R}}{m+1} \right]$ as given by Lemma 3. The reduction scales with N_{emp} .

For every simultaneously empty bin, the current scheme uses the information of the closest non-empty bin in the right. Because of the symmetry in the arguments, changing the direction to left instead of right also leads to a valid densification scheme with exactly same variance. This is where we can infuse randomness without violating the alignment necessary for unbiased densification. We show that randomly switching between left and right provably improves (reduces) the variance by making the sampling procedure of simultaneously non-empty bins more random.

5 The Improved Densification Scheme

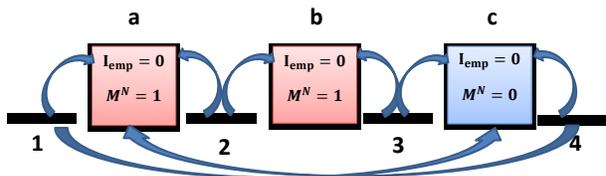

Figure 4: Illustration of the improved densification scheme. For every simultaneously empty bin, in the blank position, instead of always choosing the simultaneously non-empty bin from right, the new scheme randomly chooses to go either left or right. A simultaneously empty bin occurring at position 2 uniformly chooses among Bin a or Bin b .

Our proposal is explained in Figure 4. Instead of using the value of the closest non-empty bin from the right (circular),

we will choose to go either left or right with probability $\frac{1}{2}$. This adds more randomness in the selection procedure.

In the new scheme, we only need to store 1 random bit for each bin, which decides the direction (circular left or circular right) to proceed for finding the closest non-empty bin. The new assignment of the empty bins from Figure 1 is shown in Figure 5. Every bin number i has an i.i.d. Bernoulli random variable q_i (1 bit) associated with it. If Bin i is empty, we check the value of q_i . If $q_i = 1$, we move circular right to find the closest non-empty bin and use its value. In case when $q = 0$, we move circular left.

	Bin 0	Bin 1	Bin 2	Bin 3	Bin 4	Bin 5
Direction Bits (q)	0	1	0	0	1	1
$H^+(S_1)$	1+C	1	1+C	2	0	1
$H^+(S_2)$	0+2C	1	1+C	0	0	1+2C

Figure 5: Assigned values (in red) of empty bins from Figure 1 using the improved densification procedure. Every empty Bin i uses the value of the closest non-empty bin, towards circular left or circular right depending on the random direction bit q_i , with offset C .

For S_1 , we have $q_0 = 0$ for empty Bin 0, we therefore move circular left and borrow value from Bin 5 with offset C making the final value $1 + C$. Similarly for empty Bin 2 we have $q_2 = 0$ and we use the value of Bin 1 (circular left) added with C . For S_2 and Bin 0, we have $q_0 = 0$ and the next circular left bin is Bin 5 which is empty so we continue and borrow value from Bin 4, which is 0, with offset $2C$. It is a factor of 2 because we traveled 2 bins to locate the first non-empty bin. For Bin 2, again $q_2 = 0$ and the closest circular left non-empty bin is Bin 1, at distance 1, so the new value of Bin 2 for S_2 is $1 + C$. For Bin 5, $q_5 = 1$, so we go circular right and find non-empty Bin 1 at distance 2. The new hash value of Bin 5 is therefore $1 + 2C$. Note that the non-empty bins remain unchanged.

Formally, let $q_j = \{0, 1, 2, \dots, k-1\}$ be k i.i.d. Bernoulli random variables such that $q_j = 1$ with probability $\frac{1}{2}$. The improved hash function \mathcal{H}^+ is given by

$$\mathcal{H}_j^+(S) = \begin{cases} \begin{cases} OPH_{(j-t_1) \bmod k}(\pi(S)) + t_1 C \\ \text{if } q_j = 0 \text{ and } OPH_j(\pi(S)) = E \end{cases} \\ \begin{cases} OPH_{(j+t_2) \bmod k}(\pi(S)) + t_2 C \\ \text{if } q_j = 1 \text{ and } OPH_j(\pi(S)) = E \end{cases} \\ OPH_j(\pi(S)) & \text{otherwise} \end{cases} \quad (25)$$

where

$$t_1 = \min z, \quad s.t. \quad \text{OPH}_{(j-z) \bmod k}(\pi(S)) \neq E \quad (26)$$

$$t_2 = \min z, \quad s.t. \quad \text{OPH}_{(j+z) \bmod k}(\pi(S)) \neq E \quad (27)$$

with same $C = \frac{D}{k} + 1$. Computing k hash evaluations with \mathcal{H}^+ requires evaluating $\pi(S)$ followed by two passes over the k bins from different directions. The total complexity of computing k hash evaluations is again $O(d + k)$ which is the same as that of the existing densification scheme. We need an additional storage of the k bits (roughly hundreds or thousands in practice) which is practically negligible.

It is not difficult to show that \mathcal{H}^+ satisfies the LSH property for resemblance, which we state as a theorem.

Theorem 3

$$\Pr(\mathcal{H}_j^+(S_1) = \mathcal{H}_j^+(S_2)) = R \quad (28)$$

\mathcal{H}^+ leads to an unbiased estimator of resemblance \hat{R}^+

$$\hat{R}^+ = \frac{1}{k} \sum_{j=0}^{k-1} \mathbf{1}\{\mathcal{H}_j^+(S_1) = \mathcal{H}_j^+(S_2)\}. \quad (29)$$

6 Variance Analysis of Improved Scheme

When $m = 1$ (an event with $\text{prob}(\frac{1}{k})^{f_1+f_2-a} \simeq 0$), i.e., only one simultaneously non-empty bin, both the schemes are exactly same. For simplicity of expressions, we will assume that the number of simultaneous non-empty bins is strictly greater than 1, i.e., $m > 1$. The general case has an extra term for $m = 1$, which makes the expression unnecessarily complicated without changing the final conclusion.

Following the notation as in Sec. 3, we denote

$$M_j^{N+} = \mathbf{1}\{I_{emp}^j = 0 \text{ and } \mathcal{H}_j^+(S_1) = \mathcal{H}_j^+(S_2)\} \quad (30)$$

$$M_j^{E+} = \mathbf{1}\{I_{emp}^j = 1 \text{ and } \mathcal{H}_j^+(S_1) = \mathcal{H}_j^+(S_2)\} \quad (31)$$

The two expectations $\mathbb{E}\left[\sum_{i \neq j} M_i^{N+} M_j^{N+} \middle| m\right]$ and $\mathbb{E}\left[\sum_{i \neq j} M_i^{N+} M_j^{E+} \middle| m\right]$ are the same as given by Lemma 1 and Lemma 2 respectively, as all the arguments used to prove them still hold for the new scheme. The only change is in the term $\mathbb{E}\left[\sum_{i \neq j} M_i^{E+} M_j^{E+} \middle| m\right]$.

Lemma 4

$$\begin{aligned} \mathbb{E}\left[\sum_{i \neq j} M_i^{E+} M_j^{E+} \middle| m\right] &= (k - m)(k - m - 1) \\ &\times \left[\frac{3R}{2(m + 1)} + \frac{(2m - 1)R\tilde{R}}{2(m + 1)} \right] \end{aligned} \quad (32)$$

The theoretical variance of the new estimator \hat{R}^+ is given by the following Theorem 4.

Theorem 4

$$\begin{aligned} \text{Var}(\hat{R}^+) &= \frac{R}{k} + A^+ \frac{R}{k^2} + B^+ \frac{R\tilde{R}}{k^2} - R^2 \quad (33) \\ A^+ &= \mathbb{E}\left[\frac{N_{emp}(4k - N_{emp} + 1)}{2(k - N_{emp} + 1)}\right] \\ B^+ &= \mathbb{E}\left[\frac{2k^3 + N_{emp}^2 - N_{emp}(2k^2 + 2k + 1) - 2k}{2(k - N_{emp} + 1)}\right] \end{aligned}$$

The new scheme reduces the value of p (see Eq.(24)) from $\frac{2}{m+1}$ to $\frac{1.5}{m+1}$. As argued in Sec. 4, this reduces the overall variance. Here, we state it as theorem that $\text{Var}(\hat{R}^+) \leq \text{Var}(\hat{R})$ always.

Theorem 5

$$\text{Var}(\hat{R}^+) \leq \text{Var}(\hat{R}) \quad (34)$$

More precisely,

$$\begin{aligned} &\text{Var}(\hat{R}) - \text{Var}(\hat{R}^+) \\ &= \mathbb{E}\left[\frac{(N_{emp})(N_{emp} - 1)}{2k^2(k - N_{emp} + 1)} [R - R\tilde{R}]\right] \end{aligned} \quad (35)$$

The probability of simultaneously empty bins increases with increasing sparsity in dataset and the total number of bins k . We can see from Theorem 5 that with more simultaneously empty bins, i.e., higher N_{emp} , the gain with the improved scheme \mathcal{H}^+ is higher compared to \mathcal{H} . Hence, \mathcal{H}^+ should be significantly better than the existing scheme for very sparse datasets or in scenarios when we need a large number of hash values.

7 Evaluations

Our first experiment concerns the validation of the theoretical variances of the two densification schemes. The second experiment focuses on comparing the two schemes in the context of near neighbor search with LSH.

7.1 Comparisons of Mean Square Errors

We empirically verify the theoretical variances of \mathcal{R} and \mathcal{R}^+ and their effects in many practical scenarios. To achieve this, we extracted 12 pairs of words (which cover a wide spectrum of sparsity and similarity) from the web-crawl dataset which consists of word representation from 2^{16} documents. Every word is represented as a binary vector (or set) of $D = 2^{16}$ dimension, with a feature value of 1 indicating the presence of that word in the corresponding document. See Table 1 for detailed information of the data.

For all 12 pairs of words, we estimate the resemblance using the two estimators \mathcal{R} and \mathcal{R}^+ . We plot the empirical

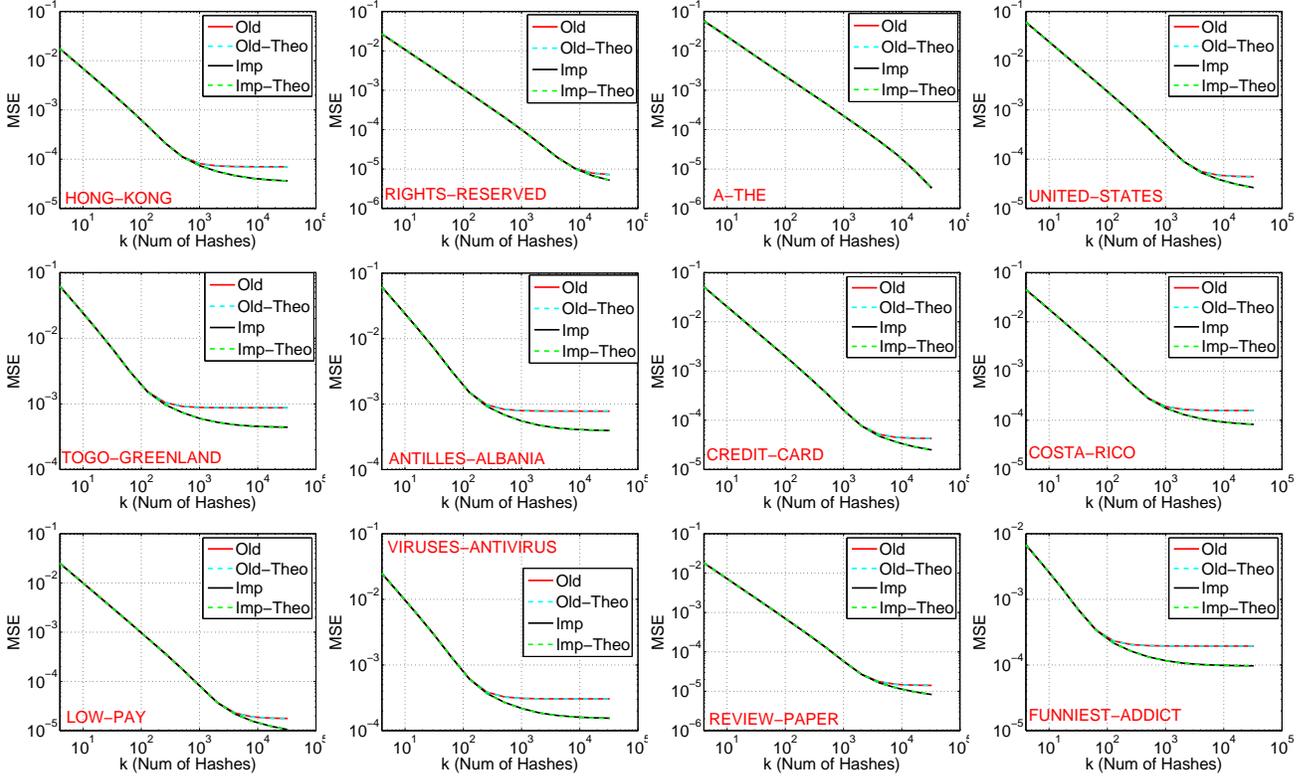

Figure 6: Mean Square Error (MSE) of the old scheme \hat{R} and the improved scheme \hat{R}^+ along with their theoretical values on 12 word pairs (Table 1) from a web crawl dataset.

Table 1: Information of 12 pairs of word vectors. Each word stands for a set of documents in which the word is contained. For example, “A” corresponds to the set of document IDs which contained word “A”.

Word 1	Word 2	f_1	f_2	R

Mean Square Error (MSE) of both estimators with respect to k which is the number of hash evaluations. To validate the theoretical variances (which is also the MSE because the estimators are unbiased), we also plot the values of the theoretical variances computed from Theorem 2 and Theorem 4. The results are summarized in Figure 6.

From the plots we can see that the theoretical and the empirical MSE values overlap in both the cases validating both Theorem 2 and Theorem 4. When k is small both the schemes have similar variances, but when k increases

the improved scheme always shows better variance. For very sparse pairs, we start seeing a significant difference in variance even for k as small as 100. For a sparse pair, e.g., “TOGO” and “GREENLAND”, the difference in variance, between the two schemes, is more compared to the dense pair “A” and “THE”. This is in agreement with Theorem 5.

7.2 Near Neighbor Retrieval with LSH

In this experiment, we evaluate the two hashing schemes \mathcal{H} and \mathcal{H}^+ on the standard (K, L) -parameterized LSH algorithm [14, 2] for retrieving near neighbors. Two publicly available sparse text datasets are described in Table 2.

Table 2: Dataset information.

Data	# dim	# nonzeros	# train	# query
RCV1	47,236	73	100,000	5,000
URL	3,231,961	115	90,000	5,000

In (K, L) -parameterized LSH algorithm for near neighbor search, we generate L different meta-hash functions. Each of these meta-hash functions is formed by concatenating K different hash values as

$$B_j(S) = [h_{j1}(S); h_{j2}(S); \dots; h_{jK}(S)], \quad (36)$$

where $h_{ij}, i \in \{1, 2, \dots, K\}, j \in \{1, 2, \dots, L\}$, are KL realizations of the hash function under consideration. The (K, L) -parameterized LSH works in two phases:

1. **Preprocessing Phase:** We construct L hash tables from the data by storing element S , in the train set, at location $B_j(S)$ in hash-table j .
2. **Query Phase:** Given a query Q , we report the union of all the points in the buckets $B_j(Q) \forall j \in \{1, 2, \dots, L\}$, where the union is over L hash tables.

For every dataset, based on the similarity levels, we chose a K based on standard recommendation. For this K we show results for a set of values of L depending on the recall values. Please refer to [2] for details on the implementation of LSH. Since both \mathcal{H} and \mathcal{H}^+ have the same collision probability, the choice of K and L is the same in both cases.

For every query point, the gold standard top 10 near neighbors from the training set are computed based on actual resemblance. We then compute the recall of these gold standard neighbors and the total number of points retrieved by the (K, L) bucketing scheme. We report the mean computed over all the points in the query set. Since the experiments involve randomization, the final results presented are averaged over 10 independent runs. The recalls and the points retrieved per query are summarized in Figure 7.

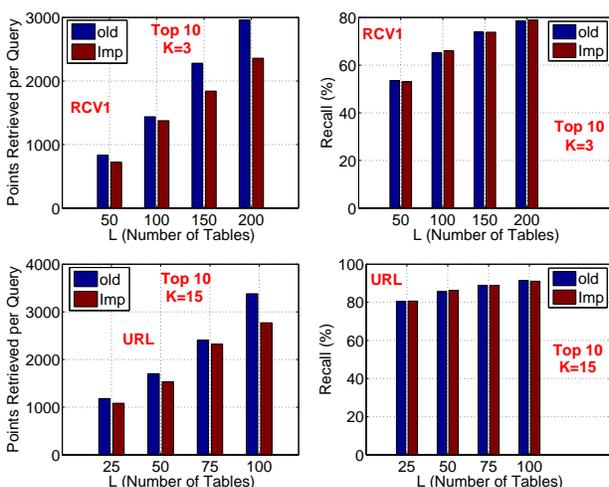

Figure 7: Average number of points scanned per query and the mean recall values of top 10 near neighbors, obtained from (K, L) -parameterized LSH algorithm, using \mathcal{H} (old) and \mathcal{H}^+ (Imp). Both schemes achieve the same recall but \mathcal{H}^+ reports fewer points compared to \mathcal{H} . Results are averaged over 10 independent runs.

It is clear from Figure 7 that the improved hashing scheme \mathcal{H}^+ achieves the same recall but at the same time retrieves less number of points compared to the old scheme \mathcal{H} . To achieve 90% recall on URL dataset, the old scheme retrieves around 3300 points per query on an average while the improved scheme only needs to check around 2700 points per query. For RCV1 dataset, with $L = 200$ the old scheme retrieves around 3000 points and achieves a re-

call of 80%, while the same recall is achieved by the improved scheme after retrieving only about 2350 points per query. A good hash function provides a right balance between recall and number of points retrieved. In particular, a hash function which achieves a given recall and at the same time retrieves less number of points is desirable because it implies better precision. The above results clearly demonstrate the superiority of the indexing scheme with improved hash function \mathcal{H}^+ over the indexing scheme with \mathcal{H} .

7.3 Why \mathcal{H}^+ retrieves less number of points than \mathcal{H} ?

The number of points retrieved, by the (K, L) parameterized LSH algorithm, is directly related to the collision probability of the meta-hash function $B_j(\cdot)$ (Eq.(36)). Given S_1 and S_2 with resemblance R , the higher the probability of event $B_j(S_1) = B_j(S_2)$, under a hashing scheme, the more number of points will be retrieved per table.

The analysis of the variance (second moment) about the event $B_j(S_1) = B_j(S_2)$ under \mathcal{H}^+ and \mathcal{H} provides some reasonable insight. Recall that since both estimators under the two hashing schemes are unbiased, the analysis of the first moment does not provide information in this regard.

$$\begin{aligned} & \mathbb{E}[1\{\mathcal{H}_{j1}(S_1) = \mathcal{H}_{j1}(S_2)\} \times 1\{\mathcal{H}_{j2}(S_1) = \mathcal{H}_{j2}(S_2)\}] \\ &= \mathbb{E}[M_{j1}^N M_{j2}^N + M_{j1}^N M_{j2}^E + M_{j1}^E M_{j2}^N + M_{j1}^E M_{j2}^E] \end{aligned}$$

As we know from our analysis that the first three terms inside expectation, in the RHS of the above equation, behaves similarly for both \mathcal{H}^+ and \mathcal{H} . The fourth term $\mathbb{E}[M_{j1}^E M_{j2}^E]$ is likely to be smaller in case of \mathcal{H}^+ because of smaller values of p . We therefore see that \mathcal{H} retrieves more points than necessary as compared to \mathcal{H}^+ . The difference is visible when empty bins dominate and $M_1^E M_2^E = 1$ is more likely. This happens in the case of sparse datasets which are common in practice.

8 Conclusion

Analysis of the densification scheme for one permutation hashing, which reduces the processing time of minwise hashes, reveals a sub-optimality in the existing procedure. We provide a simple improved procedure which adds more randomness in the current densification technique leading to a provably better scheme, especially for very sparse datasets. The improvement comes without any compromise with the computation and only requires $O(d+k)$ (linear) cost for generating k hash evaluations. We hope that our improved scheme will be adopted in practice.

A Proofs

For the analysis, it is sufficient to consider the configurations, of empty and non-empty bins, arising after throwing $|S_1 \cup S_2|$ balls uniformly into k bins with exactly m non-empty bins and $k-m$ empty bins. Under uniform throwing of balls, any ordering of m non-empty and $k-m$ empty bins is equally likely. The proofs involve elementary combinatorial arguments of counting configurations.

A.1 Proof of Lemma 1

Given exactly m simultaneously non-empty bins, any two of them can be chosen in $m(m-1)$ ways (with ordering of i and j). Each term $M_i^N M_j^N$, for both simultaneously non-empty i and j , is 1 with probability $R\tilde{R}$ (Note, $\mathbb{E}(M_i^N M_j^N | i \neq j, I_{emp}^i = 0, I_{emp}^j = 0) = R\tilde{R}$).

A.2 Proof of Lemma 2

The permutation is random and any sequence of simultaneously m non-empty and remaining $k-m$ empty bins are equal likely. This is because, while randomly throwing $|S_1 \cup S_2|$ balls into k bins with exactly m non-empty bins every sequence of simultaneously empty and non-empty bins has equal probability. Given m , there are total $2m(k-m)$ different pairs of empty and non-empty bins (including the ordering). Now, for every simultaneously empty bin j , i.e., $I_{emp}^j = 1$, M_j^E replicates M_t^N corresponding to nearest non-empty Bin t which is towards the circular right. There are two cases we need to consider:

Case 1: $t = i$, which has probability $\frac{1}{m}$ and

$$\mathbb{E}(M_i^N M_j^E | I_{emp}^j = 0, I_{emp}^j = 1) = \mathbb{E}(M_i^N | I_{emp}^i = 0) = R$$

Case 2: $t \neq i$, which has probability $\frac{m-1}{m}$ and

$$\begin{aligned} & \mathbb{E}(M_i^N M_j^E | I_{emp}^j = 0, I_{emp}^j = 1) \\ &= \mathbb{E}(M_i^N M_t^N | t \neq i, I_{emp}^i = 0, I_{emp}^t = 0) = R\tilde{R} \end{aligned}$$

Thus, the value of $\mathbb{E}\left[\sum_{i \neq j} M_i^N M_j^E \middle| m\right]$ comes out to be

$$2m(k-m) \left[\frac{R}{m} + \frac{(m-1)R\tilde{R}}{m} \right]$$

which is the desired expression.

A.3 Proof of Lemma 3

Given m , we have $(k-m)(k-m-1)$ different pairs of simultaneous non-empty bins. There are two cases, if the closest simultaneous non-empty bins towards their circular right are identical, then for such i and j , $M_i^E M_j^E = 1$ with probability R , else $M_i^E M_j^E = 1$ with probability $R\tilde{R}$. Let p be the probability that two simultaneously empty

bins i and j have the same closest bin on the right. Then $\mathbb{E}\left[\sum_{i \neq j} M_i^E M_j^E \middle| m\right]$ is given by

$$(k-m)(k-m-1) \left[pR + (1-p)R\tilde{R} \right] \quad (37)$$

because with probability $(1-p)$, it uses estimators from different simultaneous non-empty bins and in that case the $M_i^E M_j^E = 1$ with probability $R\tilde{R}$.

Consider Figure 3, where we have 3 simultaneous non-empty bins, i.e., $m = 3$ (shown by colored boxes). Given any two simultaneous empty bins Bin i and Bin j (out of total $k-m$) they will occupy any of the $m+1 = 4$ blank positions. The arrow shows the chosen non-empty bins for filling the empty bins. There are $(m+1)^2 + (m+1) = (m+1)(m+2)$ different ways of fitting two simultaneous non-empty bins i and j between m non-empty bins. Note, if both i and j go to the same blank position they can be permuted. This adds extra term $(m+1)$.

If both i and j choose the same blank space or the first and the last blank space, then both the simultaneous empty bins, Bin i and Bin j , corresponds to the same non-empty bin. The number of ways in which this happens is $2(m+1) + 2 = 2(m+2)$. So, we have

$$p = \frac{2(m+2)}{(m+1)(m+2)} = \frac{2}{m+1}.$$

Substituting p in Eq.(37) leads to the desired expression.

A.4 Proof of Lemma 4

Similar to the proof of Lemma 3, we need to compute p which is the probability that two simultaneously empty bins, Bin i and Bin j , use information from the same bin. As argued before, the total number of positions for any two simultaneously empty bins i and j , given m simultaneously non-empty bins is $(m+1)(m+2)$. Consider Figure 4, under the improved scheme, if both Bin i and Bin j choose the same blank position then they choose the same simultaneously non-empty bin with probability $\frac{1}{2}$. If Bin i and Bin j choose consecutive positions (e.g., position 2 and position 3) then they choose the same simultaneously non-empty bin (Bin b) with probability $\frac{1}{4}$. There are several boundary cases to consider too. Accumulating the terms leads to

$$p = \frac{\frac{2(m+2)}{2} + \frac{2m+4}{4}}{(m+1)(m+2)} = \frac{1.5}{m+1}.$$

Substituting p in Eq.(37) yields the desired result.

Note that $m = 1$ (an event with almost zero probability) leads to the value of $p = 1$. We ignore this case because it unnecessarily complicates the final expressions. $m = 1$ can be easily handled and does not affect the final conclusion.

First-Order Open-Universe POMDPs

Siddharth Srivastava and Stuart Russell and Paul Ruan and Xiang Cheng
Computer Science Division
University of California
Berkeley, CA 94720

Abstract

Open-universe probability models, representable by a variety of probabilistic programming languages (PPLs), handle uncertainty over the existence and identity of objects—forms of uncertainty occurring in many real-world situations. We examine the problem of extending a declarative PPL to define decision problems (specifically, POMDPs) and identify non-trivial representational issues in describing an agent’s capability for observation and action—issues that were avoided in previous work only by making strong and restrictive assumptions. We present semantic definitions that lead to POMDP specifications provably consistent with the sensor and actuator capabilities of the agent. We also describe a variant of point-based value iteration for solving open-universe POMDPs. Thus, we handle cases—such as seeing a new object and picking it up—that could not previously be represented or solved.

1 INTRODUCTION

The development of probabilistic programming languages or PPLs (Koller, McAllester, and Pfeffer, 1997; Milch et al., 2005; Goodman et al., 2008) has greatly expanded the expressive power of formal representations for probability models. In particular, PPLs express *open-universe probability models*, or OUPMs, which allow uncertainty over the existence and identity of objects. OUPMs are a natural fit to tasks such as vision, natural language understanding, surveillance, and security, where the set of relevant objects is not known in advance and the observations (pixels, strings, radar blips, login names) do not uniquely identify the entities in question.

It is natural, therefore, to consider whether the same benefits can be obtained for decision models, thereby providing a broader foundation for rational agents. A general decision

model—a partially observable Markov decision process or POMDP—includes a specification of what the agent can do and what it will perceive in any given state, as well as the reward functions.

For less expressive languages such as Bayesian networks and closed-universe first-order languages, the extension from probability models to decision models is relatively straightforward. For open-universe models, however, there are significant difficulties in defining POMDP representations that are both expressive enough to model the real world and mean exactly what is intended. When sensors supply sentences about named objects and actuators receive commands to act on named objects, problems arise if the formal names have uncertain referents. Consider the following example:

The sensors of an airport security system include passport scanners at check-in kiosks, boarding pass scanners, X-ray scanners, etc. A person passing through the airport generates observations from each of these scanners. Thus, the passport scanner at location A may generate observations of the form $IDName(p_{A,1}) = \text{“Bond”}$, $IDNumber(p_{A,1}) = 174666007$, $HeightOnID(p_{A,1}) = 185cm$, ...; a boarding-pass scanner at B may generate a sequence of the form $Destination(p_{B,7}) = \text{“Paris”}$, $IDNumber(p_{B,7}) = 174666007$, and finally, an X-ray scanner at C may generate observations of the form $MeasuredHeight(p_{C,32}) = 171cm$, $MeasuredHeight(p_{C,33}) = 183cm$.

In these observation streams, the symbols $p_{A,i}$, $p_{B,j}$ and $p_{C,k}$ are place-holder identifiers (essentially Skolem constants or “gensyms” in Lisp terminology). Although each use of a given symbol necessarily corresponds to the same individual, different symbols may or may not correspond to different individuals; thus, it is possible that $p_{A,1}$ and $p_{C,32}$ refer to the same person, while it is also possible that $p_{A,1}$ and $p_{B,7}$ refer to different people even though they are carrying documents with the same ID number.

The problems in modeling such a scenario are not limited to probabilistic models and can be illustrated using first-order

logic alone. For the observation model, we might want to say that, “Everyone in the security line will get scanned”:

$$\forall x \text{ InLine}(x) \rightarrow \text{Scanned}(x)$$

and “For everyone who gets scanned, we will observe a measured height”:

$$\forall x \text{ Scanned}(x) \rightarrow \text{Observable}(\text{MeasuredHeight}(x)). \quad (1)$$

So far, so good. Now, suppose we know, “Bond and his fiancée are in the security line.” While it is true, in a sense, that we will get a measured height for Bond’s fiancée, it is *not* true that the X-ray scanner will tell us:

$$\text{MeasuredHeight}(\text{Fiancée}(\text{Bond})) = 171\text{cm}.$$

Technically, the problem arises because we are trying to substitute $\text{Fiancée}(\text{Bond})$ for x in the universally quantified sentence (1), but one occurrence of x is inside $\text{Observable}(\cdot)$, which is a *modal operator*; thus, we have a failure of referential transparency—perhaps not surprising as we are trying to model what the agent will come to know. Practically, the problem arises because the sensor doesn’t know who Bond’s fiancée is. The same issue can arise on the action side: telling the security guard to “Arrest Bond’s fiancée” doesn’t work if the guard doesn’t know who Bond’s fiancée is. Thus, any proposed formal approach has to provide solutions to three fundamental problems: how to incorporate detected objects in an agent’s belief while allowing identity uncertainty; how to accurately state what can be sensed, and how to ensure that arguments in commands refer to something meaningful for actuators.

In fact, communication between the physical layer and the formal model requires a restricted vocabulary whose terms are guaranteed to be meaningful. This is because in a probability model, an observation has to be *true* to be conditioned on. The problem is that an OUPOMDP framework needs to ensure this even when the observations use uncertain references. We formally define the terms that will be meaningful, and therefore suitable for use in communication with the physical layer, using the concept of *rigid designators* from modal logic. This notion facilitates a framework where observations are true statements, without being restrictive. Our solution is analogous to modeling uncertain observations of a property as certain observations about a noisy version of that property.

We begin in §2.1 by showing, as a “warm-up exercise,” how POMDPs may be defined on a substrate of dynamic Bayesian networks (DBNs). §2.2 provides additional background on first-order, open-universe probability models. §3 describes our proposed semantics for a decision-theoretic extension of the BLOG language. We show that the resulting framework models sensor and actuator specifications accurately. §4 describes a variant of the point-based value iteration (PBVI) algorithm designed to handle open-universe POMDPs, and §5 describes experiments in a simple domain that illustrate the ability of the formalism and

algorithm to handle problems that previous formalisms (§6) cannot express and previous algorithms cannot solve. It has been possible for many years to program a robot to walk into a room, see something, and pick it up; now, it is possible for the robot to do this without leaving the formal framework of rational decision making.

2 BACKGROUND

2.1 POMDPs

A POMDP defines a decision-theoretic planning problem for an agent. At every step, the agent executes an action, then the environment enters a new state, then the agent receives an observation and a reward.

Definition 1. A POMDP is defined as $\langle X, U, O, T, \Omega, R, \gamma \rangle$, where X, U, O are finite sets of states, actions and observations; $T(X_{t+1} = x' \mid X_t = x, U_t = u)$ defines the transition model, i.e., the probability of reaching state x' if action u is applied in state x ; $\Omega(O_{t+1} = o \mid X_{t+1} = x', U_t = u)$ defines the observation model, i.e., the probability of receiving an observation o when state x' is reached via action u ; and $R : X \times U \rightarrow \mathbb{R}$ defines the reward that the agent receives on applying a given action at a given state.

The agent’s belief state at any timestep is the probability distribution over X at that timestep, given the initial belief and the history of executed actions and obtained observations. POMDP solutions typically map observation histories to actions (Kaelbling, Littman, and Cassandra, 1998). We will refer to such solutions as *observation-history policies*. On the other hand, *belief-state policies* map the agent’s belief states to actions. Both solution representations are equally expressive because the belief state constitutes a sufficient statistic for the agent’s history and the initial belief (Astrom, 1965). An optimal POMDP policy maximizes the expected value of the aggregate reward $\sum_{i=1, \dots, \infty} \gamma^i \cdot r(i)$ where $r(i)$ is the reward obtained at timestep i and $\gamma \leq 1$.

A DBN (Dean and Kanazawa, 1989) describes a factored, homogeneous, order-1 Markov process as a “two-slice” Bayesian network showing how variables at time $t + 1$ depend on variables at t . At each timestep, any subset of variables may be observed. To represent POMDPs, Russell and Norvig (1995) assume a fixed set of always-observable evidence nodes and define *dynamic decision networks* (DDNs) by adding to each timestep of a DBN the following variables:

- An *action variable* U_t whose values are the possible actions at time t . For now, assume this set of actions is fixed. The POMDP’s transition model is represented through the conditional dependence of variables at $t + 1$ on the value of U_t and other variables at t .
- A reward variable R_t , which depends deterministi-

cally on U_t and other variables at time t .

This definition of POMDPs by DDNs is not, however, completely general, since it does not allow for the observability of a variable to depend on the state. Clearly, different observability conditions correspond to different POMDPs. To handle state-dependent observability, one can define for each variable X_i that may be observed, a second Boolean variable $ObsX_i$ that captures whether or not X_i is observed¹. This factors out dependencies for observability from dependencies for the variable values. Thus, in order to define POMDPs we can define DDNs consisting of the following nodes in addition to the action and reward nodes:

- A Boolean *observability variable* $ObsX_i$ for each ordinary variable X_i . Each observability variable is necessarily observed at each time step, and $ObsX_i$ is true iff X_i is observed. Observability variables may have as parents other observability variables, ordinary variables, or the preceding action variable. The DBN with X_i and $ObsX_i$ variables defines Ω .

In this model, an always-observable X_i has an $ObsX_i$ with a deterministic prior set to 1.

In order to define first-order OUPOMDPs, we need to extend first-order OUPMs in a manner analogous to the DDN extension of DBNs. However, as we will show below, the analogous extension leads to conflicts with what may be known to the agent during decision making, and results in the models of sensors and actuators with unintentionally broad capabilities as seen in the introduction.

2.2 OPEN-UNIVERSE PROBABILITY MODELS

First-Order Vocabularies Given a set of *types* $\mathcal{T} = \{\tau_1, \dots, \tau_k\}$, a first-order *vocabulary* is a set of function symbols with their type signatures. Constant symbols are viewed as zero-ary function symbols and predicates as Boolean functions. A *possible world* is defined as a tuple $\langle \mathcal{U}, \mathcal{I} \rangle$ where the universe $\mathcal{U} = \langle \mathcal{U}_1, \dots, \mathcal{U}_k \rangle$ and each \mathcal{U}_i is a set of elements of type $\tau_i \in \mathcal{T}$. The interpretation \mathcal{I} has, for each function symbol in the vocabulary, a function of the corresponding type signature over $\mathcal{U}_1, \dots, \mathcal{U}_k$. The set of types includes the type *Timestep*, whose elements are the natural numbers. Functions whose last argument is of type timestep are called *fluents*. A state is defined by the values of all static functions and fluents at a particular timestep in a possible world.

¹Observability variables capture the full range of possibilities in the spectrum from missing-completely-at-random (MCAR) to not-missing-at-random (NMAR) data (Little and Rubin, 2002). An alternative would be to say that “null” values are observed when a variable is not observable. However, this approach has distinct disadvantages as it requires (a) unnecessarily large parent sets for evidence variables capturing when null values may be obtained, and (b) additional mechanisms for handling dependencies of child nodes of variables that may get a null value.

```

```

Figure 1: A BLOG model illustrating number statements.

Open-Universe Probability Models in BLOG Our approach can be applied to formal languages for generative, open-universe probability models (OUPMs). BLOG (Milch et al., 2005; Milch, 2006) is one such language. We refer the reader to the cited references for details on this system, and discuss briefly the components relevant to this paper. A BLOG model consists of two types of statements: (1) number statements, which specify conditional probability distributions (cpds) for the number of objects of each type in the universe of a structure; and (2) dependency statements, which specify cpds for the values of functions applied on the elements of the universe.

Each type can have multiple number statements and each number statement can take other objects as arguments. Fig. 1 shows a simple example of a BLOG model with two types, *Urn* and *Ball*. This model expresses a distribution over possible worlds consisting of varying numbers of urns with varying numbers of balls in each urn. The number of urns follows a Poisson(5) distribution (line 3). The number of balls in an urn depends on whether or not the urn is *Large*. *Origin* functions map the object being generated to the arguments that were used in the number statement that was responsible for generating it. In Fig. 1, *Source* maps a ball to the urn it belongs to. The number of balls in an urn follows a Poisson(10) distribution if the urn is *Large*, and a Poisson(2) distribution otherwise (lines 4-6). Finally, the probability of an urn being *Large* is 0.5 (lines 7 & 8).

Evidence statements in BLOG provide first-order sentences in the model’s vocabulary as observations; e.g.,

obs (exists Ball b exists Urn u Source(b)==u & Large(u)) = true
states that there exists a large urn that has a ball.

A *set evidence* statement provides a concise syntax for naming all the distinct objects satisfying a certain predication; e.g.,

obs {Ball b: exists Urn u Source(b)==u & !Large(u)}={b1, b2}

states that the set of balls in small urns consists of exactly two balls, referred to by the constant symbols $b1$ and $b2$.

We denote the execution of an action $u(x)$ at a timestep t using the fluent $apply_u(\bar{x}, t)$. The effects of an action are represented by defining the value of all fluents affected by the action at timestep $t + 1$ in terms of the fluents and non-

fluents at timestep t . The reward function can be expressed as a fluent in a similar manner. This notation is similar to successor-state axioms in situation calculus (Reiter, 2001). For example, a $sendToScanner(p, t)$ action may result in the person p going to the scanner. Let $followedInstructionCPD$, $leftScannerCPD$ and $defaultScannerCPD$ denote respectively the probability distribution that a person follows instructions, that s/he has left the scanner and that s/he is already at the scanner. We express the effect of this action on the predicate $atScanner$ using the fluent $apply_sendToScanner(x, t)$ as follows:

```
atScanner(Person p, Timestep t+1) {
  if apply_sendToScanner(p,t)
    then ~ followedInstructionCPD()
  else if atScanner(p, t) then ~ leftScannerCPD()
  else ~ defaultAtScannerCPD()};
```

Representation theorems for BLOG ensure that every well-founded specification (that does not create cyclic dependency statements or infinite ancestor sets) corresponds to a unique probability distribution over all possible worlds.

3 DECISION-THEORETIC BLOG

In this section we present the key components of decision-theoretic BLOG (DTBLOG), which adds to the BLOG language decision variables for representing actions and meta-predicates for representing observability.

3.1 SOLUTION APPROACH

A natural generalization of the $ObsX_i$ idea discussed in §2.1 is to write dependencies of the form: $Observable(\psi(\bar{x})) \{if \varphi(\bar{x}) then \sim cpd_1\}$, where w.l.o.g., φ and ψ can be considered to be predicates defined using FOL formulas with variables in \bar{x} as free variables. The interpretation of this formula would be “ $\psi(\bar{x})$ is observed with probability given by cpd_1 when $\varphi(\bar{x})$ holds”. As noted in the introduction, this formulation leads to problems associated with *referential transparency* in first-order reasoning. In order to model the sensor accurately, we want to describe a belief state where $Vesper = Fiancee(Bond)$, $Scanned(Vesper) = Scanned(Fiancee(Bond)) = true$, $Observable(MeasuredHeight(Vesper)) = true$, but $Observable(MeasuredHeight(Fiancee(Bond))) = false$.

However, these statements will be inconsistent in any system based on first-order reasoning. This is because first-order logic enforces all terms to be referentially transparent, as a consequence of the application of the axiom of universal instantiation on the substitution axioms for equality. The axiom of universal instantiation states that if $\forall x \alpha(x)$ is true, then for any ground term t , $\alpha(t/x)$ (the version of $\alpha(x)$ with all free occurrences of x replaced by t) is also true. Different truth values for the observability statements above stem from the fact that the sensor knows who $Vesper$ is, but not who $Fiancee(Bond)$ is. This indicates that the knowledge of sensors and actuators needs

to be taken into account while determining the possible effects of communicating with them.

To address this problem, we draw upon modal logic, where knowledge of the agent is taken into account (Levesque and Lakemeyer, 2000). The modal logic version of the axiom of universal instantiation states that if $\forall x \alpha(x)$ is true, then for any ground term t whose value is known, $\alpha(t/x)$ holds. In order to determine which terms are known, modal logic develops the notion of *rigid designators*: terms that have unique interpretations in all possible worlds according to the agent’s knowledge. Our formulation ensures that only the modal logic version of the axiom of universal instantiation is used with statements involving observability and doability. In practice, we use a modal logic of observations, so that a term is considered to be known to a system iff its value is predefined or has been observed. Our framework to ensure that (a) observations are true statements and are thus suitable for conditioning, and (b) terms used in the interface with actuators have well-defined values.

3.2 FORMAL SPECIFICATIONS

We begin our formal solution with elementary descriptions of physical sensors and actuators that clarify the types of rigid designators that sensors (actuators) can provide (act upon). We assume that the vocabulary always includes, as rigid designators, constant symbols for elements of standard types such as natural numbers and strings; e.g., the constant symbol 1 represents the natural number 1 in every possible world. We also assume that standard mathematical and string operations have fixed interpretations and that terms that are applications of fixed functions on rigid designators are therefore also rigid designators (e.g., $1 + 2$). As explained in the following sections, observations may add to the set of rigid designators.

Any physical sensor can be described in terms of the types of symbols it can generate and the type signatures of the properties that it can report:

Definition 2. A sensor specification S is a tuple $\langle \bar{T}_S, \tau_S \rangle$ where \bar{T}_S is a tuple of types for the observation values that S produces and τ_S denotes the type of new symbols that S may generate.

E.g., an X-ray scanner can be specified as: $scanner = \langle \langle PersonRef, Length \rangle, \langle PersonRef \rangle \rangle$. Such a scanner can generate new symbols of type $PersonRef$ and returns observation tuples of the type $\langle PersonRef, Length \rangle$; elements of type $Length$ are real numbers with units (not terms such as $Height(Bond)$). Note that such a specification indicates that rigid designators of type \bar{T}_S and τ_s are meaningful to the sensor, but arbitrary terms of the same types may not be.

A physical actuator can be specified similarly:

Definition 3. An actuator specification A is a tuple of types

\bar{T}_A denoting the types of its arguments.

E.g., an actuated camera may be able to take a picture given an orientation and focusing distance: $TakePhoto = \langle Orientation, Length \rangle$.

Let B be a set of beliefs, U be a set of actions, and O be a set of observations. A strategy tree $T_{B,U,O} = \langle \ell_U, \ell_O \rangle$ is defined by a mapping $\ell_U : B \rightarrow 2^U$, which defines the set of possible actions at each belief state, and a mapping $\ell_O : B, U \rightarrow 2^O$, which defines the set of possible observations when an action is applied on a belief state. Given a set of sensors \mathcal{S} and actuators \mathcal{A} , an actuator mapping $\alpha_A : U \rightarrow \mathcal{A}$ denotes the actuator responsible for executing each $u \in U$ and a sensor mapping $\sigma_S : O \rightarrow \mathcal{S}$ denotes the sensor responsible for generating o . We drop the subscripts \mathcal{S} and \mathcal{A} when they are clear from context.

Definition 4. A term is a rigid designator in a belief state b if it has a unique value in all possible worlds that have nonzero probability (in a discrete setting) or nonzero density (in a continuous setting) in b .

Definition 5. A strategy tree $T_{B,U,O} = \langle \ell_U, \ell_O \rangle$ is well-defined w.r.t. a set of sensor specifications \mathcal{S} , actuator specifications \mathcal{A} , a sensor mapping σ , and an actuator mapping α iff for every $b \in B$:

- Every $u \in \ell_U(b)$ uses as terms only the rigid designators of type \bar{T}_A in b , where $A = \alpha(u)$.
- For every $u \in \ell_U(b)$, every $o \in \ell_O(b, u)$ is either the observation of symbol of type τ_S or uses as terms only the rigid designators of type \bar{T}_S in b , where $S = \sigma(o)$.

In other words, a strategy tree is well-defined iff the actions and observations that it specifies at each step are truly possible. A framework for solving OUPOMDPs therefore needs to ensure that the strategy trees it defines and uses in its solution algorithms are well-defined w.r.t. the given sensors and actuators. We now present our formulation of sensors and actuators for achieving this objective.

3.3 MODELING SENSORS

In this section we describe our formulation for a sensor $S = \langle \bar{T}_S, \tau_S \rangle$. Recall that τ_S is the set of symbols generated by S . By definition, such symbols evaluate to themselves (just like integers) and are therefore rigid designators. We specify S using the following components in DTBLOG:

- A predicate V_S with arguments \bar{T}_S, t , representing the tuples returned by the sensor.
- The statement $ObservableType(\tau_S)$; denoting that symbols of type τ_S are returned by the sensor. Number statements for τ_S constitute a generative model for the elements generated by S . Each number statement for symbols of type τ_S includes an origin function $\tau_{S,time}$ which maps the symbol to the time when it was generated.

```

0 #Person ~ Poisson[10]; LocKnownDuration=4;
1 #PersonRef(Src = p, PersonRef_Time=t) {
2   if AtScanner(t)=p ~Bernoulli(0.5)
3   else = 0;
4   observableType(PersonRef);
5   observable(MeasuredHt(p_ref, t))=
6     (AtScanner(t) == Src(p_ref));
7   MeasuredHt(p_ref, t) ~ Normal[Ht(Src(p_ref)), 5];
8   Ht(prsn) ~ Normal[160, 30];
9
10 decision apply_TakePhoto(Orientation o, Distance d,
11   Timestep t);
12 PictureTaken(Person p, Timestep t){
13   if exists d, o RelativeDistance(TrueLoc(p, t)) == d &
14     RelativeOrientation(TrueLoc(p, t)) == o &
15     apply_takePhoto(o, d) then = true
16   else = False;
17
18 //Entrance model
19 AtScanner(t) ~ UniformChoice({Person prsn:
20   !Entered(prsn, t)});
21 Entered(prsn, t){
22   if t>0 & (AtScanner(t-1)=prsn) then = true
23   elseif t>0 then = Entered(prsn, t-1)
24   elseif t=0 then = false;
25 TrueLoc(Person p, t) ~ MovementModel(TrueLoc(p, t-1));
26 Location(p_ref, t) {
27   if PersonRef_Time(p_ref) < Horizon+1 &
28     & t<= PersonRef_Time(p_ref)+LocKnownDuration
29     then ~ TrueLoc(Src(p_ref, t))
30   else = null;

```

Figure 2: A DTBLOG model for the airport domain

- A dependency for $Observable(V_S(\bar{T}_S, Timestep))$, indicating the factors influencing the probability that S generates an observation.

For ease in representation, we also allow syntax for capturing sensors that return values of functions declared in the model’s vocabulary, rather than the default V_S predicate. Such observations also create rigid designators. For instance, it may be convenient to represent the scanner as a sensor that provides values of the measured height, captured by the function $MeasuredHt_{scanner}(p, t)$. In this case, the relational observability statements would provide dependencies for $Observable(MeasuredHt_{scanner}(p, t))$. Lines 4-6 in Fig.2 capture the DTBLOG specification for such a scanner. If the agent receives an observation of the form $MeasuredHt_{scanner}(pref_{10,1}, 7) = 171cm$, then $MeasuredHt_{scanner}(pref_{10,1}, 7)$ gets a unique interpretation, and thus becomes a rigid designator.

3.3.1 GENERATION OF OBSERVATIONS

Intuitively, if the environment is in state q at timestep t , and $Observable(\varphi(\bar{x}))$ (or $ObservableType(\tau_S)$) is true in q , then the value of $\varphi(\bar{x})$ (or the symbols of type τ_S generated at a timestep t) must be obtained as evidence at timestep t . We operationalize this intuition through two types of observations in DTBLOG: observations of the symbols generated by sensors, and observations about properties of the observed symbols.

Symbol observations All elements generated via a sensor’s symbol observability statement are assigned unique names and provided to the agent as an evidence statement. Suppose the model includes an observability declaration of

the form $ObservableType(\tau_S)$. For every possible world w at timestep t , this declaration results in the generation of a set evidence statement of the following form:

obs $\{\tau_S \ c:\tau_S_time(c) == t\} = \{c_{t,1}, \dots, c_{t,k(t)}\}$;

where $k(t) = \#\{\tau_S \ x : \tau_S_time(x) == t\}$ in w . Such a set evidence statement models the observation of a set of symbols generated by the sensor S . The semantics of BLOG ensure that $c_1, \dots, c_{k(t)}$ are interpreted as distinct objects; e.g., the scanner declaration in Fig. 2 results in the generation of a set of *PersonRef* objects at each timestep. The number of such symbols is given by the CPD for the number statement for *PersonRef*. At timestep 10, this observation could be:

obs $\{PersonRef \ x: PersonRef_Time(x) == 10\} = \{pref_{10,1}\}$;

Relational observations For every true $Observable(\varphi(\bar{x}))$ atom in a state, the DTBLOG engine creates an observation statement of the form:

obs $\varphi(\bar{x}) = v$;

where all arguments and the value v are rigid designators. E.g., if in a possible world $Observable(MeasuredHt_scanner(pref_{10,1}, 10)) = true$ and $MeasuredHt_scanner(pref_{10,1}, 10) = 171cm$, the generated relational observation would be:

obs $MeasuredHt_scanner(pref_{10,1}, 10) = 171cm$;

Each argument in such evidence statements has to be a rigid designator. Returning to the informal example described in the introduction, suppose Bond and Vesper were generated *PersonRefs*. The DTBLOG engine will not generate an observation of the form $MeasuredHeight(Fiancee(Bond), t) = 150cm$ if the value of *Fiancee(Bond)* has not been observed (unless *Fiancee* is a fixed function, which would be quite unusual), even when $MeasuredHeight()$ is observable for all *PersonRefs*. Thus, the agent being modeled will not “expect” an observation of the form “ $MeasuredHeight(Fiancee(Bond), t) = 150cm$ ”. On the other hand, if the agent receives an observation of the form $Fiancee(Bond) = Vesper$, the term on the left becomes a rigid designator and future user-provided observations and system-generated decisions may use the term *Fiancee(Bond)*.

We summarize our formulation of sensor models by noting that the set of all observations corresponding to a sensor S , $\sigma^{-1}(S)$, consists of the set evidence statements of type τ_S and value evidence statements for the predicate V_S (or its functional representation as noted above).

3.4 MODELING ACTUATORS

We represent an actuator $A = \bar{T}_A$ in a DTBLOG model as a decision function $apply_A(\bar{T}_A, t)$. Decision functions are declared using the keyword *decision*; e.g., an actuated camera $TakePhoto = \langle Orientation, Length \rangle$ can be specified as: decision $apply_TakePhoto(Orientation, Distance, Timestep)$;

The space of all possible actions in a belief state could be defined using all possible substitutions of the arguments of decision variables with terms. However, without any further restrictions, this would lead to unintended situations where the user provides a decision of the form:

apply_TakePhoto(Orientation(Loc(Src(pref_{10,1}),t)),
DistanceTo(Loc(Src(pref_{10,1}),t),t)=true;

even when $Loc(Src(pref_{10,1}),t)$ has not been observed. Such a decision would not only be meaningless to the actuator, it can lead to “fake” solutions, e.g., if the desired objective was to determine the current location of the person who generated $pref_{10,1}$ and take their photo. We eliminate such situations by allowing only rigid designators as arguments of decision functions. Lines 10-16 in Fig. 2 capture the DTBLOG specification for a camera. The remainder of Fig. 2 completes the specification with dependencies for the persons’ locations and their movement through the scanner. Since a *PersonRef* is generated when someone is at the scanner, the location (of the person) corresponding to a *PersonRef* is known for a brief period.

We summarize our formulation of actuator models by noting that the set of all decisions corresponding to an actuator A , $\alpha^{-1}(A)$, consists of decision functions of the form $apply_A(\bar{T}_A)$.

3.5 OUPOMDP DEFINED BY A DTBLOG MODEL

Let $M(S, \mathcal{A})$ be a DTBLOG model defined using the sets S and \mathcal{A} of sensors and actuators respectively. Let \mathcal{V}_M be the first-order vocabulary used in M . Then, M defines an OUPOMDP $\langle X, U, O, T, \Omega, R \rangle$ where the set of states X is the set of all timestep-indexed states corresponding to the possible worlds of vocabulary \mathcal{V}_M . U is the set of all instantiated decision functions corresponding to \mathcal{A} that are allowed in some state $x \in X$ and O is the set of all instantiated functions corresponding to sensor specifications in S that are allowed in some state $x \in X$. The transition function T and observation function Ω are defined by the probabilistic dependency statements in M . This formulation does not place any requirements on distributions of the values of observations or the effects of actions. Every BLOG model must include dependencies for every declared function; the dependencies for the values of sensor-predicates and fluents affected by decisions can be defined to capture arbitrary physical processes.

Strategy tree generated by a DTBLOG model DTBLOG represents belief states using collections of sampled, possible states. BLOG’s existing sampling subroutines are used to sample possible worlds corresponding to the initial state specified in the BLOG model. The semantics developed above implicitly define the strategy tree for a DTBLOG model: the application of a decision on a belief updates each possible world in the belief to the next timestep using the stated dependencies. When the belief

state is updated w.r.t. to a decision, the DTBLOG engine generates the set of observations corresponding to each possible updated state.

The following results follow from the semantics above.

Lemma 1. *The semantics of DTBLOG ensure that in a belief b , (a) every generated observation statement o is either a set evidence statement for symbols of type $\tau_{\sigma(o)}$ or an observation statement utilizing only rigid designators of type specified by $\bar{T}_{\sigma(o)}$, and (b) every possible decision u uses only arguments that are rigid designator tuples of the type $\bar{T}_{\alpha(u)}$.*

Theorem 1. *Let $M(S, A)$ be a DTBLOG model defined using sensor and actuator specifications S and A respectively, such that σ_S and α_A are its sensor and actuator mappings. If M satisfies BLOG's requirements for well-defined probabilistic models then it generates a well-defined strategy tree w.r.t. S , A , σ_S , and α_A .*

3.6 MODELING REAL-WORLD SITUATIONS

We now show that various non-trivial modes of sensing and acting can be expressed easily in the presented framework.

Observations of composed functions Consider a human operator who reads the passport of a passenger immediately after she exits the height scanner, and reports the date of birth along with the person reference generated by the height scanner. Intuitively, the human operator provides observations of a function composition: $DOB(PassportID(Src(PersonRef)))$, where DOB maps a passport number to the date of birth mentioned within. This appears to be a problem since the use of function application terms is specifically disallowed in our framework unless each such term has been observed. However, the situation can be modeled by defining the human operator as a sensor $\langle\langle PersonRef, Date \rangle, \langle \rangle\rangle$, that reports observations about the derived function $DOB \circ PPof \circ Src(x) = DOB(PassportID(Src(x)))$. In fact, our formulation correctly ensures that the agent will not expect an observation of $DOB(PassportID(Src(x)))$ from a sensor that reports the $DOB(y)$ function (perhaps a swipe-through scanner).

Actions on sensor-generated symbols In the real world, agents need to act upon objects that are detected through their sensors. Clearly, actuators can be specified to directly take inputs of the type generated by a sensor. Most commonly however, physical actuators such as a robot's gripper cannot act upon symbols. In such situations, sensor-generated symbols can be used in actions that can be compiled down to primitive actions respecting the semantics defined above. Consider a situation where the scanner reports the estimated *Location* of the person generating a person reference in addition to their measured heights. Let the functions *RelativeOrientation* and *CamDistance* map positions to the orientation and distance relative to the camera, respectively. We can define a camera action that takes a

snapshot given a *PersonRef* as follows:

```
apply_TakePhotoPRef(p_ref,t) :=
    apply_TakePhoto(RelativeOrientation(Location(p_ref)),
                    CamDistance(Location(p_ref)),t)
```

Every instance of *apply_TakePhotoPRef()* is compiled out into the primitive action *apply_TakePhoto()*.

Actuators that gain knowledge Although this framework cannot capture completely the beliefs of actuators or sensors with their own reasoning abilities, it can model actuators and sensors whose knowledge evolves. Consider an actuator that can dial phone numbers. Suppose this actuator models a human operator, who can read the phone book to obtain the phone number for any name. Our system correctly allows decisions such as *apply_Dial(phoneNumber("John"), t)* only if an observation of *PhoneNumber("John")* is received. However, they should also be allowed if the operator has been able to look up John's phone number in the phone book. The non-trivial part in designing such a system is to model the growth in knowledge of the operator.

Such a phone operator can be specified as $\langle String, Time \rangle$. The corresponding decision variable takes the form *apply_Dial(s, t)*. The restrictions developed above, on possibly substitutions for s , apply here. The effects of this action are determined by a predicate:

```
dialNumber(n, t) {
    if exists String s apply_Dial(s, t)
        and n == lookedUpNumber(s, t) then = true
    else = false};
```

where *lookedUpNumber(s, t)* is either the number represented by s if s is the string representation of a number, or, if s is a name, then it is the looked up number for that name according to a certain distribution:

```
lookedUpNumber(String s, Time t) {
    if strToNumber(s) != null then = strToNumber(s)
    else if exists t' < t operatorLookedUp(s, t')
        then ~ phoneBookCPD(s)
    else = null};
```

With this formulation, the application of decisions like *apply_dialNumber("John")* will result in a correctly updated belief state, contingent upon whether or not the operator performed a lookup.

4 SOLVING OUPOMDPS: OU-PBVI

In order to illustrate the efficacy of our framework, we developed and implemented an open-universe version of point-based value iteration (PBVI) (Pineau et al., 2003). OU-PBVI is designed to handle the main aspects of OUPOMDPS that prevent a direct application of POMDP algorithms: (a) belief states are infinite dimensional objects, and (b) the set of possible observations is unbounded. Thus, standard POMDP algorithms, which rely upon carrying out analytical backup operations using the domain's

transition function cannot be applied in general (although closed form backups for special cases may be possible). The following description focuses upon the key enhancements made to PBVI; a description of PBVI itself can be found in the cited reference.

PBVI restricts the Bellman backup of the value function for POMDPs to a finite set of sampled belief states, B . The $\|X\|$ -dimensional α vector for a policy represents its value function in terms of the expected value of following the policy for each state $x \in X$. PBVI approaches construct $t + 1$ step policies by computing the $t + 1$ step value function for each $b \in B$:

$$V^{t+1}(b) = \max_u \{E_b[r(s, u)] + \gamma E_{\Omega(o|b, u)}[V_{max}^t(b_o^u)]\},$$

where $V_{max}^t(b_o^u) = \max_{\alpha \in V_t} \alpha \cdot b_o^u$, and b_o^u is the belief state after action u is applied in b and observation o is obtained. $V^{t+1}(b)$ represents a 1-step backup of V for b .

In order to apply these ideas to OUPOMDPs, OU-PBVI represents belief states as sampled sets of possible worlds. Action application and the generation of observations proceeds as discussed in detail in the preceding sections. Thus, for each sampled state in a belief state b , action application results in a set of observations corresponding to the sampled states in b . We use a particle filter with N_p particles for belief propagation, and replace expectations by sample averages (Srivastava et al., 2012). In addition, we evaluate α vectors lazily. In our implementation, the number of keys (possible worlds) in α may reach a bound of $N_p \cdot \|B\|$. We also store the policy corresponding to each α vector. This allows us to dynamically compute missing components of the vector, as needed. More precisely, during backup, if the value of a policy π is required for a state that is not in the current set of states captured by α_π , that state is added to α_π and its value is computed by carrying out N_E simulations of the execution of that policy. During each simulation, after each step of policy execution and observation generation, if the resulting sampled state x is present in $\alpha_{\pi'}$ where π' is the subpolicy of π that remains to be executed, $\alpha_{\pi'}(x)$ is used and the simulation terminates. The estimates of policy value functions converge to the true value functions as the $N_p, N_E \rightarrow \infty$.

5 TEST PROBLEM AND RESULTS

We conducted experiments to investigate whether point-based approaches could be used for solving OUPOMDPs. As a test problem we developed an open-universe version of the Tiger problem. The agent is surrounded by 4 zones with an unknown, unbounded number of tigers who may move among zones at each timestep. Multiple tigers may be in a zone and the objective is to enter a zone without a tiger. The agent has two actions, a *listen*(*Timestep* t) action that allows it to make inaccurate observations about the growls made by tigers at timestep t , and an *enter*(*Zone*

z , *Timestep* t) action which it can use to enter a zone. When *listen* is applied, the agent obtains a growl from each tiger with probability 0.5.

```
observableType(Growl);
#Growl(Source = m, Time_Growl = t) {
    if apply_listen(t-1) then ~ Bernoulli(0.5)
    else = 0};
```

The listen action also gives a noisy estimate of the zones from which growls came. If a growl is made by a tiger in z , the probability of observing that a growl was made at z is 0.75, and that of observing that a growl was made at each of the zones $(z + 1 \bmod 4)$ and $(z - 1 \bmod 4)$ is 0.25. At each timestep, each tiger independently either stays in its zone with probability 0.4 or moves to each of the neighboring zones with probability 0.3. The agent receives a reward 10 for entering a door without tiger, -1 for listening, and -100 for entering a zone with a tiger. The number of tigers follows a Poisson(1) distribution. The objective is to find a policy for the belief state specified in the DTBLOG model. The unknown, *unbounded* numbers of tigers and *relevant* observations, as well as the independent movements of tigers make this a difficult OUPOMDP that cannot be expressed using existing approaches.

For our evaluation, we fixed $N_E = 100, \gamma = 0.9$ and the time horizon at 5. Fig. 3 shows the values of the obtained policies for varying values of $\|B\|$ and N_p , averaged over 10 different runs of the algorithm. To compute estimates of policy values, we carried out N_E simulations of the computed policy on each of 5000 samples for the initial state. The results show that the variance in policy value-estimates decrease as N_p and $\|B\|$ increase.

Since no other existing approach addresses OUPOMDPs, we used a *belief-state query* (BSQ) policy (Srivastava et al., 2012) as a baseline. BSQ policies map first-order probabilistic queries to belief states. Although such policies are more succinct than observation-history policies, evaluating them is non-trivial because the action to be applied at each step depends on the posterior probability of a first-order query rather than just the observation history. Algorithms for policy evaluation are discussed in detail in the cited reference. For our experiments we used the following, intuitively simple BSQ policy:

```
if Pr(no tiger behind  $d_1$  at  $t$ ) >  $\theta$ , enter( $d_1, t$ )
else if Pr(no tiger behind  $d_2$  at  $t$ ) >  $\theta$ , enter( $d_2, t$ )
```

```
...
else listen( $t$ )
```

We found that $\theta = 0.9$ resulted in the highest expected value for this BSQ policy, shown using the dashed line in Fig. 3. Our experiments show that OU-PBVI's computed policies approach the best value of our hand-written, parameterized BSQ policy as N_p and $\|B\|$ increase.

The average runtimes for OU-PBVI ranged from 420s for 8 beliefs and 200 particles to 106, 800s for 1000 particles and 128 beliefs. At least 80% of the time was spent in proba-

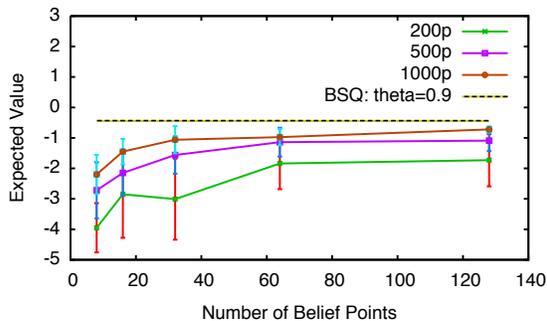

Figure 3: Expected values for OU-PBVI. Solid lines represent different numbers of particles used for the belief state representation (see text for details).

bilistic inference for carrying out belief propagation. Since we utilize PPLs to express OUPOMDPs, our approach will automatically scale with improvements in their inference engines. Indeed, using compiler techniques for improving inference in PPLs is an active area of research, and has shown speed-ups of up to 200x in preliminary experiments. We expect the runtimes of our algorithm to reduce to a fraction of the current estimates as a result of such advances.

These experiments demonstrate that our framework can be used to effectively express OUPOMDPs and solve them.

6 DISCUSSION

To the best of our knowledge, Moore (1985) presented the first comprehensive FOL formulation of actions that did not make the unique names assumption and allowed terms in the language to be partially observable, in a non-probabilistic framework. In Moore’s formulation actions could be executed by an agent only if they were “known” to it. This notion of epistemic feasibility of an action was also used in later work (Morgenstern, 1987; Davis, 1994, 2005). These approaches used a significantly larger axiomatization to address the problem of syntactically proving and communicating facts about knowledge. However, they cannot be used in open-universe probabilistic languages due to the requirement of reifying possible worlds and terms as objects in a universe. Further, they do not address the problems of expressing observability and action availability while conforming to a given agent specification.

Our formulation of action effects uses update rules similar to successor-state axioms (SSAs) (Reiter, 2001) with a significant enhancement: they allow compact expression of the so-called factored representations that are difficult to express using SSAs (Sanner and Kersting, 2010). Moreover, usually employed assumptions like having a “closed initial database” in that line of work preclude the possibility of expressing identity uncertainty: distinct terms like *Vesper* and *Fiancee(Bond)* can never represent the same object. Sanner and Kersting (2010) use this framework for first-order POMDPs and make the additional assumption

that all non-fluent terms are fully observable. They suggest a *same-as*(t_1, t_2) predicate for representing identity uncertainty between fluent terms. However, it is not clear how this predicate can be used in conjunction with their unique names axioms for actions, which assert that instances of an action applied on distinct terms must be distinct. The RDDDL language (Sanner, 2010) used in recent probabilistic planning competitions can also express closed-universe POMDPs as relational extensions of DBNs, under the assumptions that a fixed set of predicates will be observed at every time step and that all ground terms are unique and known. Wang and Khardon (2010) present a relational representation for closed-universe POMDPs where action arguments have to be in a known 1-1 mapping with actual objects in the universe. Kaelbling and Lozano-Pérez (2013) present an approach where action specifications include preconditions in the form of belief-state fluents. However, the solution approach requires action-specific regression functions over the probabilities of such queries. The approaches discussed so far assume that a POMDP definition is available. Recent work by Doshi-Velez (2010) addresses the problem of learning the transition and observation distributions for an *unfactored* POMDP with a potentially unbounded number of states.

In contrast to these approaches, our formulation allows an agent to plan and act upon objects *discovered* through its sensors. We presented the first framework for accurately expressing OUPOMDPs and solving them. The central idea of our solution is that representing observations and decisions using terms with unique meanings clarifies communication without being restrictive. We utilized this idea to construct strategy trees reflecting the true capabilities of an agent—something that could not be achieved by extending the existing formalisms. We also showed that this framework facilitates general algorithms for solving a large class of decision problems that capture real-world situations and could not previously be expressed or solved. A number of directions exist for future work. The notion of high-level actions can be developed further. For instance, one could define an action that determines the maximum likelihood estimate for the position of the person who generated a reference, and takes a picture of that location. Such actions have to be specified outside the DTBLOG model since they need to execute queries on the model to construct their arguments. However, probabilistic effects of such actions have to be defined in the model in a manner consistent with their external definitions.

Abstract

In this paper we develop a Hierarchical Switching Linear Dynamical System (HSLDS) for the detection of sepsis in neonates in an intensive care unit. The Factorial Switching LDS (FSLDS) of Quinn et al. (2009) is able to describe the observed vital signs data in terms of a number of discrete factors, which have either physiological or artifactual origin. In this paper we demonstrate that by adding a higher-level discrete variable with semantics sepsis/non-sepsis we can detect changes in the physiological factors that signal the presence of sepsis. We demonstrate that the performance of our model for the detection of sepsis is not statistically different from the auto-regressive HMM of Stanculescu et al. (2013), despite the fact that their model is given “ground truth” annotations of the physiological factors, while our HSLDS must infer them from the raw vital signs data.

1 INTRODUCTION

In condition monitoring, we are often interested in inferring when a dynamical system “switches” its mode of operation. Inside Neonatal Intensive Care Units (NICUs), one the most important “switches” is associated with the start of late onset neonatal sepsis (LONS). LONS is a bloodstream infection, usually bacterial, which generally occurs after the third day of life. It is a major cause of mortality, lifelong neurodisability and increased health care costs (Modi et al., 2009).

Since early clinical signs are subtle, making the diagnosis of infection is a great challenge. A deterioration of the baby’s condition prompts clinicians to take a

blood sample for laboratory testing. However, laboratory culture results can take up to a day before becoming available. This delay is known to prevent effective treatment (Griffin et al., 2003). Thus, a dependable early sepsis detector would have a major impact on NICU care. In this work, we discuss a solution which relies exclusively on vital signs monitoring data.

We propose a Hierarchical Switching Linear Dynamical System (HSLDS) to model a dynamical system with complex interactions between modes of operation. The structure of the model is shown in Fig. 1. In the HSLDS, the switch state is represented as a two-level discrete hierarchical structure. The top layer switch variables control the transition matrices used by the lower discrete layer, whose variables are assumed to be conditionally independent given the top layer. Conditioned on the hidden discrete structure, the model is a Linear Dynamical System (LDS), which models continuous hidden state variables and continuous observations. The observations are assumed to come from readings of the monitoring equipment.

The HSLDS can be applied for the real-world task of detecting neonatal sepsis. The discrete top layer determines the state of the infection and the lower-level discrete factors are baby-generated physiological events. The physiological events we monitor for sepsis detection are:

- *bradycardia*: a spontaneous fall in heart rate measurements (Figure 2a), and
- *desaturation*: a drop in the concentration of oxygen in arterial blood (Figure 2b).

The problem of detecting neonatal sepsis from monitoring data has been previously studied. Griffin et al. (2003) and Moorman et al. (2011) have found a positive skew in the inter-beat (RR) interval histograms in the hours before the clinical suspicion of sepsis, and an absence of skew during normal periods. They used this finding to build features subsequently fed to a logistic

regression classifier. However, this work does not use other vital signs apart from the heart rate and also assumes access to the high-frequency RR data. The work of Stanculescu et al. (2013) is probably closest to our approach. They propose using an auto-regressive HMM (AR-HMM) to capture trends of increased physiological event incidence. Unlike the HSLDS, their model uses annotations of physiological events as input, which limits the possibility of model deployment.

The main contributions of this work are: (i) to develop the FSLDS model of Quinn et al. (2009) into a HSLDS in a “deep learning” style by adding a set of higher-level variables to model correlations in the physiological factors in order to detect sepsis, and (ii) to demonstrate that the performance of our model for the detection of sepsis is almost as good as the auto-regressive HMM of Stanculescu et al. (2013), despite the fact that their model is given “ground truth” annotations of the physiological factors, while our HSLDS must infer them from the raw vital signs data.

The structure of the remainder of the paper is as follows: In Section 2 we describe the proposed model, and discuss inference, learning and related work. Section 3 explains how the HSLDS can be used to obtain early predictions about neonatal sepsis and inferences about clinical events. Experimental results are presented in Section 4 and we provide a discussion in Section 5.

2 THE HSLDS

In order to facilitate the introduction of our hierarchical model, we begin with a brief review of the Switching LDS (SLDS). The SLDS is a generative model for sequential data which switches between several different modes of operation. Each mode of operation is modelled as a LDS (Kalman filter), and thus the SLDS can be thought of as a dynamical mixture of LDS models. As the switch settings are hidden, often the main task is to recover them given the observations. Formally, at time t the SLDS has a discrete-continuous hybrid hidden state consisting of a hidden switch variable s_t and a hidden continuous state $\mathbf{x}_t \in \mathbb{R}^{d_x}$. This hybrid state attempts to explain how measurements $\mathbf{y}_t \in \mathbb{R}^{d_y}$ are generated. More precisely, the switch setting s_t determines the set of LDS parameters used at time t :

$$\mathbf{x}_t \sim \mathcal{N}(\mathbf{A}(s_t)\mathbf{x}_{t-1}, \mathbf{Q}(s_t)), \quad (1)$$

$$\mathbf{y}_t \sim \mathcal{N}(\mathbf{C}(s_t)\mathbf{x}_t, \mathbf{R}(s_t)), \quad (2)$$

where $\mathbf{A}(s_t)$ and $\mathbf{Q}(s_t)$ are the dynamics and dynamics noise covariance matrices, and $\mathbf{C}(s_t)$ and $\mathbf{R}(s_t)$ are the observation and observation noise covariance matrices. The switch settings are sampled from a Markov transition matrix $p(s_t|s_{t-1})$.

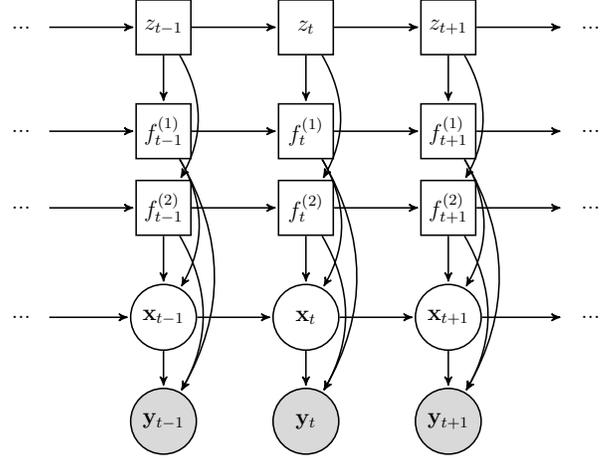

Figure 1: HSLDS with $K = 2$. Squares represent discrete variables and circles represent continuous ones. Shaded nodes are observed variables.

The FSLDS assumes a set of K discrete factors $f_t^{(1)}, f_t^{(2)}, \dots, f_t^{(K)}$ are collectively affecting the data. The model is obtained by representing the switch variable of the SLDS as the cross product $f_t^{(1)} \otimes f_t^{(2)} \otimes \dots \otimes f_t^{(K)}$. An important assumption made by the FSLDS is that the factors are a priori independent:

$$p(s_t|s_{t-1}) = \prod_{k=1}^K p(f_t^{(k)}|z_t, f_{t-1}^{(k)})$$

In the HSLDS, we propose relaxing this assumption by introducing a hierarchical structure for the discrete hidden variables. The discrete state is now represented by two layers of variables (see Figure 1). The top layer variable z_t controls the Markovian dynamics $p(f_t^{(\cdot)}|z_t, f_{t-1}^{(\cdot)})$ used by each factor. Conditional on the setting of the top layer switch variable z_t , the model becomes equivalent to an FSLDS. Thus, the HSLDS can be thought of as a dynamical mixture of FSLDS models. If we define a full expansion of the discrete hidden state as $s_t \triangleq z_t \otimes f_t^{(1)} \otimes f_t^{(2)} \otimes \dots \otimes f_t^{(K)}$, then the joint distribution of the HSLDS can be written as:

$$p(s_{1:T}, \mathbf{x}_{1:T}, \mathbf{y}_{1:T}) = p(s_1)p(\mathbf{x}_1|s_1)p(\mathbf{y}_1|\mathbf{x}_1, s_1) \prod_{t=2}^T p(s_t|s_{t-1})p(\mathbf{x}_t|\mathbf{x}_{t-1}, s_t)p(\mathbf{y}_t|\mathbf{x}_t, s_t), \quad (3)$$

where

$$p(s_1) = p(z_1) \prod_{k=1}^K p(f_1^{(k)}|z_1),$$

$$p(s_t|s_{t-1}) = p(z_t|z_{t-1}) \prod_{k=1}^K p(f_t^{(k)}|z_t, f_{t-1}^{(k)}),$$

$s_{1:T} \triangleq s_1, s_2, \dots, s_T$, and $\mathbf{x}_{1:T}$ and $\mathbf{y}_{1:T}$ are similarly defined.

Note that the top hidden layer is conditionally independent of the continuous variables given the factor settings: $\mathbf{x}_{1:T}, \mathbf{y}_{1:T} \perp\!\!\!\perp z_{1:T} | \mathbf{f}_{1:T}$, where we have defined $\mathbf{f}_t \triangleq [f_t^{(1)}, f_t^{(2)}, \dots, f_t^{(K)}]$. This simplifies both learning and inference.

2.1 RELATED WORK

The basic SLDS model has a long history, see e.g. Shumway and Stoffer (1991), and has been used in many applications. Factorization of the SLDS discrete state gives the Factorial Switching LDS (FSLDS), which has been used for neonatal condition monitoring by Williams et al. (2006) and Quinn et al. (2009), in speech recognition (Deng, 2006) and in music transcription (Cemgil et al., 2006). This mirrors the development of the factorial hidden Markov model (FHMM) of Ghahramani and Jordan (1997) from the standard HMM.

The HMM model has also been elaborated hierarchically by Fine and Singer (1998) to give the hierarchical hidden Markov model (HHMM). A similar construction can be used to create a hierarchical switching LDS (HSLDS). The only previous example of this model we are aware of in the literature is the work of Zoeter and Heskes (2003) which used a HSLDS for visualization of time-series data. Their motivation is to allow a successive refinement of a visualization, starting from projecting onto a single LDS with a two-dimensional (2-d) hidden space. This can be broken down into a SLDS of 2-d LDSes, and then each 2-d LDS can be further independently decomposed into a SLDS. Thus, a set of lower-level states correspond to one higher-level state. Also note that their use case involves interaction from the user to initialise the decomposition.

In contrast, we more naturally think of building our model bottom up, first identifying a set of factors for the FSLDS, and then modelling their correlations with a top-level variable. Notice that in our work the state of the top-level variable affects all of the second-level variables below it.

There are also some similarities between our work and the paper by Taylor et al. (2010). Under their approach, the \mathbf{x} dynamics are modelled by an Implicit Mixture of Conditional Restricted Boltzmann Machines (imCRBM). This is similar to us in that the CRBM part of the model uses a number of discrete latent variables (analogous to our \mathbf{f} 's) to affect the \mathbf{x} dynamics. The implicit mixture variable (analogous to our z) switches between different dynamics models. Of course, the details of the model are quite different as

it is in part undirected, and that there are no explicit discrete latent variable chains through time, instead these variables “hang off” the \mathbf{x} chain.

2.2 INFERENCE

Since real-time inference is the major concern in physiological condition monitoring, we are mainly interested in marginal filtering distributions. More precisely, we require sepsis predictions of the form $p(z_t | \mathbf{y}_{1:t})$ and clinical event posteriors $p(f_t^{(c)} | \mathbf{y}_{1:t})$. These marginal posteriors can be immediately obtained from the filtering distribution of the fully expanded state $p(s_t | \mathbf{y}_{1:t})$. Thus, running SLDS inference suffices for HSLDS inference. Note that the more general goal of SLDS filtering is inferring $p(\mathbf{x}_{1:t}, s_{1:t} | \mathbf{y}_{1:t})$.

Exact SLDS inference requires computing Gaussian mixtures with a number of components exponential in the length of the sequence. Clearly, this is computationally intractable for most practical purposes (Lerner and Parr, 2001). Several approximate SLDS inference methods have been previously proposed: Gaussian sum approximations (Murphy, 1998; Barber and Mesot, 2007), Rao-Blackwellised Particle Filtering (Murphy and Russell, 2001; de Freitas et al., 2004), variational inference (Ghahramani and Hinton, 2000) or expectation propagation (Zoeter and Heskes, 2003).

Here, we apply the Gaussian Sum approximation described in Murphy (1998). The method ensures tractability by using moment matching to collapse a Gaussian mixture onto a single Gaussian. At any time step, each $p(\mathbf{x}_t | s_t, \mathbf{y}_{1:t})$ is approximated by a single Gaussian, which corresponds to $p(\mathbf{x}_t | \mathbf{y}_{1:t})$ being approximated by a mixture of Gaussians.

When the hidden discrete state is a cross-product of variables, we can speed up inference by allowing at most one variable to change its setting at each time step. This procedure has been previously discussed in Quinn et al. (2009) or Kolter and Jaakkola (2012).

A particular aspect of the baby monitoring application is the presence of several missing data sources. The treatment of this problem will be discussed in detail in Section 3.3.

2.3 LEARNING

HSLDS learning is similar to FSLDS learning to a large extent. Here, we first emphasize the most significant common aspects and then discuss HSLDS learning specifics.

For our application we assume that there are a number of interpretable regimes for which labelled data are available. Labelled data for the HSLDS model are of

the form $\{\mathbf{y}_t, z_t, f_t^{(1)}, f_t^{(2)}, \dots, f_t^{(K)}\}$.

As in the FSLDS case, the availability of labelled data makes learning equivalent to learning one LDS model for each switch setting. In general, we parameterise LDS dynamics as autoregressive processes and use Expectation Maximisation (EM) for training (Ghahramani and Hinton, 1996). Learning is performed independently for each factor, and then the fitted parameters are carefully combined for each switch setting. This procedure is greatly simplified by considering the interactions between factors. For instance, the activation of one factor might “overwrite” any effect of another factor on certain observation channels. In the neonatal monitoring application, domain knowledge is used to define a factor overwriting ordering, as further discussed in Section 3.2.

For the HSLDS in particular, we use the conditional independence between the continuous variables and the top layer discrete variables to further simplify learning. This means that the (parameters of the) continuous variable distributions (eqs. 1 and 2) do not depend on the setting of z_t .

A straightforward way of learning the Markov transition matrices for individual factors $p(f_t^{(\cdot)}|z_t, f_{t-1}^{(\cdot)})$ would be to make use of the labelled data and maximize the conditional likelihood $p(\mathbf{f}_{1:T}|z_{1:T})$. Estimates of the factor transition probabilities have the form:

$$p(f_t^{(\cdot)} = j|z_t = l, f_{t-1}^{(\cdot)} = i) = \frac{n_{ijl} + n_0}{\sum_{j'}(n_{ij'l} + n_0)}, \quad (4)$$

where n_{ijl} is the number of transitions from state i to state j for factor $f^{(\cdot)}$ under the z -regime l counted over all the training data. The constant count n_0 comes from placing a Dirichlet prior which prevents probabilities from being too close to zero.

However, we have found that an alternative “deep learning” style method can give rise to better results (Section 4.1). Although the \mathbf{f} data is available at training time, at test time these labels must be inferred from the \mathbf{y} data. Hence it makes sense to build a model which looks at the actual inferences of the factors, rather than the ground truth labels.

If \mathbf{Y} is the training set of sequences and the corresponding \mathbf{F} are treated as hidden variables, we could use EM and attempt to optimise $p(\mathbf{Y}|\mathbf{Z})$. The M-step is equivalent to maximizing the expected complete data log likelihood:

$$\mathcal{Q} = \mathbb{E}_{p(\mathbf{X}, \mathbf{F}|\mathbf{Y}, \mathbf{Z})} \log p(\mathbf{Y}, \mathbf{X}, \mathbf{F}|\mathbf{Z}), \quad (5)$$

where $p(\mathbf{X}, \mathbf{F}|\mathbf{Y}, \mathbf{Z})$ was computed in the preceding E-step using the old parameter settings. Factor transi-

tion estimates are of the form:

$$p(f_t^{(\cdot)} = j|z_t = l, f_{t-1}^{(\cdot)} = i) = \frac{\tilde{n}_{ijl} + n_0}{\sum_{j'}(\tilde{n}_{ij'l} + n_0)}, \quad (6)$$

where

$$\tilde{n}_{ijl} = \sum_t p(f_{t-1}^{(\cdot)} = i, f_t^{(\cdot)} = j|\mathbf{Y}, \mathbf{Z})I(z_t = l)$$

is commonly referred to as a “soft” data count, I is the indicator function, and the sum is taken over all t 's in the training data.

Running EM until convergence is likely to be unsatisfactory, as there are no guarantees that the learnt factor transition matrices would produce good factor posteriors. Our solution is to approximate $p(\mathbf{F}|\mathbf{Y}, \mathbf{Z})$, by $p_{FSLDS}(\mathbf{F}|\mathbf{Y})$. Here, the FSLDS model is trained using the standard learning routine of Quinn et al. (2009) and the factor models discussed in Section 3.2, and is thus unaware of the existence of multiple z -regimes. In practice, we found it sufficient to obtain “soft” counts of pairwise filtering marginals $p_{FSLDS}(f_{t-1}^{(\cdot)}, f_t^{(\cdot)}|\mathbf{y}_{1:t})$ for each training sequence. Since FSLDS posteriors do not depend on the learnt HSLDS parameters, the method is non-iterative.

This procedure follows ideas in the “deep learning” literature (Hinton et al., 2006) where layer-wise training of a model is carried out. Similar ideas can also be found e.g. in Karklin and Lewicki (2005) or Farhadi et al. (2009), although in all these cases the models are not for time series.

Finally, estimates of the Markov transition matrix $p(z_t|z_{t-1})$ are learnt from the z -labels. Also note that in the absence of the labelled data, unsupervised learning for the full model would be possible using EM.

3 AN HSLDS FOR NEONATAL CONDITION MONITORING

This section is concerned with applying the HSLDS for condition monitoring in NICUs. We begin with a brief description of baby monitoring, focusing on the early detection of neonatal sepsis. We then explain how the problem can be solved by formulating it as learning and inference in an HSLDS.

3.1 NICU MONITORING AND SEPSIS DETECTION

NICU babies are born several months prematurely and are intrinsically unstable. They are nursed in incubators, and their vital signs are continuously displayed on bedside screens. Clinicians apply their expertise to interpret patterns in the monitoring traces and use

this information in support of their diagnostic inference. The task is challenging for reasons including the amount, dimensionality and frequency of the data, and the need to analyse patient physiology across multiple time scales.

The present application focuses on the early detection of neonatal sepsis based on the information contained in the monitoring data. The hypothesis is that an increased incidence of baby generated physiological events is a symptom of sepsis. In current clinical practice, the laboratory result of a blood culture is taken as the “gold standard” for diagnosing neonatal sepsis. Here, we adopted the laboratory result interpretation proposed by Modi et al. (2009) and also discussed by Stanculescu et al. (2013).

The measurement channels used in this work monitor several vital physiological systems. The heart rate measures the cardiovascular system. It is available from two sources: the ECG leads - HR (beats per minute - bpm) and the pulse oximeter - PR (bpm). The core and peripheral temperatures, TC (°C) and TP (°C), monitor the thermoregulatory system. The saturation of oxygen in arterial blood, SO (%), reflects the evolution of the respiratory system. All channels are sampled second-by-second (1Hz).

Our data samples are monitoring windows with a duration of 30 hours, and fall into either a sepsis group or a control group. Sepsis samples have been chosen such that the time the positive blood sample was collected occurs precisely 24 hours after the start of the window. For control samples, there was no suspicion of sepsis in a consecutive 3 day period around the selected windows, and no blood sample had been taken for laboratory testing.

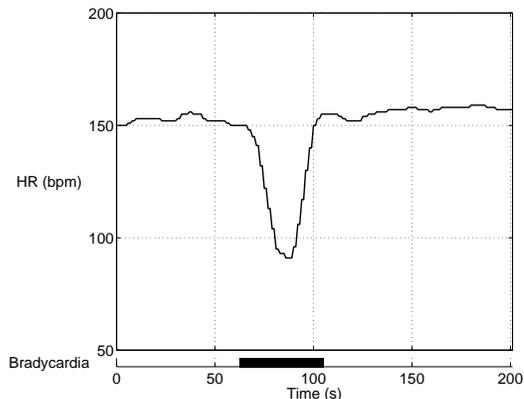

3.2 LEARNING A SEPSIS DETECTION MODEL

We now detail how the baby monitoring HSLDS is trained. We first discuss parameter fitting for the continuous variable distributions and then continue with learning the hidden discrete layers of the HSLDS.

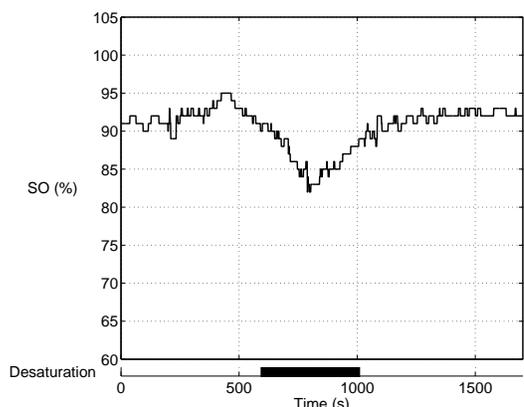

Learning continuous variable distributions

A natural classification of the regimes appearing in the NICU monitoring application is: *stability*, *known factors* and *unknown factors*.

Babies within the NICU are in a stable condition for much of the time, generally being asleep and motionless. We call this regime *stability* and separately fit univariate LDSes to each measurement channel. Thus, the dynamics parameters \mathbf{A} and \mathbf{Q} will have a block diagonal structure (see Quinn et al. (2009) for details).

(a) Bradycardia

(b) Desaturation

Figure 2: Examples of physiological events. They are notable for the lack of artifact.

When clinical events associated with stereotypical patterns occur on the monitoring traces, the regimes will be referred to as *known factors*. Here, we model two physiological events: bradycardias and desaturations (see Figure 2 for examples). Both are characterised by a drop in the monitored signal (a slowing of the heart rate for bradycardias, and a decrease in the saturation of oxygen in arterial blood for desaturations), after which measurements rise back. We model these factors as two-stage events. The first stage corresponds to measurements dropping and can be explained by an exponential decay, the discrete time equivalent of which is an $AR(1)$ process. To set the mean of the decay process we first compute the empirical distribution F of minimum channel measurements during events. The quantile q^* of F corresponding to $F(q^*) = 0.05$ is chosen to be the decay mean. In the second stage of the event the measurements rise back. This will be referred to as the recovery stage. Recovery dynamics are also modelled as an $AR(1)$ process, where the mean is now the same as the channel’s *stability* mean. The

Table 1: Overwriting Ordering of Factors

Channel	Bradycardia	Desaturation	X	Stability
HR	•		•	•
SO		•	•	•

parameters for both decay and recovery models are learnt by running EM, where we chose the dynamics initialisation $\mathbf{A} = \mathbf{0}$.

Finally, certain events cannot be explained by either stability or by any of the known factors. These patterns represent either novel dynamics or their low incidence makes them impractical to model as known factors. Here, we follow the approach of Quinn et al. (2009), where they propose a factor explaining these “known *unknowns*”, the X-factor. It shares the same dynamics matrix with stability, but uses an inflated system noise covariance matrix. As the X-factor can claim patterns of both physiology and artifact, we do not use it directly for inferring the presence of sepsis.

Once the factor models have been separately learnt, they are combined using the overwriting order shown in Table 1. For each measurement channel, factors placed towards the left of the table overwrite factors placed towards the right.

Learning discrete variable distributions

In the baby monitoring application the top discrete layer of the HSLDS models the state of the sepsis infection. Here, we assume z_t is a binary variable taking on values $z_t = \textit{sepsis}$ or $z_t = \textit{normal}$. We first explain how labels of the form $\{\mathbf{y}_t, z_t\}$ have been defined. We then discuss how these labels are used to train the HSLDS’s discrete variable layers.

The task of providing labels for the sepsis indicator variable is non-trivial. For patients in the sepsis group, clinicians only hold records for the exact time of the positive blood test. It is almost certain that the onset of the infection occurred in the hours prior to this time stamp. However, the onset cannot be assumed to be an instantaneous switch. The following labelling scheme has been proposed for samples belonging to the sepsis group; see Stanculescu et al. (2013). First, a period of 6 hours before the time of the positive blood test is labelled as *sepsis*. Second, we introduce a transition period during which the baby progresses from being in the *normal* state to being in the *sepsis* state. The transition period is defined as the 12 hour interval between 18 and 6 hours before the positive test. We do not assign a label for this period and it is not used for either training or testing the discrete layers of the HSLDS. Third, the monitoring data before the transition period (i.e. the first 6 hours of a sample in the

Table 2: Missing Data Sources Affecting Baby-generated Physiological Events.

	Bradycardia	Desaturation
Handling	•	•
Oximeter error		•
HR dropout	•	
SO dropout		•

sepsis group) is labelled as *normal*. Fourth, we do not assign a label to data after the positive test, as these measurements are likely to be affected by the patient’s response to treatment and have less relevance for the task of real-time sepsis detection. Finally, all the data in the control group is assigned the *normal* label.

Using the sepsis labels, an estimate of $p(z_t|z_{t-1})$ can be directly obtained using data counts. For learning the z -conditioned *known* factors’ transition matrices, we apply the procedure explained in Section 2.3; see eq. 5 and the surrounding text. The X-factor’s incidence is assumed to be independent of the state of the infection, and thus the factor transition matrix is copied from the previously learnt FSLDS.

3.3 INFERENCE WITH MISSING DATA

We reiterate that this work is centred on the idea of monitoring baby-generated bradycardias and desaturations in order to predict sepsis. However, there are periods of time during which labels for these events cannot be provided even by an expert annotator. We will treat such periods as missing data. There are three distinct sources of missing data: probe dropouts, oximeter errors and patient handling. We first describe these sources and then explain how inference can be performed during such periods.

During probe dropouts measurements are not available due to either malfunctioning or temporary removal of the monitoring devices. They can be readily recognised by the zero values on the recorded channels.

An oximeter error occurs when there is a disagreement between the HR and PR traces. This indicates a temporary unreliability of the SO trace, and thus the impossibility to monitor desaturations. Here, we adopt the approach in Stanculescu et al. (2013), where an automated oximeter error detection algorithm has been applied as a preprocessing step.

Patients are regularly handled by clinical staff (e.g. for changing nappies). During such episodes, we usually see an increased variability in the monitoring channels and often patterns of bradycardia or desaturation. We cannot distinguish whether such instances are caused merely by handling an extremely fragile baby, or they actually reflect the patient’s true

Table 3: Population Demographics: Gestation, Birth Weight (BW) and Post Partum Age

Group	Statistic	Gestation	BW	Age
Sepsis	mean	27.2 weeks	873 gr	14.5 days
	std.dev.	1.5 weeks	256 gr	8.5 days
Control	mean	26.7 weeks	837 gr	15.2 days
	std.dev.	1.7 weeks	139 gr	14 days

state of health. Thus, for sepsis detection we analyse only physiological events happening outside handling episodes. Our work still relies on having expert annotations for handling. Quinn et al. (2009) have shown that these episodes can be inferred by monitoring environmental channels such as the incubator’s humidity, but such channels have not been available in this work.

Table 2 shows how physiological events are affected by the presence of each missing data source.

For running inference with missing data, we extend the ideas in Quinn et al. (2009). Whenever a missing data source is present, the measurements do not carry information about the true physiology of the patient, and thus should not influence the hidden state estimates. The latter continue to evolve according to the dynamics equations, but without measurement update. Technically, rows of the observation matrix are set to zero whenever there is missing data on the corresponding measurement channel. For these channels the Kalman gain will be zero. Thus, the corresponding hidden continuous state dimensions will be estimated with increasing uncertainty before reaching the stable state of the Kalman filter.

4 EXPERIMENTS

This section describes the experiments we have performed to assess the neonatal condition monitoring model introduced in Section 3. The detection of sepsis is discussed in Section 4.1. Section 4.2 is concerned with the quality of physiological event posteriors.

The dataset we use in this work consists of data collected exclusively from very low birth weight patients (VLBW, birth weight < 1500 grams). It has been previously used by Stanculescu et al. (2013), and contains 36 monitoring samples equally split between the sepsis and the control groups. All sepsis samples come from different patients. In the control group we have two samples from each of 9 different babies. Three patients have samples in both groups, corresponding to a total of 24 different patients. The demographics of the two groups are shown in Table 3.

Expert annotations have been obtained for all the data. A summary of the annotation process is pro-

Table 4: Clinical Event Incidence

Event	Group	Incidence	Total	Median
Bradycardia	Sepsis	1718	24 hrs	39 sec
	Control	1133	12 hrs	35 sec
Desaturation	Sepsis	738	32 hrs	101 sec
	Control	231	11 hrs	132 sec
X-factor	Sepsis	226	10 hrs	94 sec
	Control	171	7 hrs	114 sec
Handling	Sepsis	204	44 hrs	530 sec
	Control	210	55 hrs	592 sec
Ox. err.	Sepsis	4051	45 hrs	16 sec
	Control	3395	36 hrs	18 sec

vided in Table 4. The total amount of data for each group is $18 \times 30 = 540$ hours and only baby generated physiological events have been considered. Importantly, the incidence of baby generated bradycardias and desaturations is higher in the sepsis group. As expected, the differences for the X-factor are much smaller. In terms of missing data sources, the amounts of handling and oximeter error are similar between patient groups. Probe dropout statistics are different for each channel, but on average we lack observations for 2% of the time. In addition, a *stability* period of 15–30 minutes was marked near the start of each sample.

In order to reduce bias, we test our predictions using N -fold cross-validation. Considering the size of our dataset we decided to use $N = 9$ folds. Each fold contains 4 data samples, 2 from each patient group. The 2 control samples are chosen such that they belong to the same patient. Apart from these constraints, the folds have been randomly chosen.

4.1 SEPSIS DETECTION

To gain a better understanding of the HSLDS’s effectiveness, we compare its predictions against filtering results obtained with the AR-HMM model of Stanculescu et al. (2013). While the HSLDS infers the posterior distributions of bradycardias and desaturations, the AR-HMM uses expert annotations of these events as input. Note that in the AR-HMM it was possible to run inference exactly and also marginalise over the missing data exactly. For the purposes of this work, the central question is how well the HSLDS inferences match the AR-HMM ones.

In the following we discuss two HSLDS models. The HSLDS learnt as explained in Section 2.3 will be referred to as HSLDSdeep. We will compare it against an HSLDS where the factor transitions for baby-generated events are learnt directly from the expert annotations, HSLDSkf (known factors).

We provide the second-by-second sepsis inferences produced by both the AR-HMM and HSLDSdeep in Fig-

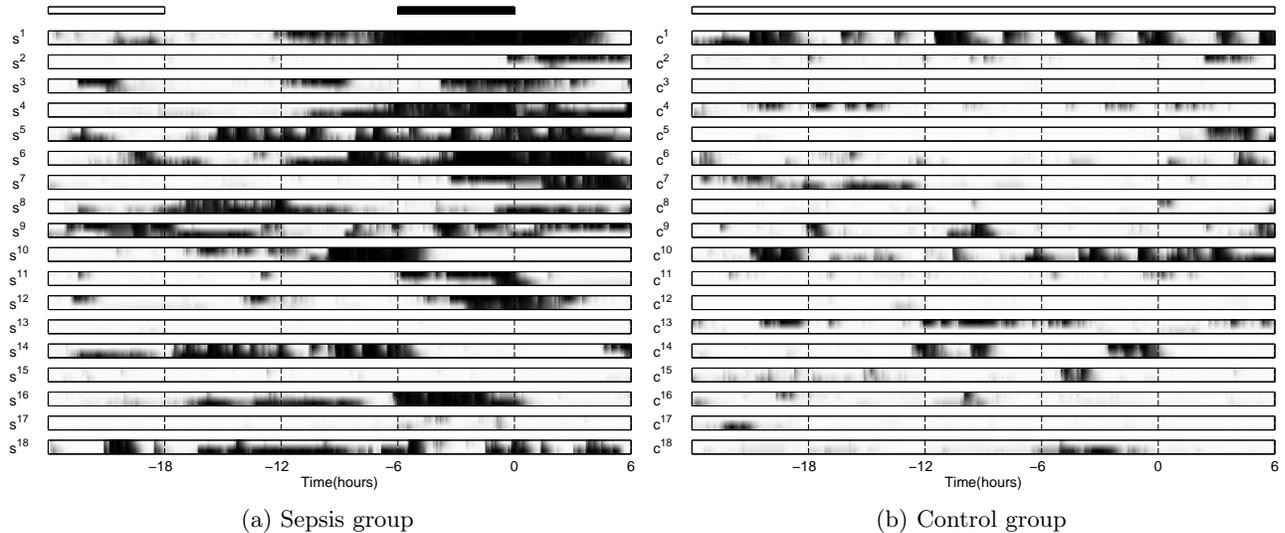

Figure 3: Sepsis filtering distributions obtained using 9-fold Cross-Validation. On the x -axis, 0 denotes the time the positive blood sample was taken. For each group, the top row represents the sepsis labelling: normal periods are white (probability 0), sepsis periods are black (probability 1); transitioning and treatment periods are not assigned labels. For each data sample the top row corresponds to the AR-HMM model, the bottom row corresponds to HSLDSdeep.

Table 5: Sepsis Inference Summaries Using 9-fold Cross-Validation

Model	Second-by-second		Episode-based	
	AUC	EER	AP	F-score
AR-HMM	0.72	0.34	0.62	0.65
HSLDSdeep	0.69	0.37	0.51	0.54
HSLDSkf	0.62	0.41	0.45	0.47

ure 3. In general, there is strong correlation between the predictions of the two models and we find the inferences of HSLDSdeep to be a good match to the AR-HMM ones. However, in samples s^2 , s^7 and s^{11} HSLDSdeep detects sepsis noticeably later than the AR-HMM, and in samples s^4 and s^6 it does so earlier. In the control group, HSLDSdeep does slightly worse on samples c^7 and c^{18} , but outperforms the AR-HMM on samples c^4 and c^{13} .

For quantifying those results, we project the inferences onto two different metrics. This opens the possibility to reveal different aspects of performance.

Firstly, we are mainly interested in the *second-by-second* inferences produced by our hierarchical models and use the z -labels to draw ROC curves. The AUC (area under the ROC curve) and EER¹ computed by aggregating predictions over folds are shown in Ta-

¹EER is the error rate computed for the threshold at which the false positive rate (FPR) equals the false negative rate (FNR).

ble 5. Compared to HSLDSkf, HSLDSdeep produced results much closer to the AR-HMM benchmark.

We obtained more insight into how the HSLDS predictions compare against the AR-HMM results via an N -fold cross-validated paired t test on the AUC. We found the performance difference between the AR-HMM and our proposed HSLDSdeep model not to be statistically significant ($p = 0.552$). This is a good indication that the HSLDSdeep model can be used instead of the AR-HMM, and thus significantly reduce the need for expert input needed to detect sepsis. At the same time the performance difference between the AR-HMM and the HSLDSkf model is statistically significant ($p = 0.0064$). This suggests HSLDSkf should not be used instead of the AR-HMM.

Secondly, we analyse the inferred *episodes* of infection and draw precision-recall (PR) curves. This analysis has been proposed by Stanculescu et al. (2013), where they argue that it could be more relevant in clinical practice than a second-by-second one. Here we report average precision (AP) and the maximum F-score (see Table 5). Again, the performance of HSLDSdeep is closer to the AR-HMM than the HSLDSkf.

4.2 PHYSIOLOGICAL EVENT POSTERiors

We can obtain filtering distributions for physiological events by marginalising the sepsis variable from

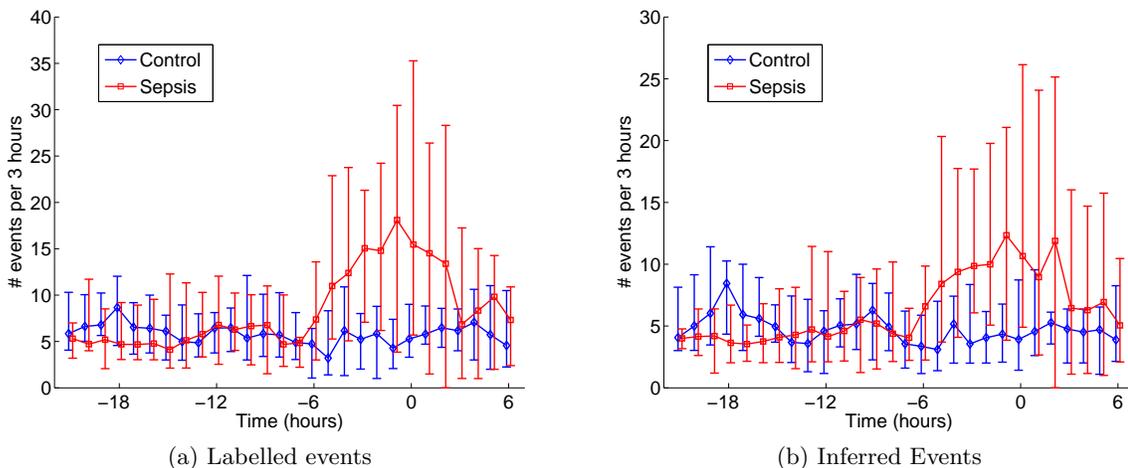

Figure 4: Median weighted number of true and inferred bradycardias separately computed for each patient group. The counts were computed hourly and summarize the preceding 3 hour period. Error bars mark first and third quartiles. The small offset between the two patient groups was used to improve readability.

Table 6: Factor Inference Summaries Using 9-fold Cross-Validation

		Brady.	Desat.	X
FSLDS	AUC	0.85	0.81	0.63
	EER	0.21	0.28	0.40
HSLDSdeep	AUC	0.86	0.82	0.60
	EER	0.21	0.27	0.42

HSLDS posteriors. As we have labelled data for the predicted factors, we can compare HSLDS posteriors against FSLDS ones. Summary results computed by aggregating predictions obtained with 9-fold cross-validation are shown in Table 6. Even though the FSLDS has been trained solely for inferring clinical events, there is very little difference between the performance of the two models.

Bradycardia and X-factor inferences obtained using an FSLDS have been previously assessed in (Quinn et al., 2009). The bradycardia results reported here are very similar to that work, but X-factor predictions are worse. Results on oxygen desaturation have not been previously reported.

We also found it interesting to compare the true incidence of baby-generated physiological events against the inferred one. For this purpose we obtained inferred events by binarising factor posteriors. Figure 4 shows a comparative visualisation of the time evolution of annotated and inferred bradycardias. The counts have been weighted in accordance to the amount of missing data in the analysed 3 hour periods. On both plots, there is a clear increase in the incidence of bradycardias in the hours before the sepsis diagnosis.

5 CONCLUSION

In this paper, we have proposed a framework for condition monitoring in situations when the factors that govern the data can be organised in a hierarchy. The structure of our model allows domain knowledge to be naturally incorporated. In addition, we have described a “deep learning” inspired training method.

The effectiveness of our model has been demonstrated for the difficult task of detecting the onset of sepsis in NICU patients. When compared against an AR-HMM model which heavily relies on expert annotations, we found the performance difference not to be statistically significant.

There are several directions in which this work could be extended. It would be interesting to run (H)SLDS smoothing, e.g. as described by Barber and Mesot (2007). This would prove useful both as a retrospective analysis of sepsis detection, and for refining our approach to learning factor transitions. Explicit modelling of event duration could improve the results, as demonstrated by Stanculescu et al. (2013). While we showed that the HSLDS performs similarly to the AR-HMM, sepsis predictions still need improvement. Finally, the X-factor predictions indicate more work could be done on novelty detection.

Abstract

The Brown clustering algorithm (Brown *et al.*, 1992) is widely used in natural language processing (NLP) to derive lexical representations that are then used to improve performance on various NLP problems. The algorithm assumes an underlying model that is essentially an HMM, with the restriction that each word in the vocabulary is emitted from a single state. A greedy, bottom-up method is then used to find the clustering; this method does not have a guarantee of finding the correct underlying clustering. In this paper we describe a new algorithm for clustering under the Brown *et al.* model. The method relies on two steps: first, the use of canonical correlation analysis to derive a low-dimensional representation of words; second, a bottom-up hierarchical clustering over these representations. We show that given a sufficient number of training examples sampled from the Brown *et al.* model, the method is guaranteed to recover the correct clustering. Experiments show that the method recovers clusters of comparable quality to the algorithm of Brown *et al.* (1992), but is an order of magnitude more efficient.

1 INTRODUCTION

There has recently been great interest in the natural language processing (NLP) community in methods that derive lexical representations from large quantities of unlabeled data (Brown *et al.*, 1992; Pereira *et al.*, 1993; Ando and Zhang, 2005; Liang, 2005; Turian *et al.*, 2010; Dhillon *et al.*, 2011; Collobert *et al.*, 2011; Mikolov *et al.*, 2013a,b). These representations can be used to improve accuracy on various NLP problems, or to give significant reductions in the number of training examples required for learning. The Brown clustering algorithm (Brown *et al.*, 1992) is one of the most widely used algorithms for this task. Brown clustering representations have been shown to be useful in a

diverse set of problems including named-entity recognition (Miller *et al.*, 2004; Turian *et al.*, 2010), syntactic chunking (Turian *et al.*, 2010), parsing (Koo *et al.*, 2008), and language modeling (Kneser and Ney, 1993; Gao *et al.*, 2001).

The Brown clustering algorithm assumes a model that is essentially a hidden Markov model (HMM), with a restriction that each word in the vocabulary can only be emitted from a single state in the HMM (i.e., there is a deterministic mapping from words to underlying states). The algorithm uses a greedy, bottom-up method in deriving the clustering. This method is a heuristic, in that there is no guarantee of recovering the correct clustering. In practice, the algorithm is quite computationally expensive: for example in our experiments, the implementation of Liang (2005) takes over 22 hours to derive a clustering from a dataset with 205 million tokens and 300,000 distinct word types.

This paper introduces a new algorithm for clustering under the Brown *et al.* model (henceforth, the Brown model). Crucially, under an assumption that the data is generated from the Brown model, our algorithm is guaranteed to recover the correct clustering when given a sufficient number of training examples (see the theorems in Section 5). The algorithm draws on ideas from canonical correlation analysis (CCA) and agglomerative clustering, and has the following simple form:

1. Estimate a normalized covariance matrix from a corpus and use singular value decomposition (SVD) to derive low-dimensional vector representations for word types (Figure 4).
2. Perform a bottom-up hierarchical clustering of these vectors (Figure 5).

In our experiments, we find that our clusters are comparable to the Brown clusters in improving the performance of a supervised learner, but our method is significantly faster. For example, both our clusters and Brown clusters improve the F1 score in named-entity recognition (NER) by 2-3 points, but the runtime of our method is around 10 times faster than the Brown algorithm (Table 3).

The paper is structured as follows. In Section 2, we discuss

Input: corpus with N tokens of n distinct word types $w^{(1)}, \dots, w^{(n)}$ ordered by decreasing frequency; number of clusters m .

Output: hierarchical clustering of $w^{(1)}, \dots, w^{(n)}$.

1. Initialize active clusters $\mathcal{C} = \{\{w^{(1)}\}, \dots, \{w^{(m)}\}\}$.
2. For $i = m + 1$ to $n + m - 1$:
 - (a) If $i \leq n$: set $\mathcal{C} = \mathcal{C} \cup \{\{w^{(i)}\}\}$.
 - (b) Merge $c, c' \in \mathcal{C}$ that cause the smallest decrease in the likelihood of the corpus.

Figure 1: A standard implementation of the Brown clustering algorithm.

related work. In Section 3, we establish the notation we use throughout. In Section 4, we define the Brown model. In Section 5, we present the main result and describe the algorithm. In Section 6, we report experimental results.

2 BACKGROUND

2.1 THE BROWN CLUSTERING ALGORITHM

The Brown clustering algorithm (Brown *et al.*, 1992) has been used in many NLP applications (Koo *et al.*, 2008; Miller *et al.*, 2004; Liang, 2005). We briefly describe the algorithm below; a part of the description was taken from Koo *et al.* (2008).

The input to the algorithm is a corpus of text with N tokens of n distinct word types. The algorithm initializes each word type as a distinct cluster, and repeatedly merges the pair of clusters that cause the smallest decrease in the likelihood of the corpus according to a discrete hidden Markov model (HMM). The observation parameters of this HMM are assumed to satisfy a certain disjointedness condition (Assumption 4.1). We will explicitly define the model in Section 4.

At the end of the algorithm, one obtains a hierarchy of word types which can be represented as a binary tree as in Figure 2. Within this tree, each word is uniquely identified by its path from the root, and this path can be compactly represented with a bit string. In order to obtain a clustering of the words, we select all nodes at a certain depth from the root of the hierarchy. For example, in Figure 2 we might select the four nodes at depth 2 from the root, yielding the clusters $\{\text{apple}, \text{pear}\}$, $\{\text{Apple}, \text{IBM}\}$, $\{\text{bought}, \text{run}\}$, and $\{\text{of}, \text{in}\}$. Note that the same clustering can be obtained by truncating each word’s bit string to a 2-bit prefix. By using prefixes of various lengths, we can produce clusterings of different granularities.

A naive implementation of this algorithm has runtime $O(n^5)$. Brown *et al.* (1992) propose a technique to reduce the runtime to $O(n^3)$. Since this is still not acceptable

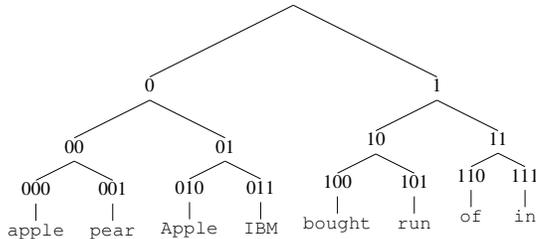

Figure 2: An example of a Brown word-cluster hierarchy taken from Koo *et al.* (2008). Each node in the tree is labeled with a bit string indicating the path from the root node to that node, where 0 indicates a left branch and 1 indicates a right branch.

for large values of n , a common trick used for practical implementation is to specify the number of active clusters $m \ll n$, for example, $m = 1000$. A sketch of this implementation is shown in Figure 1. Using this technique, it is possible to achieve $O(N + nm^2)$ runtime. We note that our algorithm in Figure 5 has a similar form and asymptotic runtime, but is empirically much faster. We discuss this issue in Section 6.3.1.

In this paper, we present a very different algorithm for deriving a word hierarchy based on the Brown model. In all our experiments, we compared our method against the highly optimized implementation of the Brown algorithm in Figure 1 by Liang (2005).

2.2 CCA AND AGGLOMERATIVE CLUSTERING

Our algorithm in Figure 4 operates in a fashion similar to the mechanics of CCA. CCA is a statistical technique used to maximize the correlation between a pair of random variables (Hotelling, 1936). A central operation in CCA to achieve this maximization is SVD; in this work, we also critically rely on SVD to recover the desired parameters.

Recently, it has been shown that one can use CCA-style algorithms, so-called spectral methods, to learn HMMs in polynomial sample/time complexity (Hsu *et al.*, 2012). These methods will be important to our goal since the Brown model can be viewed as a special case of an HMM.

We briefly note that one can view our approach from the perspective of spectral clustering (Ng *et al.*, 2002). A spectral clustering algorithm typically proceeds by constructing a graph Laplacian matrix from the data and performing a standard clustering algorithm (e.g., k -means) on reduced-dimensional points that correspond to the top eigenvalues of the Laplacian. We do not make use of a graph Laplacian, but we do make use of spectral methods for dimensionality reduction before clustering.

Agglomerative clustering refers to hierarchical grouping of n points using a bottom-up style algorithm (Ward Jr, 1963; Shanbehzadeh and Ogunbona, 1997). It is commonly used for its simplicity, but a naive implementation

requires $O(dn^3)$ time where d is the dimension of a point. Franti *et al.* (2000) presented a faster algorithm that requires $O(\gamma dn^2)$ time where γ is a data-dependent quantity which is typically much smaller than n . In our work, we use a variant of this last approach that has runtime $O(\gamma dmn)$ where $m \ll n$ is the number of active clusters we specify (Figure 5). We also remark that under our derivation, the dimension d is always equal to m , thus we express the runtime simply as $O(\gamma nm^2)$.

3 NOTATION

Let $[n]$ denote the set $\{1, \dots, n\}$. Let $[[\Gamma]]$ denote the indicator of a predicate Γ , taking value 1 if Γ is true and 0 otherwise. Given a matrix M , we let \sqrt{M} denote its element-wise square-root and M^+ denote its Moore-Penrose pseudoinverse. Let $I_{m \times m} \in \mathbb{R}^{m \times m}$ denote the identity matrix. Let $\text{diag}(v)$ denote the diagonal matrix with the vector $v \in \mathbb{R}^m$ appearing on its diagonal. Finally, let $\|v\|$ denote the Euclidean norm of a vector v , and $\|M\|$ denote the spectral norm of a matrix M .

4 BROWN MODEL DEFINITION

A Brown model is a 5-tuple (n, m, π, t, o) for integers n, m and functions π, t, o where

- $[n]$ is a set of states that represent word types.
- $[m]$ is a set of states that represent clusters.
- $\pi(c)$ is the probability of generating $c \in [m]$ in the first position of a sequence.
- $t(c'|c)$ is the probability of generating $c' \in [m]$ given $c \in [m]$.
- $o(x|c)$ is the probability of generating $x \in [n]$ given $c \in [m]$.

In addition, the model makes the following assumption on the parameters $o(x|c)$. This assumption comes from Brown *et al.* (1992) who require that the word clusters partition the vocabulary.

Assumption 4.1 (Brown *et al.* assumption). *For each $x \in [n]$, there is a unique $C(x) \in [m]$ such that $o(x|C(x)) > 0$ and $o(x|c) = 0$ for all $c \neq C(x)$.*

In other words, the model is a discrete HMM with a many-to-one deterministic mapping $C : [n] \rightarrow [m]$ from word types to clusters. Under the model, a sequence of N tokens $(x_1, \dots, x_N) \in [n]^N$ has probability

$$p(x_1, \dots, x_N) = \pi(C(x_1)) \times \prod_{i=1}^N o(x_i|C(x_i)) \times \prod_{i=1}^{N-1} t(C(x_{i+1})|C(x_i))$$

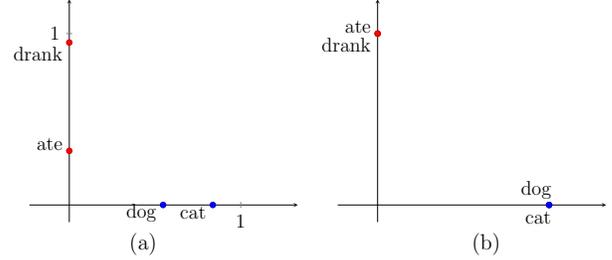

Figure 3: Illustration of our clustering scheme. (a) Original rows of \sqrt{O} . (b) After row-normalization.

An equivalent definition of a Brown model is given by organizing the parameters in matrix form. Under this definition, a Brown model has parameters (π, T, O) where $\pi \in \mathbb{R}^m$ is a vector and $T \in \mathbb{R}^{m \times m}, O \in \mathbb{R}^{n \times m}$ are matrices whose entries are set to:

- $\pi_c = \pi(c)$ for $c \in [m]$
- $T_{c',c} = t(c'|c)$ for $c, c' \in [m]$
- $O_{x,c} = o(x|c)$ for $c \in [m], x \in [n]$

Throughout the paper, we will assume that T, O have rank m . The following is an equivalent reformulation of Assumption 4.1 and will be important to the derivation of our algorithm.

Assumption 4.2 (Brown *et al.* assumption). *Each row of O has exactly one non-zero entry.*

5 CLUSTERING UNDER THE BROWN MODEL

In this section, we develop a method for clustering words based on the Brown model. The resulting algorithm is a simple two-step procedure: an application of SVD followed by agglomerative hierarchical clustering in Euclidean space.

5.1 AN OVERVIEW OF THE APPROACH

Suppose the parameter matrix O is known. Under Assumption 4.2, a simple way to recover the correct word clustering is as follows:

1. Compute $\bar{M} \in \mathbb{R}^{n \times m}$ whose rows are the rows of \sqrt{O} normalized to have length 1.
2. Put words x, x' in the same cluster iff $\bar{M}_x = \bar{M}_{x'}$, where \bar{M}_x is the x -th row of \bar{M} .

This works because Assumption 4.2 implies that the rows of \sqrt{O} corresponding to words from the same cluster lie along the same coordinate-axis in \mathbb{R}^m . Row-normalization puts these rows precisely at the standard basis vectors. See Figure 3 for illustration.

In Section 5.2, we prove that the rows of \sqrt{O} can be recovered, up to an orthogonal transformation $Q \in \mathbb{R}^{m \times m}$, just from unigram and bigram word probabilities (which can be estimated from observed sequences). It is clear that the correctness of the above procedure is unaffected by the orthogonal transformation. Let M denote the row-normalized form of $\sqrt{O}Q^\top$: then M still satisfies the property that $M_x = M_{x'}$ iff x, x' belong to the same cluster. We give an algorithm to estimate this M from a sequence of words in Figure 4.

5.2 SPECTRAL ESTIMATION OF OBSERVATION PARAMETERS

To derive a method for estimating the observation parameter \sqrt{O} (up to an orthogonal transformation), we first define the following random variables to model a single random sentence. Let $(X_1, \dots, X_N) \in [n]^N$ be a random sequence of tokens drawn from the Brown model, along with the corresponding (hidden) cluster sequence $(C_1, \dots, C_N) \in [m]^N$; independently, pick a position $I \in [N-1]$ uniformly at random. Let $B \in \mathbb{R}^{n \times n}$ be a matrix of bigram probabilities, $u, v \in \mathbb{R}^n$ vectors of unigram probabilities, and $\tilde{\pi} \in \mathbb{R}^m$ a vector of cluster probabilities:

$$\begin{aligned} B_{x,x'} &:= P(X_I = x, X_{I+1} = x') & \forall x, x' \in [n] \\ u_x &:= P(X_I = x) & \forall x \in [n] \\ v_x &:= P(X_{I+1} = x) & \forall x \in [n] \\ \tilde{\pi}_c &:= P(C_I = c) & \forall c \in [m]. \end{aligned}$$

We assume that $\text{diag}(\tilde{\pi})$ has rank m ; note that this assumption is weaker than requiring $\text{diag}(\pi)$ to have rank m . We will consider a matrix $\Omega \in \mathbb{R}^{n \times n}$ defined as

$$\Omega := \text{diag}(u)^{-1/2} B \text{diag}(v)^{-1/2} \quad (1)$$

Theorem 5.1. *Let $U \in \mathbb{R}^{n \times m}$ be the matrix of m left singular vectors of Ω corresponding to nonzero singular values. Then there exists an orthogonal matrix $Q \in \mathbb{R}^{m \times m}$ such that $U = \sqrt{O}Q^\top$.*

To prove Theorem 5.1, we need to examine the structure of the matrix Ω . The following matrices $A, \tilde{A} \in \mathbb{R}^{n \times m}$ will be important for this purpose:

$$\begin{aligned} A &= \text{diag}(O\tilde{\pi})^{-1/2} O \text{diag}(\tilde{\pi})^{1/2} \\ \tilde{A} &= \text{diag}(OT\tilde{\pi})^{-1/2} OT \text{diag}(\tilde{\pi})^{1/2} \end{aligned}$$

The first lemma shows that Ω can be decomposed into A and \tilde{A}^\top .

Lemma 5.1. $\Omega = A\tilde{A}^\top$.

Proof. It can be algebraically verified from the definition of B, u, v that $B = O \text{diag}(\tilde{\pi})(OT)^\top$, $u = O\tilde{\pi}$, and $v = OT\tilde{\pi}$. Plugging in these expressions in Eq. (1), we have

$$\begin{aligned} \Omega &= \text{diag}(O\tilde{\pi})^{-1/2} O \text{diag}(\tilde{\pi})^{1/2} \\ &\quad (\text{diag}(OT\tilde{\pi})^{-1/2} OT \text{diag}(\tilde{\pi})^{1/2})^\top = A\tilde{A}^\top. \quad \square \end{aligned}$$

The second lemma shows that A is in fact the desired matrix. The proof of this lemma crucially depends on the disjoint-cluster assumption of the Brown model.

Lemma 5.2. $A = \sqrt{O}$ and $A^\top A = I_{m \times m}$.

Proof. By Assumption 4.2, the x -th entry of $O\tilde{\pi}$ has value $O_{x,C(x)} \times \tilde{\pi}_{C(x)}$, and the $(x, C(x))$ -th entry of $O \text{diag}(\tilde{\pi})^{1/2}$ has value $O_{x,C(x)} \times \sqrt{\tilde{\pi}_{C(x)}}$. Thus the $(x, C(x))$ -th entry of A is

$$A_{x,C(x)} = \frac{O_{x,C(x)} \sqrt{\tilde{\pi}_{C(x)}}}{\sqrt{O_{x,C(x)} \tilde{\pi}_{C(x)}}} = \sqrt{O_{x,C(x)}}$$

The columns of A have disjoint supports since A has the same sparsity pattern as O . Furthermore, the l_2 (Euclidean) norm of any column of A is the l_1 norm of the corresponding column of O . This implies $A^\top A = I_{m \times m}$ \square

Now we give a proof of the main theorem.

Proof of Theorem 5.1. The orthogonal projection matrix onto $\text{range}(\Omega)$ is given by UU^\top and also by $\Omega(\Omega^\top \Omega)^+ \Omega^\top$. Hence from Lemma 5.1 and 5.2, we have

$$\begin{aligned} UU^\top &= \Omega(\Omega^\top \Omega)^+ \Omega^\top \\ &= (A\tilde{A}^\top)(\tilde{A}A^\top A\tilde{A}^\top)^+(A\tilde{A}^\top)^\top \\ &= (A\tilde{A}^\top)(\tilde{A}\tilde{A}^\top)^+(A\tilde{A}^\top)^\top = A\Pi A^\top \end{aligned}$$

where $\Pi = \tilde{A}(\tilde{A}^\top \tilde{A})^+ \tilde{A}^\top$ is the orthogonal projection matrix onto $\text{range}(\tilde{A})$. But since \tilde{A} has rank m , $\text{range}(\tilde{A}) = \mathbb{R}^m$ and thus $\Pi = I_{m \times m}$. Then we have $UU^\top = A A^\top$ where both U and A have orthogonal columns (Lemma 5.2). This implies that there is an orthogonal matrix $Q \in \mathbb{R}^{m \times m}$ such that $U = A Q^\top$. \square

5.3 ESTIMATION FROM SAMPLES

In Figure 4, we give an algorithm for computing an estimate of M from a sample of words $(x_1, \dots, x_N) \in [n]^N$ (where M is described in Section 5.1). The algorithm estimates unigram and bigram word probabilities u, v, B to form a plug-in estimate $\hat{\Omega}$ of Ω (defined in Eq. (1)), computes a low-rank SVD of a sparse matrix, and normalizes the rows of the resulting left singular vector matrix.

The following theorem implies the consistency of our algorithm, assuming the consistency of $\hat{\Omega}$.

Theorem 5.2. *Let $\varepsilon := \|\hat{\Omega} - \Omega\|/\sigma_m(\Omega)$, where $\sigma_m(\Omega)$ is the m -th largest singular value of Ω . If $\varepsilon \leq 0.07 \min_{x \in [n]} \{O_{x,C(x)}^{1/2}\}$, then the word embedding $f : x \mapsto \hat{M}_x$ (where \hat{M}_x is the x -th row of \hat{M}) satisfies the following property: for all $x, x', x'' \in [n]$,*

$$\begin{aligned} C(x) &= C(x') \neq C(x'') \\ \implies \|f(x) - f(x')\| &< \|f(x) - f(x'')\|; \end{aligned}$$

Input: sequence of $N \geq 2$ words $(x_1, \dots, x_N) \in [n]^N$; number of clusters m ; smoothing parameter κ .

Output: matrix $\hat{M} \in \mathbb{R}^{n \times m}$ defining $f : x \mapsto \hat{M}_x \forall x \in [n]$.

1. Compute $\hat{B} \in \mathbb{R}^{n \times n}$, $\hat{u} \in \mathbb{R}^n$, and $\hat{v} \in \mathbb{R}^n$ where

$$\hat{B}_{x,x'} := \frac{1}{N-1} \sum_{i=1}^{N-1} [[x_i = x, x_{i+1} = x']] \quad \forall x, x' \in [n]$$

$$\hat{u}_x := \frac{1}{N-1} \sum_{i=1}^{N-1} [[x_i = x]] + \frac{\kappa}{N-1} \quad \forall x \in [n]$$

$$\hat{v}_x := \frac{1}{N-1} \sum_{i=1}^{N-1} [[x_{i+1} = x]] + \frac{\kappa}{N-1} \quad \forall x \in [n]$$

2. Compute rank- m SVD of the sparse matrix

$$\hat{\Omega} := \text{diag}(\hat{u})^{-1/2} \hat{B} \text{diag}(\hat{v})^{-1/2}.$$

Let $\hat{U} \in \mathbb{R}^{n \times m}$ be a matrix of m left singular vectors of $\hat{\Omega}$ corresponding to the m largest singular values.

3. Let \hat{M} be the result of normalizing every row of \hat{U} to have length 1.

Figure 4: Estimation of M from samples.

(i.e., the embedding of any word x is closer to that of other words x' from the same cluster than it is to that of any word x'' from a different cluster).

The property established by Theorem 5.2 (proved in the appendix) allows many distance-based clustering algorithms to recover the correct clustering (e.g., single-linkage, average-linkage; see Balcan *et al.*, 2008). Moreover, it is possible to establish the finite sample complexity bounds for the estimation error of $\hat{\Omega}$ (and we do so for a simplified scenario in the (supplementary) Appendix C).

In practice, it is important to regularize the estimates \hat{u} and \hat{v} using a smoothing parameter $\kappa \geq 0$. This can be viewed as adding pseudocounts to alleviate the noise from infrequent words, and has a significant effect on the resulting representations. The practical importance of smoothing is also seen in previous methods using CCA (Cohen *et al.*, 2013; Hardoon *et al.*, 2004).

Another practical consideration is the use of richer context. So far, the context used for the token X_I is just the next token X_{I+1} ; hence, the spectral estimation is based just on unigram and bigram probabilities. However, it is straightforward to generalize the technique to use other context—details are in the appendix. For instance, if we use the previous and next tokens (X_{I-1}, X_{I+1}) as context, then we form $\hat{\Omega} \in \mathbb{R}^{n \times 2n}$ from $\hat{B} \in \mathbb{R}^{n \times 2n}$, $\hat{u} \in \mathbb{R}^n$, $\hat{v} \in \mathbb{R}^{2n}$; however, we still extract $\hat{M} \in \mathbb{R}^{n \times m}$ from $\hat{\Omega}$ in the same way to form the word embedding.

Input: vectors $\mu^{(1)}, \dots, \mu^{(n)} \in \mathbb{R}^m$ corresponding to word types $[n]$ ordered in decreasing frequency.

Output: hierarchical clustering of the input vectors.

Tightening: Given a set of clusters \mathcal{C} , the subroutine $\text{tighten}(c)$ for $c \in \mathcal{C}$ consists of the following three steps:

$$\text{nearest}(c) := \arg \min_{c' \in \mathcal{C}: c' \neq c} d(c, c')$$

$$\text{lowerbound}(c) := \min_{c' \in \mathcal{C}: c' \neq c} d(c, c')$$

$$\text{tight}(c) := \text{True}$$

Main body:

1. Initialize active clusters $\mathcal{C} = \{\{\mu^{(1)}\}, \dots, \{\mu^{(m)}\}\}$ and call $\text{tighten}(c)$ for all $c \in \mathcal{C}$.
2. For $i = m + 1$ to $n + m - 1$:
 - (a) If $i \leq n$: let $c := \{\mu^{(i)}\}$, call $\text{tighten}(c)$, and let $\mathcal{C} := \mathcal{C} \cup \{c\}$.
 - (b) Let $c^* := \arg \min_{c \in \mathcal{C}} \text{lowerbound}(c)$.
 - (c) While $\text{tight}(c^*)$ is False,
 - i. Call $\text{tighten}(c^*)$.
 - ii. Let $c^* := \arg \min_{c \in \mathcal{C}} \text{lowerbound}(c)$.
 - (d) Merge c^* and $\text{nearest}(c^*)$ in \mathcal{C} .
 - (e) For each $c \in \mathcal{C}$: if $\text{nearest}(c) \in \{c^*, \text{nearest}(c^*)\}$, set $\text{tight}(c) := \text{False}$.

Figure 5: Variant of Ward’s algorithm from Section 5.4.

5.4 AGGLOMERATIVE CLUSTERING

As established in Theorem 5.2, the word embedding obtained by mapping words to their corresponding rows of \hat{M} permits distance-based clustering algorithms to recover the correct clustering. However, with small sample sizes and model approximation errors, the property from Theorem 5.2 may not hold exactly. Therefore, we propose to compute a hierarchical clustering of the word embeddings, with the goal of finding the correct clustering (or at least a good clustering) as some pruning of the resulting tree. Simple agglomerative clustering algorithms can provably recover the correct clusters when idealized properties (such as that from Theorem 5.2) hold (Balcan *et al.*, 2008), and can also be seen to be optimizing a sensible objective regardless (Dasgupta and Long, 2005). These algorithms also yield a hierarchy of word types—just as the original Brown clustering algorithm.

We use a form of average-linkage agglomerative clustering called Ward’s algorithm (Ward Jr, 1963), which is particularly suited for hierarchical clustering in Euclidean spaces. In this algorithm, the cost of merging clusters c and c' is defined as

$$d(c, c') = \frac{|c||c'|}{|c| + |c'|} \|\mu_c - \mu_{c'}\|^2 \quad (2)$$

where $|c|$ refers to the number of elements in cluster c and $\mu_c = |c|^{-1} \sum_{u \in c} u$ is the mean of cluster c . The algorithm starts with every point (word) in its own cluster, and repeat-

edly merges the two clusters with cheapest merge cost.

Figure 5 sketches a variant of Ward’s algorithm that only considers merges among (at most) $m + 1$ clusters at a time. The initial $m + 1$ (singleton) clusters correspond to the $m + 1$ most frequent words (according to \hat{u}); after a merge, the next most frequent word (if one exists) is used to initialize a new singleton cluster. This heuristic is also adopted by the original Brown algorithm, and is known to be very effective.

Using an implementation trick from Franti *et al.* (2000), the runtime of the algorithm is $O(\gamma nm^2)$, where γ is a data-dependent constant often much smaller than m , as opposed to $O(nm^3)$ in a naive implementation in which we search for the closest pair among $O(m^2)$ pairs at every merge.

The basic idea of Franti *et al.* (2000) is the following. For each cluster, we keep an estimation of the lower bound on the distance to the nearest cluster. We also track if this lower bound is tight; in the beginning, every bound is tight. When searching for the nearest pair, we simply look for a cluster with the smallest lower bound among m clusters instead of $O(m^2)$ cluster pairs. If the cluster has a tight lower bound, we merge it with its nearest cluster. Otherwise, we tighten its bound and again look for a cluster with the smallest bound. Thus γ is the effective number of searches at each iteration. At merge, the bound of a cluster whose nearest cluster is either of the two merged clusters becomes loose. We report empirical values of γ in our experimental study (see Table 3).

6 EXPERIMENTS

To evaluate the effectiveness of our approach, we used the clusters from our algorithm as additional features in supervised models for NER. We then compared the improvement in performance and also the time required to derive the clusters against those of the Brown clustering algorithm. Additionally, we examined the mutual information (MI) of the derived clusters on the training corpus:

$$\sum_{c,c'} \frac{\text{count}(c,c')}{N} \log \frac{\text{count}(c,c')N}{\text{count}(c)\text{count}(c')} \quad (3)$$

where N is the number of tokens in the corpus, $\text{count}(c)$ is the number of times cluster c appears, and $\text{count}(c,c')$ is the number of times clusters c,c' appear consecutively. Note that this is the quantity the Brown algorithm directly maximizes (Brown *et al.*, 1992).

6.1 EXPERIMENTAL SETTINGS

For NER experiments, we used the scripts provided by Turian *et al.* (2010). We used the greedy perceptron for NER experiments (Ratinov and Roth, 2009) using the standard features as our baseline models. We used the CoNLL

Table 1: Performance gains in NER.

	vocab	context	dev	test
Baseline	—	—	90.03	84.39
Spectral	50k	LR1	92	86.72
($\kappa = 200$)	300k	LR2	92.31	87.76
Brown	50k	—	92	88.56
	300k	—	92.68	88.76

Table 2: Mutual information computed as in Eq. (3) on the RCV1 corpus.

	vocab size	context	MI
Spectral	50k	LR2	1.48
($\kappa = 5000$)	300k	LR2	1.54
Brown	50k	—	1.52
	300k	—	1.6

2003 dataset for NER with the standard train/dev/test split.

For the choice of unlabeled text data, we used the Reuters-RCV1 corpus which contains 205 million tokens with 1.6 million distinct word types. To keep the size of the vocabulary manageable and also to reduce noise from infrequent words, we used only a selected number of the most frequent word types and replaced all other types in the corpus with a special token. For the size of the vocabulary, we used 50,000 and 300,000.

Our algorithm can be broken down into two stages: the SVD stage (Figure 4) and the clustering stage (Figure 5). In the SVD stage, we need to choose the number of clusters m and the smoothing parameter κ . As mentioned, we can easily define Ω to incorporate information beyond one word to the right. We experimented with the following configurations for context:

1. R1 ($\Omega \in \mathbb{R}^{n \times n}$): 1 word to the right. This is the version presented in Figure 4.
2. LR1 ($\Omega \in \mathbb{R}^{n \times 2n}$): 1 word to the left/right.
3. LR2 ($\Omega \in \mathbb{R}^{n \times 4n}$): 2 words to the left/right.

6.2 COMPARISON TO THE BROWN ALGORITHM: QUALITY

There are multiple ways to evaluate the quality of clusters. We considered the improvement in the F1 score in NER from using the clusters as additional features. We also examined the MI on the training corpus. For all experiments in this section, we used 1,000 clusters for both the spectral algorithm (i.e., $m = 1000$) and the Brown algorithm.

6.2.1 NER

In NER, there is significant improvement in the F1 score from using the clusters as additional features (Table 1).

Table 3: Speed and performance comparison with the Brown algorithm for different numbers of clusters and vocabulary sizes. In all the reported runtimes, we exclude the time to read and write data. We report the F1 scores on the NER dev set; for the spectral algorithm, we report the best scores.

m	vocab	Spectral runtime				Brown runtime	Ratio (%)	Spectral F1	Brown F1
		γ	SVD	cluster	total				
200	50k	3.35	4m24s	13s	4m37s	10m37s	43.48	91.53	90.79
400		5.17	6m39s	1m8s	7m47s	37m16s	20.89	91.73	91.21
600		9.80	5m29s	3m1s	8m30s	1h33m55s	9.05	91.68	91.79
800		12.64	9m26s	6m59s	16m25s	2h20m40s	11.67	91.81	91.83
1000		12.68	11m10s	10m25s	21m35s	3h37m	9.95	92.00	92.00
1000	300k	13.77	59m38s	1h4m37s	2h4m15s	22h19m37s	9.28	92.31	92.68

The dev F1 score is improved from 90.03 to 92 with either spectral or Brown clusters using 50k vocabulary size; it is improved to 92.31 with the spectral clusters and to 92.68 with the Brown clusters using 300k vocabulary size. The spectral clusters are a little behind the Brown clusters in the test set results. However, we remark that the well-known discrepancy between the dev set and the test set in the CoNLL 2003 dataset makes a conclusive interpretation difficult. For example, Turian *et al.* (2010) report that the F1 score using the embeddings of Collobert and Weston (2008) is higher than the F1 score using the Brown clusters on the dev set (92.46 vs 92.32) but lower on the test set (87.96 vs 88.52).

6.2.2 MI

Table 2 shows the MI computed as in Eq. (3) on the RCV1 corpus. The Brown algorithm optimizes the MI directly and generally achieves higher MI scores than the spectral algorithm. However, the spectral algorithm also achieves a surprisingly respectable level of MI scores even though the MI is not its objective. That is, the Brown algorithm specifically merges clusters in order to maximize the MI score in Eq. (3). In contrast, the spectral algorithm first recovers the model parameters using SVD and perform hierarchical clustering according to the parameter estimates, without any explicit concern for the MI score.

6.3 COMPARISON TO THE BROWN ALGORITHM: SPEED

To see the runtime difference between our algorithm and the Brown algorithm, we measured how long it takes to extract clusters from the RCV1 corpus for various numbers of clusters. In all the reported runtimes, we exclude the time to read and write data. We report results with 200, 400, 600, 800, and 1,000 clusters. All timing experiments were done on a machine with dual-socket, 8-core, 2.6GHz Intel Xeon E5-2670 (Sandy Bridge). The implementations for both algorithms were written in C++. The spectral algorithm also made use of Matlab for matrix calculations such as the SVD calculation.

Table 3 shows the runtimes required to extract these clusters as well as the F1 scores on the NER dev set obtained with these clusters. The spectral algorithm is considerably faster than the Brown algorithm while providing comparable improvement in the F1 scores. The runtime difference becomes more prominent as the number of clusters increases. Moreover, the spectral algorithm scales much better with larger vocabulary size. With 1,000 clusters and 300k vocabulary size, the Brown algorithm took over 22 hours whereas the spectral algorithm took 2 hours, 4 minutes, and 15 seconds—less than 10% of the time the Brown algorithm takes.

We also note that for the Brown algorithm, the improvement varies significantly depending on how many clusters are used; it is 0.76 with 200 clusters but 1.97 with 1,000 clusters. For the spectral algorithm, this seems to be less the case; the improvement is 1.5 with 200 clusters and 1.97 with 1,000 clusters.

6.3.1 Discussion on Runtimes

The final asymptotic runtime is $O(N + \gamma nm^2)$ for the spectral algorithm and $O(N + nm^2)$ for the Brown algorithm, where N is the size of the corpus, n is the number of distinct word types, m is the number of clusters, and γ is a data-dependent constant. Thus it may be puzzling why the spectral algorithm is significantly faster in practice. We explicitly discuss the issue in this section.

The spectral algorithm proceeds in two stages. First, it constructs a scaled covariance matrix in $O(N)$ time and performs a rank- m SVD of this matrix. Table 3 shows that SVD scales well with the value of m and the size of the corpus.

Second, the algorithm performs hierarchical clustering in $O(\gamma nm^2)$ time. This stage consists of $O(\gamma nm)$ calls to an $O(m)$ time function that computes Eq. (2), that is,

$$d(c, c') = \frac{|c||c'|}{|c| + |c'|} \|\mu_c - \mu_{c'}\|^2$$

This function is quite simple: it calculates a scaled distance

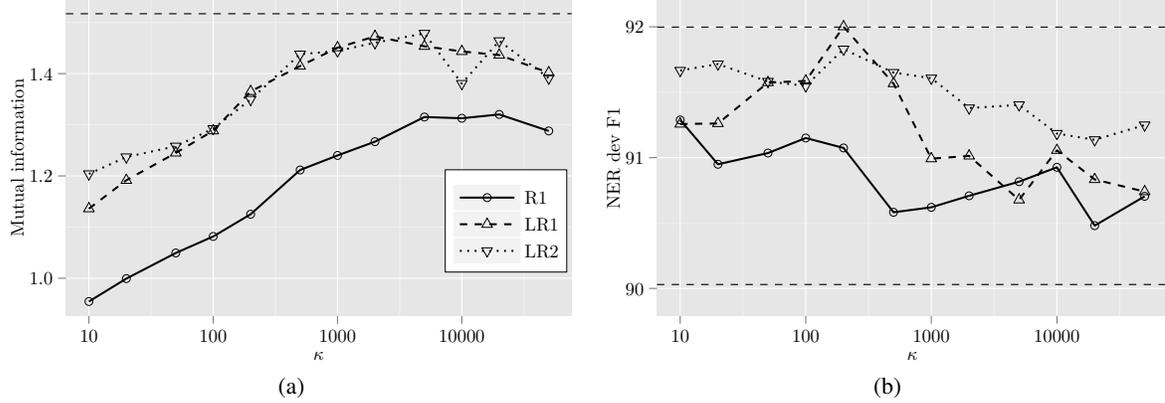

Figure 6: Effect of the choice of κ and context on (a) MI and (b) NER dev F1 score. We used 1,000 clusters on RCV1 with vocabulary size 50k. In (a), the horizontal line is the MI achieved by Brown clusters. In (b), the top horizontal line is the F1 score achieved with Brown clusters and the bottom horizontal line is the baseline F1 score achieved without using clusters.

```

computeL2usingOld(s, t, u, v, w) = L2[v][w]
- q2[v][s] - q2[s][v] - q2[w][s] - q2[s][w]

```

Figure 7: A $O(1)$ function that is called $O(nm^2)$ times in Liang’s implementation of the Brown algorithm, accounting for over 40% of the runtime. Similar functions account for the vast majority of the runtime. The values in the arrays $L2, q2, p2, p1$ are precomputed. $p2[v][w] = p(v, w)$, i.e, the probability of cluster v being followed by cluster w ; $p1[v] = p(v)$ is the probability of cluster v ; $q2[v][w] = p(v, w) \log((p(v)p(w))^{-1}p(v, w))$ is the contribution of the mutual information between clusters v and w . The function recomputes $L2[v][w]$, which is the loss in log-likelihood if clusters v and w are merged. The function updates $L2$ after clusters s and t have been merged to form a new cluster u . There are many operations involved in this calculation: 6 divisions, 12 multiplications, 36 additions (26 additions and 10 subtractions), and 6 log operations.

between two vectors in \mathbb{R}^m . Moreover, it avails itself readily to existing optimization techniques such as vectorization.¹ Finally, we found that the empirical value of γ was typically small: it ranged from 3.35 to 13.77 in our experiments reported in Table 3 (higher m required higher γ).

In contrast, while the main body of the Brown algorithm requires $O(N + nm^2)$ time, the constant factors are high due to fairly complex book-keeping that is required. For example, the function in Figure 7 (obtained from Liang’s

¹Many linear algebra libraries automatically support vectorization. For instance, the Eigen library in our implementation enables vectorization by default, which gave a 2-3 time speedup in our experiments.

implementation) is invoked $O(nm^2)$ times in total: specifically, whenever two clusters s and t are merged to form a new cluster u (this happens $O(n)$ times), the function is called $O(m^2)$ times, for all pairs of clusters v, w such that v and w are not equal to s, t , or u . The function recomputes the loss in likelihood if clusters v and w are merged, after s and t are merged to form u . It requires a relatively large number of arithmetic operations, leading to high constant factors. Calls to this function alone take over 40% of the runtime for the Brown algorithm; similar functions account for the vast majority of the algorithm’s runtime. It is not clear that this overhead can be reduced.

6.4 EFFECT OF THE CHOICE OF κ AND CONTEXT

Figure 6 shows the MI and the F1 score on the NER dev set for various choices of κ and context. For NER, around 100-200 for the value of κ gives good performance. For the MI, the value of κ needs to be much larger.

LR1 and LR2 perform much better than R1 but are very similar to each other across the results, suggesting that words in the immediate vicinity are necessary and nearly sufficient for these tasks.

7 CONCLUSION

In this paper, we have presented a new and faster alternative to the Brown clustering algorithm. Our algorithm has a provable guarantee of recovering the underlying model parameters. This approach first uses SVD to consistently estimate low-dimensional representations of word types that reveal their originating clusters by exploiting the implicit disjoint-cluster assumption of the Brown model. Then agglomerative clustering is performed over these representations to build a hierarchy of word types. The resulting clusters give a competitive level of improvement in performance in NER as the clusters from the Brown algorithm,

but the spectral algorithm is significantly faster.

There are several areas for the future work. One can try to speed up the algorithm even more via a top-down rather than bottom-up approach for hierarchical clustering, for example recursively running the 2-means algorithm. Experiments with the clusters in tasks other than NER (e.g., dependency parsing), as well as larger-scale experiments, can help further verify the quality of the clusters and highlight the difference between the spectral algorithm and the Brown algorithm.

A INCORPORATING RICHER CONTEXT

We assume a function ϕ such that for $i \in [N]$, it returns a set of positions other than i . For example, we may define $\phi(i) = \{i-1, i+1\}$ to look at one position to the left and to the right. Let $s = |\phi(i)|$ and enumerate the elements of $\phi(i)$ as j_1, \dots, j_s . Define $B^{(j)} \in \mathbb{R}^{n \times n}$, $v^{(j)} \in \mathbb{R}^n$ for all $j \in \phi(i)$ as follows:

$$\begin{aligned} B_{x,x'}^{(j)} &= P(X_i = x, X_j = x') & \forall x, x' \in [n] \\ v_x^{(j)} &= P(X_j = x) & \forall x \in [n] \end{aligned}$$

The new definitions of $B \in \mathbb{R}^{n \times ns}$, $v \in \mathbb{R}^{ns}$ are given by $B = [B^{(j_1)}, \dots, B^{(j_s)}]$ and $v = [(v^{(j_1)})^\top, \dots, (v^{(j_s)})^\top]^\top$. Letting $\Omega \in \mathbb{R}^{n \times ns}$ as in Eq. (1), it is easy to verify Theorem 5.1 using similar techniques.

B PROOF OF THEOREM 5.2

Write the rank- m SVD of Ω as $\Omega = USV^\top$, and similarly write the rank- m SVD of $\hat{\Omega}$ as $\hat{\Omega} = \hat{U}\hat{S}\hat{V}^\top$. Since Ω has rank m , it follows by Eckart-Young that

$$\|\hat{U}\hat{S}\hat{V}^\top - \hat{\Omega}\| \leq \|\Omega - \hat{\Omega}\|.$$

Therefore, by the triangle inequality,

$$\|\hat{U}\hat{S}\hat{V}^\top - USV^\top\| \leq 2\|\Omega - \hat{\Omega}\| = 2\varepsilon\sigma_m(\Omega).$$

This implies, via applications of Wedin's theorem and Weyl's inequality,

$$\|U_\perp^\top \hat{U}\| \leq 2\varepsilon \quad \text{and} \quad \|\hat{U}_\perp^\top U\| \leq \frac{2\varepsilon}{1-2\varepsilon} \quad (4)$$

where $U_\perp \in \mathbb{R}^{n \times (n-m)}$ is a matrix whose columns form an orthonormal basis for the orthogonal complement of the

range of U , and $\hat{U}_\perp \in \mathbb{R}^{n \times (n-m)}$ is similarly defined (and note that $\varepsilon < 1/2$ by assumption).

Recall that by Theorem 5.1, there exists an orthogonal matrix $Q \in \mathbb{R}^{m \times m}$ such that $U = \sqrt{O}Q^\top$. Define $\hat{Q} := \hat{U}^\top \sqrt{O} = \hat{U}^\top UQ$, and, for all $c \in [m]$, $\hat{q}_c := \hat{Q}e_c$. The fact that $\|UQe_c\| = 1$ implies

$$\|\hat{q}_c\| = \sqrt{1 - \|\hat{U}_\perp \hat{U}_\perp^\top UQe_c\|^2} \leq 1.$$

Therefore, by Eq. (4),

$$1 \geq \|\hat{q}_c\| \geq \|\hat{q}_c\|^2 \geq 1 - \left(\frac{2\varepsilon}{1-2\varepsilon}\right)^2. \quad (5)$$

We also have, for $c \neq c'$,

$$\hat{q}_c^\top \hat{q}_{c'} \leq \|\hat{U}_\perp^\top UQe_c\| \|\hat{U}_\perp^\top UQe_{c'}\| \leq \left(\frac{2\varepsilon}{1-2\varepsilon}\right)^2, \quad (6)$$

where the first inequality follows by Cauchy-Schwarz, and the second inequality follows from (4). Therefore, by Eq. (5) and Eq. (6), we have for $c \neq c'$,

$$\|\hat{q}_c - \hat{q}_{c'}\|^2 \geq 2 \left(1 - 2 \left(\frac{2\varepsilon}{1-2\varepsilon}\right)^2\right). \quad (7)$$

Let $\bar{o}_x := O_{x,C(x)}^{1/2}$. Recall that $\sqrt{O}^\top e_x = \bar{o}_x e_{C(x)} \in \mathbb{R}^m$, so $\hat{Q}\sqrt{O}^\top e_x = \bar{o}_x \hat{q}_{C(x)}$ and $\|\hat{Q}\sqrt{O}^\top e_x\| = \bar{o}_x \|q_{C(x)}\|$. By the definition of \hat{Q} , we have

$$\hat{U} - \sqrt{O}\hat{Q}^\top = \hat{U} - UU^\top \hat{U} = U_\perp U_\perp^\top \hat{U}$$

This implies, for any $x \in [n]$,

$$\begin{aligned} \|\hat{U}^\top e_x - \bar{o}_x \hat{q}_{C(x)}\| &= \|(\hat{U} - \sqrt{O}\hat{Q}^\top)^\top e_x\| \\ &= \|\hat{U}^\top U_\perp U_\perp^\top e_x\| \leq 2\varepsilon \end{aligned} \quad (8)$$

by Eq. (4). Moreover, by the triangle inequality,

$$\| \|\hat{U}^\top e_x\| - \bar{o}_x \|q_{C(x)}\| \| \leq 2\varepsilon. \quad (9)$$

Since $\hat{M}^\top e_x = \|\hat{U}^\top e_x\|^{-1} \hat{U}^\top e_x$, we have

$$\begin{aligned} \|\hat{M}^\top e_x - \hat{q}_{C(x)}\| &= \left\| \frac{1}{\|\hat{U}^\top e_x\|} \hat{U}^\top e_x - \hat{q}_{C(x)} \right\| \\ &\leq \frac{1}{\bar{o}_x} \|\hat{U}^\top e_x - \bar{o}_x \hat{q}_{C(x)}\| + |1 - \|\hat{q}_{C(x)}\|| \\ &\quad + \frac{|\bar{o}_x \|\hat{q}_{C(x)}\| - \|\hat{U}^\top e_x\|}{\bar{o}_x} \\ &\leq \frac{4\varepsilon}{\bar{o}_x} + \left(\frac{2\varepsilon}{1-2\varepsilon}\right)^2, \end{aligned} \quad (10)$$

where the first inequality follow by the triangle inequality and norm homogeneity, and the second inequality uses Eq. (8), Eq. (9), and Eq. (5). Using Eq. (10), we may upper bound the distance $\|\hat{M}^\top e_x - \hat{M}^\top e_{x'}\|$ when $C(x) = C(x')$; using Eq. (7) and Eq. (10), we may lower bound the distance $\|\hat{M}^\top e_x - \hat{M}^\top e_{x''}\|$ when $C(x) \neq C(x'')$. The theorem then follows by invoking the assumption on ε .

Abstract

The continuous time Bayesian network (CTBN) enables temporal reasoning by representing a system as a factored, finite-state Markov process. The CTBN uses a traditional Bayesian network (BN) to specify the initial distribution. Thus, the complexity results of Bayesian networks also apply to CTBNs through this initial distribution. However, the question remains whether propagating the probabilities through time is, by itself, also a hard problem. We show that exact and approximate inference in continuous time Bayesian networks is NP-hard even when the initial states are given.

1 INTRODUCTION

Currently, little theoretical work has been done on the complexity of inference in CTBNs. Most of what is known about the complexity of CTBNs is derived from the fact that a Bayesian network is used to specify the initial distribution. However, despite the similarity in the names, inference in CTBNs is different than inference in Bayesian networks because the CTBN must reason over continuous time. The question becomes whether this problem of calculating evolving probabilities through time is also NP-hard, independent of the initial distribution.

The only known exact inference procedure for CTBNs is exponential in the number of nodes, but this does not necessarily imply that there does not exist an alternative approach for exact inference that performs in polynomial time even for the worst case. Furthermore, what expectations might we have about the various approximate inference algorithms that have been developed for CTBNs? Does the accuracy vs. complexity trade-off of these approximation algorithms avoid the NP-hardness of their discrete-time counterparts? In

this work, we prove that exact and approximate inference in CTBNs are both NP-hard, even when the initial states are given. Thus, the complexity is also in reasoning over the factored Markov process, not just in reasoning over the Bayesian network for determining the probabilities for the initial states.

2 BACKGROUND

To place our work in context, we begin by presenting background information on Bayesian networks, dynamic Bayesian networks, and then CTBNs.

2.1 BAYESIAN NETWORKS

Bayesian networks are probabilistic graphical models that use nodes and arcs in a directed acyclic graph to represent a joint probability distribution over a set of variables (Koller & Friedman, 2009). Let $P(\mathbf{X})$ be a joint probability distribution over n variables $X_1, \dots, X_n \in \mathbf{X}$. A Bayesian network \mathcal{B} is a directed, acyclic graph in which each variable X_i is represented by a node in the graph. Let $\mathbf{Pa}(X_i)$ denote the parents of node X_i in the graph. The graph representation of \mathcal{B} factors the joint probability distribution as:

$$P(\mathbf{X}) = \prod_{i=1}^n P(X_i | \mathbf{Pa}(X_i)).$$

2.2 DYNAMIC BAYESIAN NETWORKS

The traditional Bayesian network is a static model. However, we can introduce the concept of time (or at least sequence) into the network by assigning discrete timesteps to the nodes to create a dynamic Bayesian network.

A dynamic Bayesian network (DBN) is a type of Bayesian network that uses a series of connected timesteps, each of which contains a copy of a Bayesian network \mathbf{X}_t indexed by timestep t . The probability

distribution of a variable at a given timestep can be conditionally dependent on states of that variable or other variables throughout previous timesteps. For first-order DBNs, dependence does not go further than the immediately previous timestep. Therefore, the joint probability distribution for a first-order DBN of T timesteps factors as:

$$P(\mathbf{X}_0, \dots, \mathbf{X}_{T-1}) = P(\mathbf{X}_0) \prod_{t=0}^{T-1} P(\mathbf{X}_{t+1} | \mathbf{X}_t).$$

2.3 CONTINUOUS TIME BAYESIAN NETWORKS

As can be seen from the preceding section, the DBN is restricted to discrete timesteps. The CTBN avoids discretizing time by using conditional Markov processes instead of conditional probability tables. We now formally define the CTBN and then survey its inference algorithms and applications.

2.3.1 CTBN Definition

Let \mathbf{X} be a set of Markov processes $\{X_1, X_2, \dots, X_n\}$, where each process X_i has a finite number of discrete states. A continuous time Bayesian network is a tuple $\mathcal{N} = \langle \mathcal{B}, \mathcal{C} \rangle$. The Bayesian network \mathcal{B} has nodes corresponding to \mathbf{X} and is used only for determining $P(\mathbf{X}_0)$, the initial distribution of the process. Evidence at the initial time ($t = 0$) is incorporated by setting evidence in \mathcal{B} and performing Bayesian network inference. The continuous-time transition model \mathcal{C} describes the evolution of the process from this initial distribution and is specified as:

- A directed (possibly cyclic) graph \mathcal{G} with nodes X_1, X_2, \dots, X_n , where $\mathbf{Pa}(X_i)$ denotes the parents of X_i in \mathcal{G} ,
- A set of conditional intensity matrices (CIMs) $\mathbf{A}_{X|\mathbf{Pa}(X)}$ associated with X for each possible combination of state instantiations of $\mathbf{Pa}(X)$.

Each conditional intensity matrix $\mathbf{A}_{X|\mathbf{Pa}(X)}$ gives the dynamics of node X when the states of $\mathbf{Pa}(X)$ are fixed. Each entry $a_{i,j} \geq 0$, $i \neq j$ gives the transition intensity of the node moving from state i to state j , and each entry $a_{i,i} < 0$ controls the amount of time the node remains in state i . With the diagonal entries constrained to be non-positive, the probability density function for the node remaining in state i is given by $|a_{i,i}| \exp(a_{i,i}t)$, with t being the amount of time spent in state i , making the probability of remaining in a state decrease exponentially with respect to time. The expected sojourn time for state i is $1/|a_{i,i}|$. Each row is constrained to sum to zero, $\sum_j a_{i,j} = 0 \forall i$, meaning

that the transition probabilities from state i can be calculated as $a_{i,j}/|a_{i,i}| \forall j, i \neq j$.

2.3.2 CTBN Inference Algorithms

The only exact inference algorithm that exists so far for CTBNs combines all of the conditional intensity matrices into the single full joint intensity matrix, with states as the Cartesian product of all of the node's states (Fan, Xu, & Shelton, 2010). Thus, the size of this matrix is exponential in the number of nodes and the number of states. Because this method ignores the factored nature of the network, research on CTBN inference has focused exclusively on approximation algorithms.

Expectation propagation (Nodelman, Koller, & Shelton, 2005; Saria, Nodelman, & Koller, 2007) has been developed for CTBNs, in which neighboring nodes employ a message-passing scheme for each interval of evidence. The messages are approximate “marginals,” a projection of a node's conditional intensity matrix onto a single, approximating unconditional intensity matrix. Messages are continually passed until all of the nodes have a consistent distribution over the interval of evidence.

There have been a number of sample-based inference algorithms developed for CTBNs, including importance sampling (Fan et al., 2010; Fan & Shelton, 2008; Weiss, Natarajan, & Page, 2013) and Gibbs sampling (El-Hay, Friedman, & Kupferman, 2008; Rao & Teh, 2013). Importance sampling answers queries from a set of weighted samples that are generated in conformance to the evidence. The weight of each sample is the likelihood of the sample given the evidence. Gibbs sampling, by contrast, is a sampling procedure that takes a Markov Chain Monte Carlo (MCMC) approach. For each variable over each interval of evidence, the states in the Markov blanket (that is, the node's parents, children, and children's parents) are held constant and a random walk is performed on the state of the node. After sufficient sampling, the distribution of the random walk will converge to the true distribution for that interval of evidence.

Methods using variational techniques, such as mean-field approximation (Cohn, 2009; Cohn, El-Hay, Friedman, & Kupferman, 2009) and belief propagation (El-Hay, Cohn, Friedman, & Kupferman, 2010) have also been developed. These methods propagate the products of inhomogeneous Markov processes to approximate the distribution using systems of ordinary differential equations.

2.3.3 CTBN Applications

CTBNs have found use in a wide variety of temporal applications. For example, CTBNs have been used for inferring users' presence, activity, and availability over time (Nodelman & Horvitz, 2003); robot monitoring (Ng, Pfeffer, & Dearden, 2005); modeling server farm failures (Herbrich, Graepel, & Murphy, 2007); modeling social network dynamics (Fan & Shelton, 2009; Fan, 2009); modeling sensor networks (Shi, Tang, & You, 2010); building intrusion detection systems (Xu & Shelton, 2010; Xu, 2010; Xu & Shelton, 2008); predicting the trajectory of moving objects (Qiao et al., 2010); and diagnosing cardiogenic heart failure and anticipating its likely evolution (Gatti, Luciani, & Stella, 2011; Gatti, 2011).

2.4 PREVIOUS COMPLEXITY RESULTS

As mentioned, most of the complexity theory surrounding CTBNs is derived from the Bayesian network for the initial distribution. However, one complexity result specific to CTBNs arises from the difference between BN and CTBN structure learning. In structure learning, it is common to assign a scoring function to arcs in the network that quantifies how well the network topology matches the training data. Nodelman (2007) gives a polynomial-time algorithm for finding the highest-scoring set of k parents for a CTBN node. The corresponding problem in a Bayesian network has been shown to be NP-hard, even for $k = 2$, due to the acyclic constraint of Bayesian networks (Chickering, 1996). Essentially, because cycles are allowed in CTBNs, each node can maximize its score independently.

Because the CTBN is relatively new, much of the complexity theory surrounding CTBNs has yet to be fully explored. This work intends to expand the complexity theory of CTBN inference. The work builds on the complexity results of BNs, which we now review.

Theorem 2.1. (Cooper, 1990) *Exact inference in Bayesian networks is NP-hard.*

Proof. Cooper proved the NP-hardness of Bayesian network inference via a reduction from 3SAT. The 3SAT problem consists of a set of m clauses $C = \{c_1, c_2, \dots, c_m\}$ made up of a finite set V of n Boolean variables. Each clause contains a disjunction of three literals over V , for example, $c_3 = (v_2 \wedge \neg v_3 \wedge v_4)$. The 3SAT problem is determining whether there exists a truth assignment for V such that all the clauses in C are satisfied.

The 3SAT problem can be reduced to a Bayesian network decision problem of whether, for a $True(T)/False(F)$ node X in the network,

$P(X = T) > 0$ or $P(X = T) = 0$. We can represent any 3SAT instance by a Bayesian network as follows. For each Boolean variable v_i in V , we add a corresponding $True(T)/False(F)$ node V_i to the network such that $P(V_i = T) = \frac{1}{2}$ and $P(V_i = F) = \frac{1}{2}$. For each clause C_j , we add a corresponding $True(T)/False(F)$ node C_j to the network as a child of the three nodes corresponding to its three Boolean variables. Let w_j be the clause corresponding to the state of the three parents of C_j , and let $eval(w_j)$ be the truth function for this clause. The conditional probabilities of the node are

$$P(C_j = T|w_j) = \begin{cases} 1 & \text{if } eval(w_j) = T \\ 0 & \text{if } eval(w_j) = F \end{cases}$$

Finally, for each clause C_k , we add a $True(T)/False(F)$ node D_k . Each D_k is conditionally dependent on C_k and on D_{k-1} (except for D_1). The conditional probabilities for D_1 are

$$P(D_1 = T|C_1) = \begin{cases} 1 & \text{if } C_1 = T \\ 0 & \text{otherwise} \end{cases}$$

Similarly, the conditional probabilities for D_k ($k > 1$) are

$$P(D_k = T|C_k, D_{k-1}) = \begin{cases} 1 & \text{if } C_k = T \wedge D_{k-1} = T \\ 0 & \text{otherwise} \end{cases}$$

Figure 1 shows the BN topology and conditional probability tables for determining the satisfiability of the clause $(v_1 \vee v_2 \vee v_3) \wedge (\neg v_1 \vee \neg v_2 \vee v_3) \wedge (v_2 \vee \neg v_3 \vee v_4)$.

Importantly, the construction of this Bayesian network is polynomial in the length of the Boolean expression. For a 3SAT instance of $|V|$ variables and $|C|$ clauses, the corresponding Bayesian network has $|V| + 2|C|$ nodes. Furthermore, each node of the Bayesian network has no more than three parents, constraining the largest conditional probability table to have no more than 16 entries, for a maximum of $2|V| + 16|C| + 8(|C| - 1) + 4$ entries for the entire network.

The probabilities of the V nodes allow for every combination of truth assignments to the Boolean variables. From there, the C and D nodes enforce the logical relations of the clauses using the Bayesian network's conditional probability tables. As such, the 3SAT instance is satisfiable if and only if $P(D_m = T) > 0$, that is, if and only if there is a non-zero probability that some instantiation of the V nodes to T and F will cause all of the clauses to be satisfied. Thus, if an algorithm exists that is able to efficiently compute the exact probabilities in arbitrary Bayesian networks, the algorithm

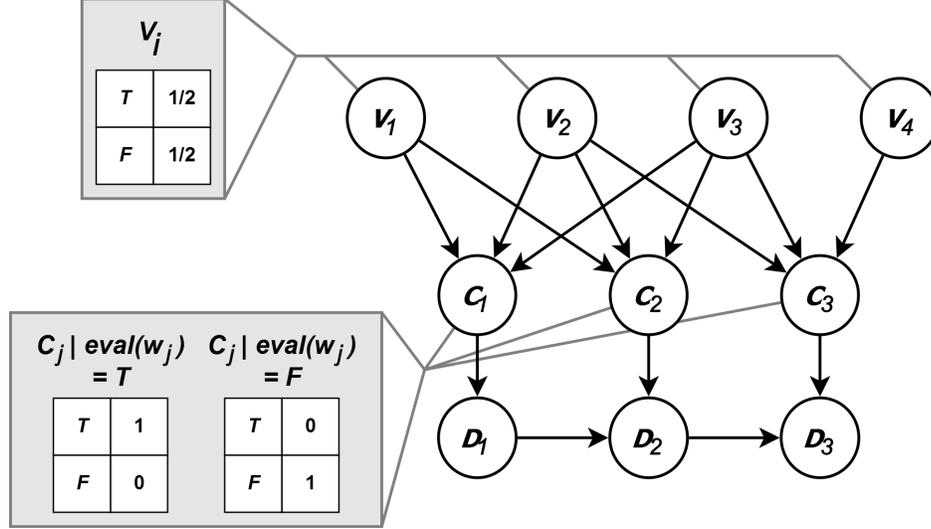

Figure 1: Network with conditional probability tables for example reduction from 3SAT to BN inference.

can efficiently decide whether $P(D_m = T) > 0$ for the specially constructed networks that can represent arbitrary instances of 3SAT. \square

Furthermore, it is known that even absolute and relative approximations in BNs is NP-hard (Dagum & Luby, 1993). These approximations are defined formally as follows. Suppose we have a real value ϵ between 0 and 1, a BN with binary-valued nodes V , and two nodes X and Y in V instantiated to x and y , respectively.

Definition 2.1. A relative approximation is an estimate $0 \leq Z \leq 1$ such that

$$\frac{P(X = x|Y = y)}{(1 + \epsilon)} \leq Z \leq P(X = x|Y = y)(1 + \epsilon).$$

Definition 2.2. An absolute approximation is an estimate $0 \leq Z \leq 1$ such that

$$P(X = x|Y = y) - \epsilon \leq Z \leq P(X = x|Y = y) + \epsilon.$$

The proof of NP-hardness for relative approximation follows directly from the proof for exact inference. Satisfiability of the clause is determined whether $Z = 0$ or $Z > 0$, which is not influenced by the choice of ϵ .

Theorem 2.2. (Dagum & Luby, 1993) Absolute approximate inference in Bayesian networks is NP-hard.

The proof of NP-hardness for absolute approximation starts with the reduction for exact inference as above, representing the variables and clauses with the same network and parameters. This time, one by one a truth assignment is set for each Boolean variable v_i , and the corresponding node V_i is removed from the

network. The truth assignment for v_i is determined by the higher probability of $P(V_i = T|D_m = T)$ and $P(V_i = F|D_m = T)$. However, if there exists an efficient approximate BN inference algorithm that can guarantee to be within $\epsilon = \frac{1}{2}$ of the exact probability on arbitrary Bayesian networks, this algorithm can be used to efficiently determine satisfying truth assignments to all Boolean variables of an arbitrary instance of 3SAT. Furthermore, any approximation with $\epsilon \geq \frac{1}{2}$ for a two-state node (the simplest case) is no better than random guessing.

These proofs are for Bayesian networks, which apply to the initial distribution of a CTBN. While the CTBN and DBN are formulated differently, Cohn, El-Hay, Friedman, and Kupferman (2010) prove that a DBN becomes asymptotically equivalent to a CTBN as the interval of time between timesteps approaches zero. One might be tempted to argue that the Bayesian network complexity proofs therefore apply to the CTBN. However, it is not always clear that moving from a discrete space to a continuous space preserves the complexity results. For example, take the difference between linear programming and integer linear programming, the former being solvable in polynomial time with the latter being NP-hard. Thus, we prove the complexity results for CTBNs explicitly.

3 EXACT INFERENCE IN CTBNS

We show that exact inference in CTBNs is NP-hard, even when given the exact initial states, following a similar reduction as the proof for BNs but using the conditional intensity matrices of the CTBN instead of the conditional probability tables. Figure 2 shows the

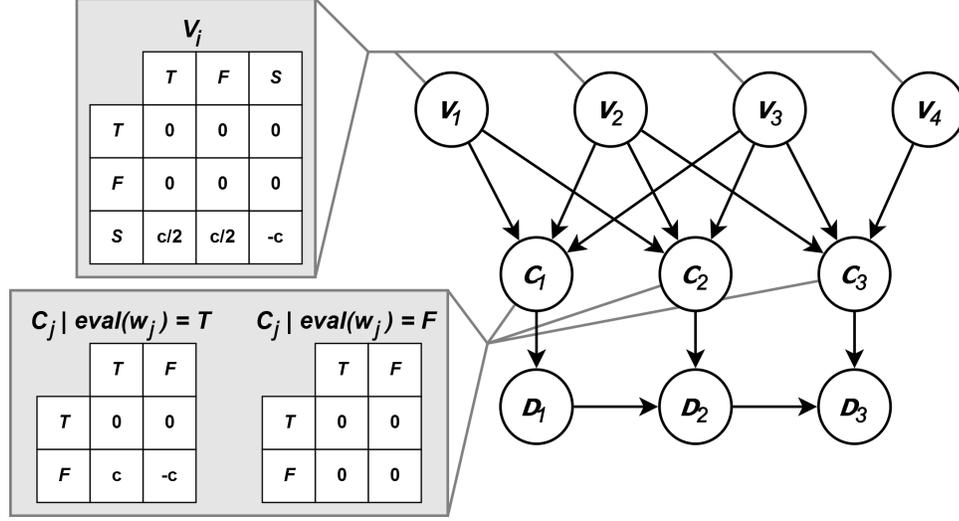

Figure 2: Network with conditional intensity matrices for example reduction from 3SAT to CTBN inference.

CTBN topology and conditional intensity matrices for determining the satisfiability of the clause $(v_1 \vee v_2 \vee v_3) \wedge (\neg v_1 \vee \neg v_2 \vee v_3) \wedge (v_2 \vee \neg v_3 \vee v_4)$.

Theorem 3.1. *Exact inference in Continuous Time Bayesian Networks is NP-hard even when given the initial states.*

Proof. The CTBN topology matches that of the BN for representing variables and clauses, but the nodes are specified differently. For each Boolean variable v_i in V , we add a corresponding three-state node V_i to the network. The three states in order are *True*(T), *False*(F), and *Start*(S), which is the initial state for node V_i . We set the unconditional intensity matrix of V_i to be

$$\mathbf{A}_{V_i} = \begin{pmatrix} 0 & 0 & 0 \\ 0 & 0 & 0 \\ c/2 & c/2 & -c \end{pmatrix}$$

for some constant $c > 0$.

For each clause C_j , we add a corresponding *True*(T)/*False*(F) node C_j to the network as a child of the three nodes corresponding to its three Boolean variables. As before, let w_j be the clause corresponding to the state of the three parents of C_j , and let $eval(w_j)$ be the truth function for this clause. The function $eval$ is extended to return *False* whenever the clause w_j contains a node in state S . The conditional intensity matrices of C_j are

$$\mathbf{A}_{C_j | eval(w_j)=T} = \begin{pmatrix} 0 & 0 \\ c & -c \end{pmatrix}$$

and

$$\mathbf{A}_{C_j | eval(w_j)=F} = \begin{pmatrix} 0 & 0 \\ 0 & 0 \end{pmatrix}.$$

We set the initial state of each C_j to be the *False*(F) state (the second row of the matrices).

Finally, for each clause C_k , we add a *True*(T)/*False*(F) node D_k . Each D_k is conditionally dependent on C_k and on D_{k-1} (except for D_1). The conditional intensity matrices for D_k are

$$\mathbf{A}_{D_k | eval(C_k \wedge D_{k-1})=T} = \begin{pmatrix} 0 & 0 \\ c & -c \end{pmatrix}$$

and

$$\mathbf{A}_{D_k | eval(C_k \wedge D_{k-1})=F} = \begin{pmatrix} 0 & 0 \\ 0 & 0 \end{pmatrix}.$$

As with the C_j nodes, we set the initial state of each D_k to be the *False*(F) state.

The conditional intensity matrices of the CTBN enforce the logical constraints of the Boolean expression, replacing the conditional probability tables of the Bayesian network. As before, a 3SAT instance of $|V|$ variables and $|C|$ clauses generates $|V| + 2|C|$ nodes in the corresponding CTBN. Each node still has no more than three parents but now each intensity matrix has 9 or 4 entries, meaning that there is a maximum of $9|V| + 108|C| + 16(|C| - 1) + 8$ conditional intensity matrix entries for the entire network.

Let $D_m(t)$ be the state of D_m at time t . The 3SAT instance is satisfiable if and only if $P(D_m(t) = T) > 0$ for any time $t > 0$. Assume that the Boolean expression is satisfiable by some combination of T/F state assignments to the variables in V . The V_i nodes start in the S state at time $t = 0$. The time that each variable remains in S is exponentially distributed, after which the variables transition to either T or F with equal probability and remain in that state. Therefore, there is a non-zero probability for each combi-

nation of T/F states in the V_i 's at $t > 0$. Whenever three of these states satisfy a clause C_j , there is a non-zero probability for C_j to transition from F to T when $t > 0$. Likewise, once the parents of D_k are in T there is a non-zero probability for D_k to transition from F to T when $t > 0$. Thus, if the Boolean expression is satisfiable, there is a non-zero probability that each each clause is satisfied at $t > 0$, and therefore $P(D_m(t) = T) > 0$. On the other hand, assume that the Boolean expression is not satisfiable. Then there exists some clause C_j that remains in F for all $t > 0$. Therefore, D_k will remain in F for all $k \geq j$, which means that $P(D_m(t) = T) = 0$ for all $t \geq 0$. \square

4 APPROXIMATE INFERENCE IN CTBNS

We prove similar results for approximate inference with CTBNs as well.

Theorem 4.1. *Relative approximate inference in Continuous Time Bayesian Networks is NP-hard even when given the initial states.*

Proof. Because the determination is whether $P(D_m(t) = T) = 0$ or $P(D_m(t) = T) > 0$, a relative approximation for $P(D_m(t) = T)$ with any error bound also gives a solution to the satisfiability of the Boolean expression. \square

We now turn to the absolute approximation. Because even approximate inference in BNs is NP-hard, it seems reasonable to suspect that a similar conclusion also holds for approximate inference in CTBNs. We now show how an absolute error approximation algorithm for CTBNs can be used to find a satisfying assignment to the Boolean expression or to determine that it is not satisfiable.

Theorem 4.2. *Absolute approximate inference in Continuous Time Bayesian Networks is NP-hard even when given the initial states.*

Proof. We start by assuming that the expression has at least one satisfying assignment. A satisfying truth assignment can be found one variable at a time by choosing $t > 0$ conditioning on $D_m(t) = T$. Let $t' \geq t$.

By construction, $P(V_i(t') = S | D_m(t) = T) = 0$. This is important, because it ensures that $P(V_i(t') = T | D_m(t) = T) + P(V_i(t') = F | D_m(t) = T) = 1$. Let $a \in \{T, F\}$, and let \hat{P}_a^i denote the absolute error approximation with ϵ for the probability $P(V_i(t') = a | D_m(t) = T)$. Without loss of generality, assume that V_i can be satisfied only when $a = T$. Then $P(V_i(t') = T | D_m(t) = T) = 1$ and $P(V_i(t') = F | D_m(t) = T) = 0$.

Therefore, it must be that $\hat{P}_T^i > \hat{P}_F^i$ whenever $\epsilon < \frac{1}{2}$. We compute both \hat{P}_T^i and \hat{P}_F^i and change the initial state of V_i to T if $\hat{P}_T^i > \hat{P}_F^i$ and to F otherwise. This process continues for $i = 1, \dots, |V|$ to determine truth assignments for all variables in the Boolean expression. Therefore, if there exists a polynomial-time approximation algorithm for CTBN inference with $\epsilon < \frac{1}{2}$ that can condition on evidence, it can be used to solve arbitrary instances of 3SAT in polynomial time as well. \square

5 EMPIRICAL VALIDATION

We can empirically validate these theoretical results by taking Boolean expressions and performing inference in the corresponding CTBN. Specifically, we demonstrate three Boolean expressions, listed as follows.

$$BE1 = (v_1 \vee v_2 \vee v_3) \wedge (\neg v_1 \vee \neg v_2 \vee v_3) \\ \wedge (v_2 \vee \neg v_3 \vee v_4)$$

$$BE2 = (v_1 \vee v_1 \vee v_1) \wedge (\neg v_2 \vee \neg v_2 \vee \neg v_2) \\ \wedge (v_3 \vee v_3 \vee v_3)$$

$$BE3 = (v_1 \vee v_1 \vee v_2) \wedge (v_1 \vee v_1 \vee \neg v_2) \\ \wedge (\neg v_1 \vee \neg v_1 \vee v_2) \wedge (\neg v_1 \vee \neg v_1 \vee \neg v_2)$$

Note that $BE1$ is the Boolean expression given as an example earlier and with the CTBN shown in Figure 2. A total of 10 out of its 16 possible truth assignments satisfy the expression. Note that $BE2$ has a single satisfying assignment and that $BE3$ is unsatisfiable.

To determine the satisfiability of each of these expressions using the corresponding CTBN, we performed forward sampling with 100,000 samples and $c = 100$ over the interval time $[0, 0.2)$. We queried the proportion of samples with which $D_m(t) = T$ for $t = 0$ to $t = 0.2$ in increments of 0.01. The results are shown in Figure 3. For the two satisfiable expressions, $BE1$ and $BE2$, $P(D_m(t) = T) > 0$ for $t \geq 0.01$, while for the unsatisfiable query $BE3$, $P(D_m(t) = T) = 0$ for all $t \in [0, 0.2)$.

Also note the values to which the probabilities are converging. For $BE1$, the probability ended at an estimated 0.622, whereas the proportion of satisfying assignments is $10/16 = 0.625$. For $BE2$, the probability ended at an estimated 0.127, whereas the proportion of satisfying assignments is $1/8 = 0.125$. As the number of samples increases, the probabilities converge to the proportion of satisfying assignments.

Next, we validate the approach through which an approximation of $P(V_i(t) = T | D_m(t) = T)$ is able to determine a satisfying assignment to each V_i . Because we are conditioning on evidence, we use importance sampling (Fan et al., 2010) and smooth zero entries in the unconditional intensity matrices with $\pm 10^{-6}$. We

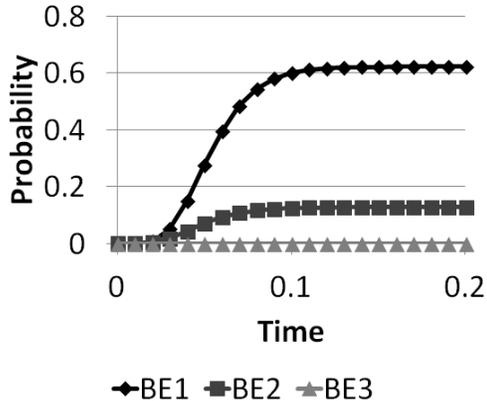

Figure 3: Empirical satisfiability results for the three Boolean expressions.

Table 1: Empirical results for approximating $P(V_i(0.2) = T | D_m(0.2) = T)$

	V_1	V_2	V_3	V_4
<i>BE1</i>	≈ 0.50	≈ 0.60	≈ 0.60	≈ 0.60
<i>BE2</i>	1	0	1	-
<i>BE3</i>	NaN	NaN	-	-

ignore samples with infinitesimal weights, as an infinitesimal weight implies that the corresponding sample contains a transition that violates the Boolean expression. The results with 100,000 samples are shown in Table 1.

The table shows that the importance sampling algorithm was correctly able to determine a satisfying truth assignments to each variable or determine that no truth assignments was possible. For *BE1*, by setting v_2 , v_3 , and v_4 to T , the Boolean expression is satisfied regardless of the value of v_1 , which is why the estimate was approximately 0.5, that is, either T or F is equally probably for satisfying the expression. For *BE2*, the importance sampling algorithm determined the single satisfying truth assignment. For *BE3*, no feasible samples could be generated because it is conditioned on an impossible event $D_m(0.2) = T$, indicating that the expression is unsatisfiable.

While we showed that we are able to solve these instances of 3SAT by CTBN sampling methods, the complexity is still exponential in the length of the Boolean expression. To demonstrate this, we show the average sample count necessary to determine the satisfiability of the Boolean expression

$$\bigwedge_{i=1, \dots, n} (v_i \vee v_i \vee v_i)$$

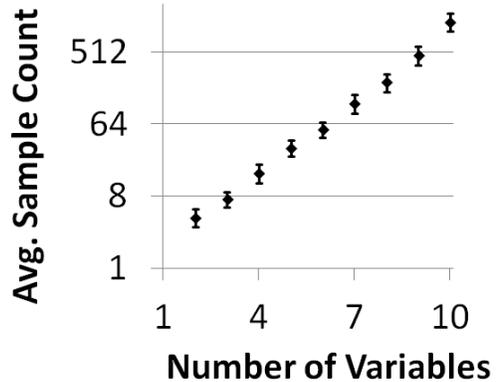

Figure 4: Sample complexity for CTBN inference.

for $n = 2, \dots, 9$. Each expression has exactly one truth assignment that satisfies it (all variables set to *True*). We count the number of samples generated until we have the first sample for which $D_m(0.2) = T$, making $P(D_m(0.2) = T) > 0$ and thus showing that the 3SAT instance is satisfiable. For each number of variables, we average the number of samples generated over 100 runs. The average sample counts along with confidence intervals for $\alpha = 0.01$ are plotted in Figure 4. The \log_2 scale on the y -axis shows that the algorithm is exponential in the length of the expression.

6 CONCLUSION

We have shown that exact and approximate inference in CTBNs is NP-hard, even when given the initial states. Thus, the difficulty of CTBN inference is found not only in Bayesian network inference for calculating the initial distribution, but also in accurately propagating the probabilities forward in time. Given the similar results with Bayesian networks, these results are not surprising. However, as with Bayesian networks, further research may reveal special cases of the CTBN, whether in their structures or their parameters, which admit polynomial-time algorithms for approximate or even exact inference.

Model Regularization for Stable Sample Rollouts

Erik Talvitie

Department of Mathematics and Computer Science
Franklin & Marshall College
Lancaster, PA 17604

Abstract

When an imperfect model is used to generate sample rollouts, its errors tend to compound – a flawed sample is given as input to the model, which causes more errors, and so on. This presents a barrier to applying rollout-based planning algorithms to learned models. To address this issue, a training methodology called “hallucinated replay” is introduced, which adds samples from the model into the training data, thereby training the model to produce sensible predictions when its own samples are given as input. Capabilities and limitations of this approach are studied empirically. In several examples hallucinated replay allows effective planning with imperfect models while models trained using only real experience fail dramatically.

1 INTRODUCTION

Online Monte Carlo-based planning algorithms such as Sparse Sampling (Kearns et al. 2002), UCT (Kocsis & Szepesvári 2006), and POMCP (Silver & Veness 2010) are attractive in large problems because their computational complexity is independent of the size of the state space. This type of planning has been successful in many domains where a perfect model is available to the agent, but there is a fundamental barrier in the way of applying these methods to *learned* models. The core operation in Monte Carlo planning is sampling possible futures by composing the model’s one-step predictions (in a process called *rollout*). When an imperfect model is used, errors in one sampled observation cause more errors in the next sample, and so on until the rollout bears little or no resemblance to any plausible future, making it worthless for planning purposes.

To illustrate, consider the following simple planning problem, which will serve as a running example throughout the paper. In “Mini-Golf” (pictured in Figure 1a), the agent’s

observations are 20×3 binary images. The image shows a ball, a wall, and a pit. A cover slides back and forth over the pit. The agent selects between two actions: *no-op* and *hit*; once the *hit* action is selected, only the *no-op* action is available thereafter. When the ball is hit, it travels to the right, knocks the wall down (i.e., the wall disappears), bounces back to the left, hits the left edge, and bounces back to the right. If the cover is in the correct position, the ball reaches the right side, the episode ends, and the agent receives 1 reward. Otherwise, the ball falls into the pit which ends the episode with no reward.

Imagine that the agent learns a factored model over pixels. There is a separate component model responsible for predicting each pixel; the prediction for the full image is the product of the component models’ predictions. The component model at position $\langle x, y \rangle$ is given the pixel values in an $n \times m$ neighborhood centered at $\langle x, y \rangle$ for the previous two time-steps, as well as the most recent two actions.

If $n = 9$ and $m = 3$, there is enough information to make perfectly accurate predictions, but imagine that $n = 7$. This simulates the common situation that the minimum set of features necessary for perfect accuracy is either unknown or computationally impractical. The consequences of the limitation are illustrated in Figure 1b. The main problem is that a pixel immediately adjacent to the ball cannot tell if the ball is next to a wall, and therefore whether the ball will bounce back. As a result, the model for this pixel is uncertain whether the pixel will be black or white.

Figure 2 shows a rollout from a perfect model ($n = 9$) on the left and a rollout from an imperfect model ($n = 7$) in the center. When the model is very accurate, rollouts are plausible futures. When the model is imperfect, the model’s limitation eventually causes an error – a pixel next to the ball stochastically turns black, as if the ball were bouncing back. This creates a context for the nearby pixel models that is unlike any they have seen before. This causes new artifacts to appear in the next sample, and so on. The meaningful structure in the observations is quickly obliterated making it impossible to tell whether the ball will eventually reach the other side.

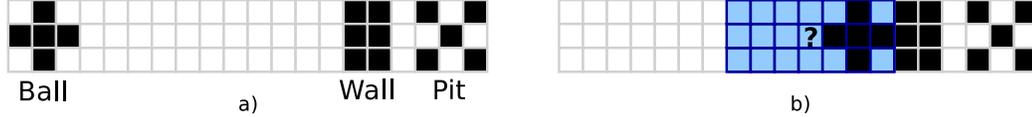

Figure 1: a) The Mini-Golf problem. b) The pixel marked with the ? cannot be predicted perfectly with a 7×3 neighborhood (shaded) because it cannot tell if the ball will bounce off of a wall.

This issue can be framed as a mismatch between the model’s training data and test data. Specifically, the model’s training data is drawn from real world experience but when it is actually used for planning (i.e., “tested”), the inputs to the model are samples generated from the model itself, which may be very different than real observations. In a sense, the model in this example has overfit to the real world! The approach taken in this paper to address this train/test mismatch is to mix samples from the model into the training data. The resulting method is called “hallucinated replay,” in analogy to “experience replay” (Lin 1992). On the right of Figure 2 is a rollout of a model trained using hallucinated replay. Note that it makes the same initial error (a spurious black pixel still appears), but it has learned that lone black pixels should turn white. In effect, it has learned to correct for its own sampling errors.

This paper has two main goals. The first is to highlight the dramatic impact of this mismatch between real inputs and sampled inputs on model-based reinforcement learning. In several examples seemingly innocuous model limitations cause catastrophic planning failures. The second is to empirically investigate hallucinated replay as an approach to addressing this issue. Most notably, hallucinated replay will be used to learn imperfect models that can nevertheless be used for effective planning. These results indicate that this method may be an important tool for model-based reinforcement learning in problems where one cannot expect to learn a perfect model.

2 ENVIRONMENTS AND MODELS

The development of hallucinated replay will focus on the setting of multi-dimensional, discrete, deterministic dynamical systems. Time proceeds in discrete steps. At each step t , the agent selects an action a_t from a finite set of actions \mathcal{A} . Given the action, the environment deterministically produces an observation vector \mathbf{o}_t . Let $\mathcal{O} = \mathcal{O}_1 \times \mathcal{O}_2 \times \dots \times \mathcal{O}_n$ be the observation space, where \mathcal{O}_i is the finite set of possible values for component i of the observation. Note that *not all* $\mathbf{o} \in \mathcal{O}$ will necessarily be reachable in the world. Let $\mathcal{O}_E \subseteq \mathcal{O}$ be the subset of observations that the environment can ever produce. For example, in Mini-Golf, \mathcal{O} would be the set of *all* 20×3 binary images, and \mathcal{O}_E would be the set of binary images with a ball, a pit, and either a wall or no wall.

Let \mathcal{H} be the set of all sequences $a_1 \mathbf{o}_1 \dots a_k \mathbf{o}_k$ for all

lengths k and let $\mathbf{o}_t = T(a_t, h_{t-1})$ where $h_{t-1} = a_1 \mathbf{o}_1 \dots a_{t-1} \mathbf{o}_{t-1}$ is the *history* at time $t - 1$ and T is the *transition function* $T : \mathcal{A} \times \mathcal{H} \rightarrow \mathcal{O}_E$. Note that typically not all sequences in \mathcal{H} are reachable. Let $\mathcal{H}_E \subseteq \mathcal{H}$ be the set of histories that could be produced by taking some action sequence in the environment.

At each step the environment also produces a reward value r_t and, in the episodic case, a Boolean termination signal ω_t . For simplicity’s sake, these values are assumed to be contained in the observation vector \mathbf{o}_t so correctly predicting the next observation also involves correctly predicting the reward and whether the episode will terminate. Assume that if $\omega_t = True$ then $\omega_{t'} = True$ and $r_{t'} = 0$ for all $t' > t$. The goal of an agent in this environment is to maximize the expected discounted return $E[\sum_{t=1}^{\infty} \gamma^{t-1} r_t]$, where $\gamma \in [0, 1]$ is the discount factor and the expectation is over the agent’s behavior (the environment is deterministic).

Note that even though the environment is assumed to be deterministic, it may be too complex to be perfectly captured by a model. Thus models will, in general, be stochastic. Also note that because \mathcal{O}_E and \mathcal{H}_E are unknown *a priori*, models will be defined over the full spaces \mathcal{O} and \mathcal{H} instead. So, an imperfect model not only has an incorrect probability distribution over possible observations, but it may assign positive probability to *impossible* observations, as seen in the Mini-Golf example. Furthermore, during rollouts the model will have to make predictions given histories in $\mathcal{H} \setminus \mathcal{H}_E$, though no amount of experience in the environment will provide guidance about what those predictions should be.

In an abstract sense, a *model* M provides a conditional probability $T_M(\mathbf{o} \mid ha)$ for every observation vector $\mathbf{o} \in \mathcal{O}$, action $a \in \mathcal{A}$, and history sequence $h \in \mathcal{H}$. As assumed above, predicting the next observation also involves predicting the reward value and whether the episode will terminate. Note that the history h is an arbitrarily long and ever expanding sequence of actions and observations. Most practical models will rely upon some finite dimensional summary of history $\mathbf{c}(ha)$, which is hereafter called the model’s *context*. For the sake of simplifying notation, let $\mathbf{c}_t = \mathbf{c}(h_{t-1} a_t)$. For instance, a Markov model’s context would include the most recent action and observation and a POMDP model’s context would include the belief state associated with the history.

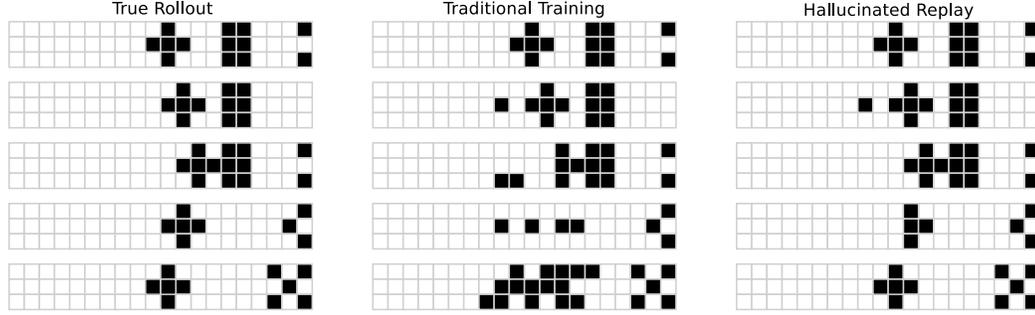

Figure 2: Rollouts using a perfect model (left), a model trained with only real experience (center) and a model trained with hallucinated replay (right). Hallucinated replay makes the model robust to its own errors.

3 HALLUCINATED REPLAY

Consider learning a model using a set of training trajectories $\{h^1, \dots, h^k\}$, where trajectory h^i is of length $|h^i|$. The training data can be seen as a set of training pairs for a supervised learning algorithm: $\{\langle \mathbf{c}_t^i, \mathbf{o}_t^i \rangle \mid i = 1 \dots k, t = 1 \dots |h^i|\}$, where the context \mathbf{c}_t^i is the input and the observation \mathbf{o}_t^i is the target output. Let \mathcal{M} be the space of possible models, or the *model class*. Most model learning methods aim to find the model $M^* \in \mathcal{M}$, which maximizes the log-likelihood:

$$\begin{aligned}
 M^* &= \operatorname{argmax}_{M \in \mathcal{M}} \sum_{i=1}^k \sum_{t=1}^{|h^i|} \log(T_M(\mathbf{o}_t^i \mid \mathbf{c}(h_{t-1}^i a_t^i))) \\
 &= \operatorname{argmax}_{M \in \mathcal{M}} \sum_{i=1}^k \sum_{t=1}^{|h^i|} \log(T_M(\mathbf{o}_t^i \mid \mathbf{c}_t^i))
 \end{aligned}$$

If a perfect model exists in \mathcal{M} , one for which $T_M(\mathbf{o}_t^i \mid \mathbf{c}_t^i) = 1$ for all i and t , then M^* is a perfect model. So in this case M^* is a sensible learning target for the purposes of model-based reinforcement learning.

If there is no perfect model in \mathcal{M} , M^* may not be a very good model for planning. Note that the log-likelihood only measures the accuracy of the model’s one-step predictions given contexts produced by the environment. However, as seen above, in order to prevent errors from compounding during planning, the model must make sensible predictions *in contexts the environment will never produce*. As will be demonstrated empirically, a model that accomplishes this may yield better planning performance than M^* , even if it incurs more prediction error (lower log-likelihood).

The high-level idea behind *hallucinated replay* is to train the model on contexts it will see during sample rollouts in addition to those from the world. Hallucinated replay augments the training data by randomly selecting a context \mathbf{c}_t^i from the training set, replacing it with a “hallucinated” context $\hat{\mathbf{c}}_t^i$ that contains sampled observations from the model, and finally adding the training pair $\langle \hat{\mathbf{c}}_t^i, \mathbf{o}_t^i \rangle$ to the training set. The model is trained with inputs that are generated

from its own predictions, but outputs from real experience.

The experiments below consider three concrete instantiations of this abstract idea, which are described below and illustrated in Figure 3. All three begin by randomly selecting a trajectory i and timestep t to select the “output” component of the new training pair.

Shallow Sample: The simplest form of hallucinated replay is to replace the observation at step $t - 1$ with a sample $\hat{\mathbf{o}}_{t-1}^i \sim T_M(\cdot \mid \mathbf{c}_{t-1}^i)$. Then the hallucinated context is $\hat{\mathbf{c}}_t^i = \mathbf{c}(h_{t-2}^i a_{t-1}^i \hat{\mathbf{o}}_{t-1}^i a_t^i)$. This approach essentially imagines that there might be errors in the first sample of a rollout (the sampled observation placed at the end of history) and trains the model to behave reasonably despite those errors (i.e., to predict the true next observation).

Deep Sample: A flaw in the above approach is that, even if a rollout recovers from an error the erroneous observation will still persist in history, possibly affecting predictions deeper in the rollout. A simple fix is to randomly select an observation in recent history (not just the most recent one) to replace with a sample. Specifically, randomly select an offset $j > 0$ and replace the observation at step $t - j$ with a sample $\hat{\mathbf{o}}_{t-j}^i \sim T_M(\cdot \mid \mathbf{c}_{t-j}^i)$ to generate the hallucinated context $\hat{\mathbf{c}}_t^i = \mathbf{c}(h_{t-j-1}^i a_{t-j}^i \hat{\mathbf{o}}_{t-j}^i a_{t-j+1}^i \mathbf{o}_{t-j+1}^i \dots a_{t-1}^i \mathbf{o}_{t-1}^i a_t^i)$. If the model is Markovian (that is, if its context only considers the most recent observation), then these two strategies are equivalent. In the experiments, the model is 2nd-order Markov, so j is either 1 or 2.

Deep Context: The above approaches have the drawback that they only introduce a single sampled observation into the context, whereas the contexts encountered by the model during a rollout will largely consist *entirely* of sampled observations. Even if the context only makes use of one observation, the above approaches sample that observation as if it is the first in the rollout, whereas the contexts encountered by the model will largely be sampled after a long rollout. To address this, randomly select a rollout length l and sample observations $\hat{\mathbf{o}}_j^i$ for $j = t - l \dots t - 1$. Then the hallucinated context is

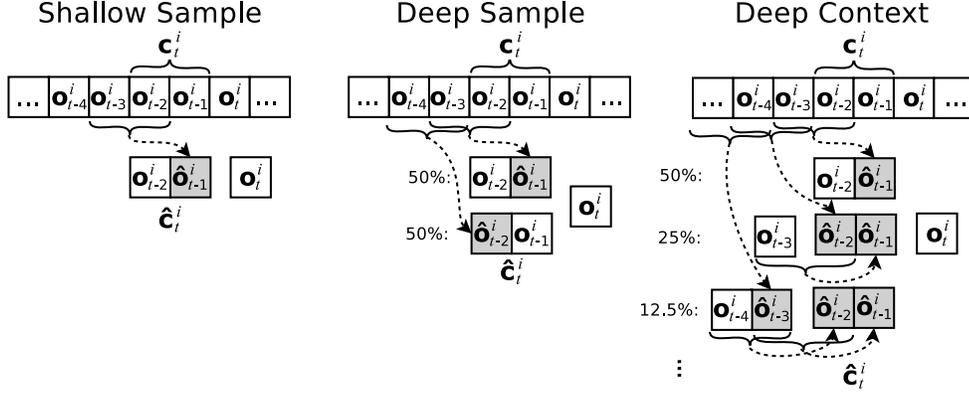

Figure 3: Methods for producing hallucinated contexts, illustrated with a 2nd-order Markov context. Samples are shaded; dashed arrows indicate the contexts which generated the samples. Actions are not shown.

$\hat{c}_t^i = \mathbf{c}(h_{t-l-1}^i a_{t-l}^i \hat{o}_{t-l}^i \dots a_{t-1}^i \hat{o}_{t-1}^i a_t^i)$. In the experiments below, $l > 0$ is drawn with probability $\Pr(l) = \frac{1}{2^l}$. This biases the distribution toward short rollouts, since long rollouts are expected to produce very noisy observations.

3.1 IMPORTANCE OF DETERMINISM

Note that hallucinated replay as described can not sensibly be applied to stochastic environments. In a deterministic environment, the only reason \hat{c}_t^i can differ from c_t^i is that the model is imperfect. In a stochastic environment, even a perfect model could generate $\hat{c}_t^i \neq c_t^i$ by sampling a different stochastic outcome. In that case, training on the pair $\langle \hat{c}_t^i, o_t^i \rangle$ could harm the model by contradicting temporal dependencies the model may have correctly identified. One exception to this limitation is when the source of stochasticity is “measurement error,” noise that is uncorrelated over time and does not affect the evolution of the underlying state. In that case, hallucinated replay would re-sample the noise to no ill effect. This work focuses on the case of stochastic models of deterministic environments (assuming the environment may be too complex to model perfectly). This is, in itself, a large and interesting class of problems. The possibility of extending the idea to stochastic environments is briefly discussed in Section 5.2.

4 EXPERIMENTS

This section contains the main results of the paper, an empirical exploration of the properties of hallucinated replay under different modeling conditions. The experiments will be performed on variations of the Mini-Golf problem described in the introduction. One of the key features of this domain is that, though it is a simple planning problem (the agent needs only to select *hit* at the right moment), a long rollout is necessary to sample the eventual reward value and determine whether it is better to *hit* or *no-op*. The experiments employ the simple *1-ply Monte Carlo* algorithm:

at each step, for each available action a , perform 50 rollouts of length at most 80 that begin with a and uniformly randomly select actions thereafter. After the rollouts, execute the action that received the highest average return. In these experiments model learning and planning are both performed online – at each step, the planner uses the current model, which is then updated with the resulting training pair. All of the replay strategies train on 5 additional pairs from past experience per step.

The model of the pixels is factored, as described in the introduction. If a neighborhood contains pixels outside the boundaries of the image they are encoded with a special “out of bounds” color. In all the experiments data is shared across all positions, providing some degree of positional invariance in the predictions. To predict the reward and termination signals r_t and ω_t (which do not have positions on the screen) the context is the pixel values at all positions in \mathbf{o}_t and \mathbf{o}_{t-1} , as well as the actions a_t and a_{t-1} . During sampling the pixel values are sampled before reward and termination so the sampled image can be supplied as input.

In most of the experiments below the *Context Tree Weighting* (CTW) algorithm (Willems et al. 1995) is used to learn the component models, similar to the FAC-CTW algorithm (Veness et al. 2011), which was also applied in a model-based reinforcement learning setting. Very briefly, CTW maintains a Bayesian posterior over all prunings of a fixed decision tree. Amongst its attractive properties are computationally efficient updates, a lack of free parameters, and guaranteed zero asymptotic regret with respect to the maximum likelihood tree in the model class. In order to apply CTW, an ordering must be selected for the variables in the context tree. In all cases the actions and observations were ordered by recency. For the pixel models, neighboring pixels within a timestep were ordered by proximity to the pixel being predicted. For the reward and termination models, pixel values were in reverse column-major order (bottom-to-top, right-to-left).

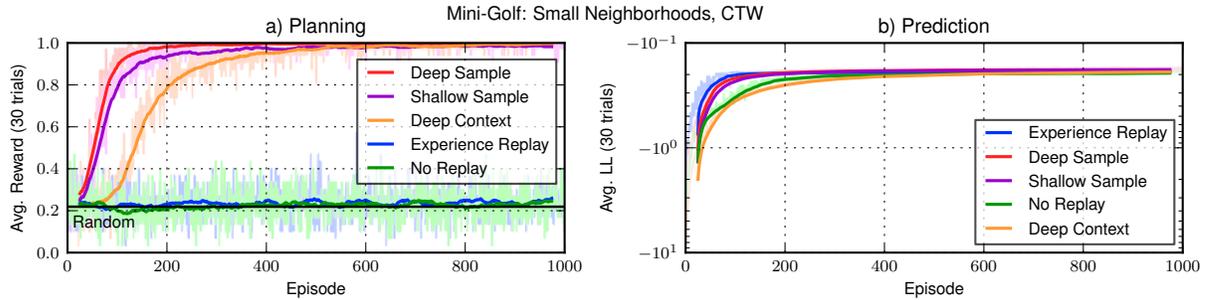

Figure 4: CTW results in Mini-Golf with small neighborhoods, averaged over 30 independent trials. Curves are smoothed using a sliding average of width 50. Unsmoothed data is shown in faint colors. The legends list the replay method in decreasing order of the value of the curve at episode 200 (in both cases, higher is better). Note the log scale in the prediction performance graph. These conventions are maintained in subsequent figures.

4.1 CORRECTING SAMPLE ERRORS

The first experiment considers the setting described in the introduction in which models are learned with 7×3 neighborhoods. Figure 4 shows the results of training with the three hallucinated replay variations proposed above and training with pure “Experience replay” (re-training on randomly selected training pairs from past experience without modifying the context). The results of training with only the agent’s experience (“No Replay”) are also provided as a baseline to show the effects of replay alone.

The most dramatic result can be seen in the planning performance (Figure 4a): the models trained only with experience from the environment (regardless of whether replay was used) result in behavior that is no better than an agent that chooses actions uniformly randomly (indicated by the solid black line). As can be seen in Figure 4b, the models trained using hallucinated replay achieve no better (and in one case much worse) prediction accuracy, as measured by average per-step log-likelihood over the training data (not counting replay). Nevertheless, they all result in near perfect planning performance. This matches the intuition described above, and indeed the rollouts in Figure 2 were generated using these learned models.

It is unsurprising that the Deep Sample replay strategy would outperform the Shallow Sample strategy – it was indeed important that sampled observations appear in both positions in the context. It is somewhat surprising that Deep Sample outperformed Deep Context as well. The hypothesis that it would be important for the model to be trained on contexts sampled far into a rollout is not supported by these results. It may be that the noisy samples obtained from long rollouts, especially early in training, were misleading enough to harm performance. It is also possible that this effect is an artifact of this example. Nevertheless, these qualitative findings were consistent across the variations explored below so, to reduce clutter, only Deep Sample results are reported in the subsequent experiments.

4.2 FULL NEIGHBORHOODS

The previous experiment is an example of hallucinated replay making meaningful planning possible when a perfect model is not contained within the model class. This is the most common case in problems of genuine interest. Nevertheless, it is relevant to ask what effect it has when a perfect model *is* in the class.

Figures 5a and 5b show the results in the Mini-Golf problem when the models used 9×3 neighborhoods (sufficient to make accurate predictions). Both the Experience Replay and No Replay models are able to support planning, and experience replay clearly improves sample efficiency. The Hallucinated Replay model has consistently lower prediction accuracy and lags behind the Experience Replay model in planning performance, though it eventually catches up. Noting that the hallucinated contexts in the very beginning of training are likely to be essentially meaningless, Figure 5 also shows the results of performing experience replay for the first 50 episodes, and hallucinated replay thereafter. This model’s planning performance is nearly identical to that of the Experience Replay model. Once the model has had some time to learn, the sampled observations become more and more like real observations, so this similarity is not surprising.

Note that though a perfect model is in the class, the intermediate models during learning are imperfect and their sampling errors do impact planning performance. It is interesting that hallucinated replay does not aid planning performance by making the model more robust to these errors. One hypothesis might be that if the rollouts were much longer, errors would be more likely to affect planning, and hallucinated replay might have more of an impact.

Figures 5c and 5d show the results of a variation on Mini-Golf that is the same in every respect, except that there are 6 walls to knock down rather than 1. Thus rollouts must be *much* longer for successful planning. First note that the

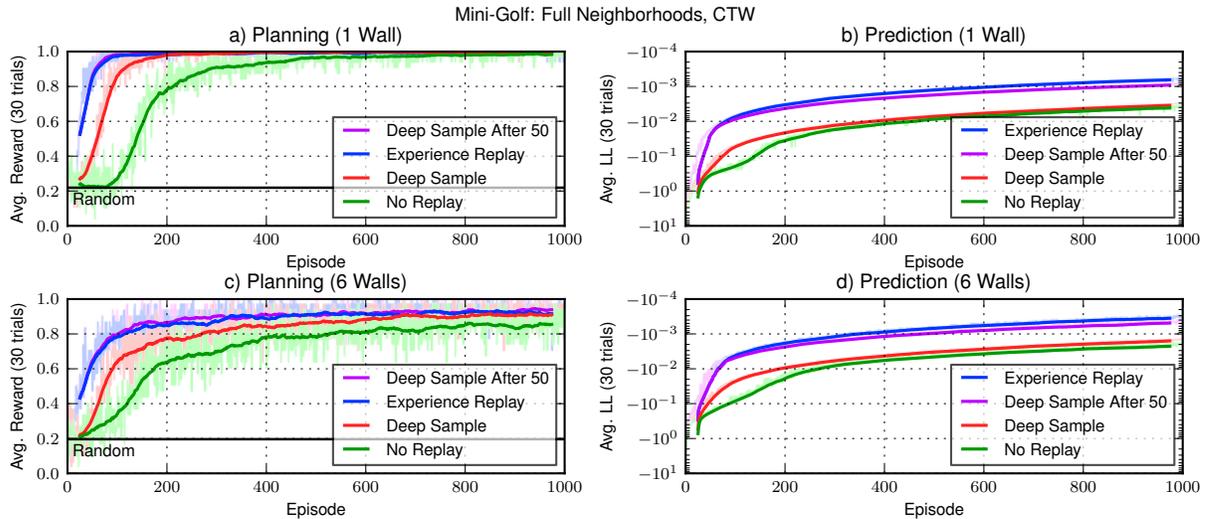

Figure 5: CTW results in Mini-Golf with full neighborhoods, both with 1 wall and with 6 walls.

hypothesis that longer rollouts will cause more sampling errors is borne out. For a comparable level of prediction accuracy, the models achieve substantially better planning performance in the 1 wall version than the 6 wall version. Still, hallucinated replay was not able to mitigate the impact of the model errors.

The errors produced by these “models-in-training” tend to be “salt-and-pepper” noise caused by pixel models that all assign small but positive probability to the incorrect outcome. This is a relatively unstructured type of noise in comparison to that seen in the first experiment. It may simply be that more data is required to learn to correct for the noise than to simply improve accuracy. Or, since objects in this problem consist of only a few pixels, this type of noise may be too destructive to be compensated for.

4.3 A DIFFERENT MODEL CLASS

In order to validate that the benefits of hallucinated replay are robust to the choice of model class, Figure 6 shows the results of training feed forward neural networks in the Mini-Golf domain. The same model architecture was used except here the pixel, reward, and termination models are neural networks with 10 logistic hidden units and a logistic output layer, trained using standard backpropagation (Rumelhart et al. 1986). Several values of the learning rate α were tested and the results using the best value of α for each method are presented. Figures 6a and 6b show the planning and prediction performance of the neural network models when given 7×3 neighborhoods. The results are very similar to those using CTW models. Figures 6c and 6d show the results using 9×3 neighborhoods. Here, unlike with CTW, the hallucinated replay training does not seem to cause a significant loss in performance. The neural

network is likely less sensitive to the initially uninformative hallucinated samples because it is easily able to ignore irrelevant features.

Notably, waiting to start hallucinated replay *hurts* performance rather than helps. The reason for this can be seen in the prediction performance graphs: a large drop in prediction performance is observed when hallucinated replay begins – this is because the hidden units must adjust to a sudden change in the distribution of input vectors. This indicates that the compatibility of a model learning method with hallucinated replay may depend on its ability to gracefully handle the non-stationarity it creates in the training data. No-regret algorithms like CTW may be particularly well-suited for that reason.

Neural network models also provide an opportunity to examine another source of model error. Figure 7 shows the results (planning only) of using neural network models with too few hidden nodes (but with full neighborhoods). In Figure 7a, the networks have 5 hidden nodes. The models trained with experience replay are able to learn quickly, but level off at sub-optimal behavior. Training with hallucinated replay is slower, but planning performance ultimately surpasses that of the experience replay model. In Figure 7b, the average score of the last 100 episodes (out of 5000) is shown for various numbers of hidden nodes. The best learning rate for each method and each number of hidden nodes is used. With a small number of hidden nodes, the model is unable to make good predictions or correct for errors. With a large number, an accurate model can be learned and hallucinated replay is unnecessary. For intermediate values hallucinated replay is able to compensate somewhat for the model’s representational deficiency.

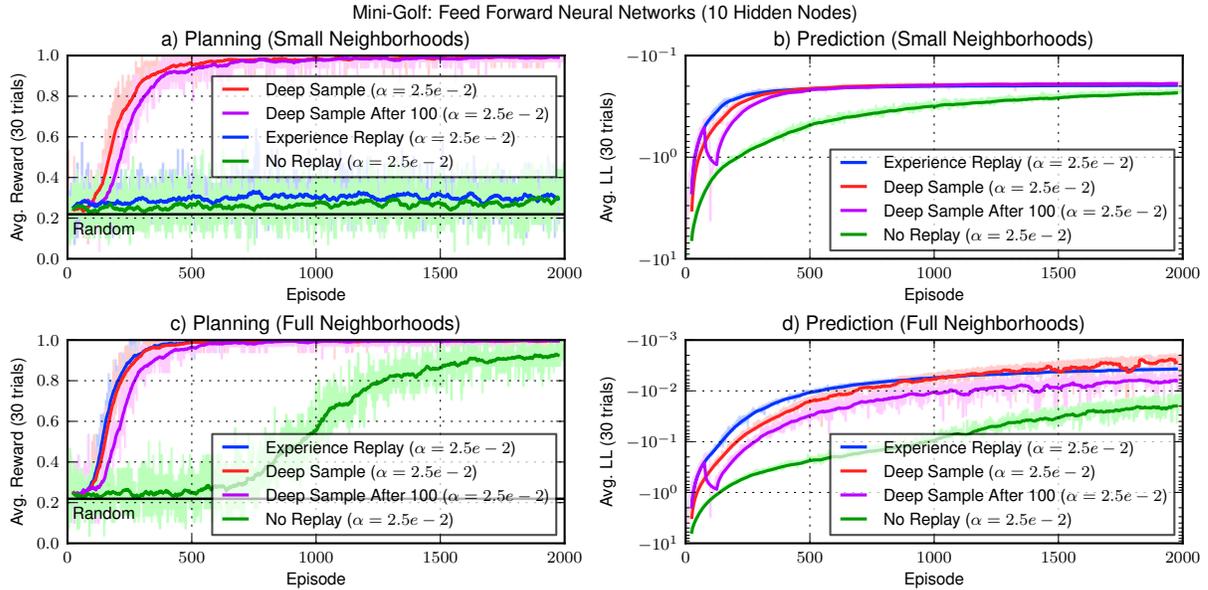

Figure 6: Neural network results in Mini-Golf with 10 hidden nodes.

4.4 ADDITIONAL EXAMPLES

Finally, as additional examples of model impairments that hallucinated replay can help to overcome, consider two variations on the Mini-Golf domain.

4.4.1 DECEPTIVELY INFORMATIVE FEATURES

In the first variation, a score display is added. The observations are now 20×6 images. The bottom three rows of the image are blank for the most part, but at the end of an episode the 3×3 area in the bottom right displays a digit (“0” or a “1”) to show the reward received.

As can be seen in Figure 8a, when the model is trained using only real experience this seemingly innocuous addition causes severe planning problems, even though the pixel models are given sufficient contexts to perfectly model the dynamics of the game. The problem arises because the neighborhood size is *not* sufficient to model the score display. When trained only on real experience, the reward and termination models rightly learn that the score display is a reliable predictor. However, during rollouts, those pixels no longer behave as they do in the world, and the reward and termination models make erratic predictions.

In contrast, the models trained with hallucinated replay learn that the score display pixels cannot be relied upon and focus instead on other relevant contextual information (such as the ball’s position). This allows the models to provide meaningful predictions that result in good planning performance. Note again that hallucinated replay has not fixed the errors. The hallucinated replay models are no bet-

ter at predicting what the score display will do. They are able to make good predictions about the reward and termination signals *despite* sample errors in the score display.

4.4.2 COMPLICATED, IRRELEVANT FEATURES

In the second variation, an irrelevant but hard-to-predict component is added to the image. Specifically, the images are 21×3 where the last column displays a set of “blinking lights.” Only one pixel in the last column is white on any given step, but the pattern of which pixel is white is 3rd-order Markov. Since the model is 2nd-order Markov, it cannot reliably predict the light pattern. That said, the lights have no impact on the rest of the dynamics and the models have sufficient context to make perfect predictions for every other pixel. Nevertheless, as can be seen in Figure 8b, this addition once again causes the model trained only on real experience to fail when used for planning.

In this case the problem is that rollout samples of the blinking lights will not resemble those seen in the world. In the world, only one light can be on a time but in samples lights stochastically turn on and off, causing novel configurations. The pixel models neighboring these unfamiliar configurations have higher uncertainty as a result, and the now familiar error compounding process ensues, corrupting the important parts of the sampled image as well as the unimportant parts. The models trained using hallucinated replay, in contrast, learn to make predictions given the distribution of light configurations that will actually be encountered during a rollout.

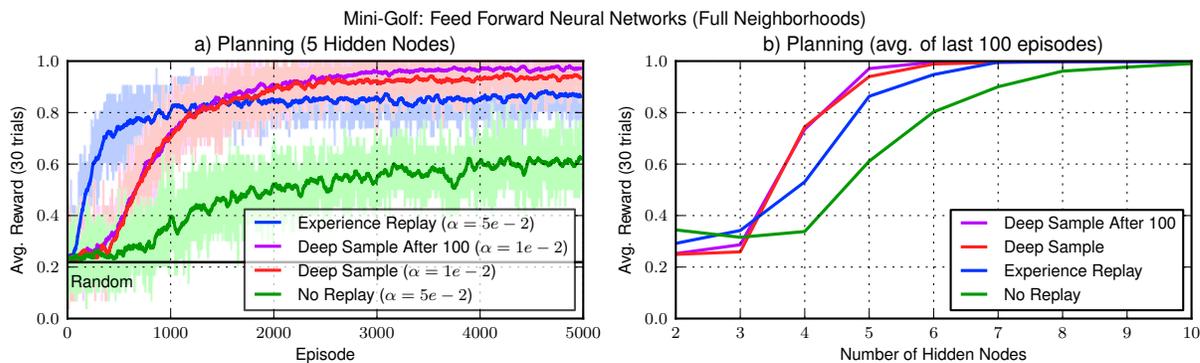

Figure 7: Neural network results in Mini-Golf with full neighborhoods but too few hidden nodes.

5 DISCUSSION

The results have shown that even mildly limited factored models that can accurately predict nearly every aspect of the environment’s dynamics can dramatically fail when used in combination with Monte-Carlo planning. Since factored models and Monte-Carlo planning are both important, successful tools in problems with large state/observation spaces, resolving this issue may be a key step toward scaling up model-based reinforcement learning. Overall, hallucinated replay was effective in its purpose: to train models to be more robust to their own sampling errors during rollouts.

When a perfect model was contained within the class (a rare occurrence in problems of genuine interest), hallucinated replay was comparable to (but slightly less effective than) pure experience replay. Though in this case the models are imperfect during training, hallucinated replay did not seem to be effective at compensating for the type of wide-spread, unstructured noise that resulted from transient parameter settings (as opposed to the more systematic errors resulting from class limitations in other examples).

It was also observed that when the model class is *extremely* limited (e.g. the neural network models with only 2 hidden nodes), hallucinated replay may be ineffective at compensating for errors because the model simply cannot learn to make meaningful predictions at all. Of course, in this case the model is ineffective no matter how it is trained. It seems that hallucinated replay is most effective when the model can capture *some but not all* of the environment’s dynamics. When a model is performing poorly hallucinated replay may be able to magnify the impact of improving the model’s expressive power (as was seen when the neural networks were given more hidden nodes).

5.1 RELATED WORK

Other authors have noted that the most accurate model in a limited class may not be the best model for planning. Sorg,

Singh & Lewis (2010) argue that when the model or planner are limited, reward functions other than the true reward may lead to better planning performance. Sorg, Lewis & Singh (2010) use policy gradient to learn a reward function for use with online planning algorithms. Joseph et al. (2013) make a similar observation regarding the dynamics model and use policy gradient to learn model parameters that lead to good planning, rather than low prediction error (demonstrating that the two do not always coincide). The results presented here add to the evidence that simply training to maximize one-step prediction accuracy may not yield the best planning results.

Siddiqi et al. (2007) addressed the problem of learning stable dynamics models of linear dynamical systems. The key idea was to project the learned dynamics matrix into the constrained space of matrices with spectral radius of at most 1, and which therefore remain bounded even when multiplied with themselves arbitrarily many times. Though certainly conceptually related (their work has the same goal of learning a model whose predictions are sensible when given its own output as input), their specific approach is unlikely to apply to the setting considered here, as the concept of “stability” is not so easily quantified.

There is a long history in the supervised learning setting of adding noise to training data (or otherwise intentionally corrupting it) to obtain regularization and generalization benefits (see e.g. Matsuoka 1992, Burges & Schölkopf 1997, Maaten et al. 2013). There the issue is not typically prediction composition but more broadly the existence of inputs that the training set may not adequately cover. Without access to the true distribution over inputs, noise is typically generated via some computationally or analytically convenient distribution (e.g. Gaussian) or via a distribution that incorporates prior knowledge about the problem. In contrast, we have access to the model which generates its own inputs, and can thus sample corrupting noise from a learned, but more directly relevant distribution.

Ross & Bagnell (2012) observed a similar train/test mis-

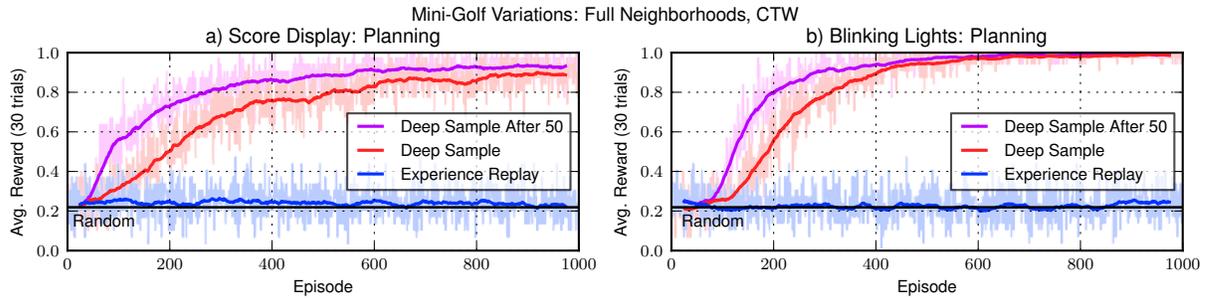

Figure 8: CTW results in two variations of Mini-Golf (described in text).

match in the model-based reinforcement learning setting when the model is trained on a fixed batch of data. In that case, the plan generated using the model may visit states that were underrepresented in training, resulting in poor performance. Their algorithm DAGger mixes experience obtained using model-generated plans into the training data as the model learns, thereby closing the gap between training and test distributions. Roughly speaking, they prove that their approach achieves good planning performance when a model in the class has low prediction error. In the examples considered here *no* model in the class has low prediction error, but near perfect planning performance is nevertheless possible.

5.2 FUTURE DIRECTIONS

The results indicate that, in addition to one-step accuracy, a model’s robustness to its own errors should be a key concern for model based reinforcement learning. They also indicate that training a model on its own outputs is a promising approach to addressing this concern. These observations open the door to a number of interesting questions and issues for further study.

As discussed in Section 3, hallucinated replay is not immediately applicable in stochastic domains. While a lot of perceived stochasticity can be attributed to unmodeled (but deterministic) complexity, it would nevertheless be valuable to explore whether this approach can be applied to inherently stochastic dynamics. The main challenge in this case is forcing the model’s hallucinated data to choose the same stochastic outcome that was observed in the real data. It may be that this could be accomplished by learning reverse correlations from real world outcomes to hallucinated contexts and applying rejection sampling when generating hallucinated data.

The hallucinated replay algorithm presented in this paper is simple and offers no theoretical guarantees. It may, however, be possible to incorporate the basic idea of hallucinated replay into more principled algorithms that admit more formal analysis. For instance, it may be possible to extend the DAGger algorithm given by Ross & Bagnell

(2012) using a form of hallucinated replay. This would allow the analysis to take into account the learned model’s robustness (or lack thereof) to its own errors. It would also be valuable, if possible, to develop algorithms that have the benefits of hallucinated replay but are able to promise that the hallucinated data will not harm asymptotic performance if an accurate model is in the class.

Perhaps most important would be to develop a more formal understanding of the relationships between accuracy, robustness, and planning performance. In sufficiently interesting environments, model errors will be inevitable. Successfully planning despite those errors is key to applying model based reinforcement learning to larger, more complex problems. A characterization of the properties beyond simple accuracy that make a model good for planning and a more nuanced understanding of which types of model error are acceptable and which are catastrophic could yield improved forms of hallucinated replay, or other model learning approaches that have good planning performance as an explicit goal rather than an implicit effect of accuracy.

6 CONCLUSIONS

Hallucinated replay trains a model using inputs drawn from its own predictions, making it more robust when its predictions are composed. This training methodology was empirically shown to substantially improve planning performance compared to using only real experience. The results suggest that hallucinated replay is most effective when combined with model-learning methods that gracefully handle non-stationarity and when the model class’ limitations allow it to capture some but not all of the environment’s dynamics.

Abstract

Learning the structure of probabilistic graphical models for complex real-valued domains is a formidable computational challenge. This inevitably leads to significant modelling compromises such as discretization or the use of a simplistic Gaussian representation. In this work we address the challenge of *efficiently* learning truly expressive copula-based networks that facilitate a mix of varied copula families within the *same* model. Our approach is based on a simple but powerful bivariate building block that is used to highly efficiently perform local model selection, thus bypassing much of computational burden involved in structure learning. We show how this building block can be used to learn general networks and demonstrate its effectiveness on varied and sizeable real-life domains. Importantly, favorable identification and generalization performance come with dramatic runtime improvements. Indeed, the benefits are such that they allow us to tackle domains that are prohibitive when using a standard learning approaches.

1 INTRODUCTION

Probabilistic graphical models [Pearl, 1988] in general and Bayesian networks (BNs) in particular, have become popular as a flexible and intuitive framework for modeling multivariate densities, a central goal of the data sciences. At the heart of the formalism is a combination of a qualitative graph structure that encodes the regularities (independencies) of the domain and quantitative local conditional densities of a variable given its parents in the graph. The result is a decomposable model that facilitates relatively efficient inference and estimation. Unfortunately, learning the structure of such models remains a formidable challenge, particularly when dealing with real-valued domains that are non-Gaussian. The computational bottleneck lies in the need to

assess the merit of many candidate structures, each requiring potentially costly maximum likelihood evaluation.

The situation is further compounded in realistic domains where we also want to allow for the combination of different local representations within the same model. Specifically, such a scenario requires that we perform non-trivial local model selection *within* an already challenging structure learning procedure. In practice, with as few as tens of variables, learning any real-valued graphical model beyond the simple linear Gaussian BN can be computationally impractical. At the same time, it is clear that, for many domains, the Gaussian representation is too restrictive. Our goal in this work is to overcome this barrier and to *efficiently* learn the structure of expressive networks that do not only go beyond the Gaussian, but that also allow for a mix of varied local representations.

In the search for expressive representations, several recent works use copulas as a building block within the framework of graphical models [Kirshner, 2007, Elidan, 2010, Wilson and Ghahramani, 2010]. Briefly, copulas [Joe, 1997, Nelsen, 2007] flexibly capture distributions of few dimensions: easy to estimate univariate marginals are joined together using a copula function that focuses solely on the dependence pattern of the joint distribution. Appealingly, regardless of the dependency pattern, any univariate representation can be combined with any copula. In all of the above works, the resulting copula graphical model proved quite effective at capturing complex high-dimensional domains, far surpassing the Gaussian representation.

Recently, Elidan [2012] proposed a structure learning method that is tailored to the so called copula network representation, and that is essentially as efficient as learning a simple linear Gaussian BN. However, an important drawback of the approach is that it constrains all local copulas in the model to be of the same type. Tenzer and Elidan [2013] offer a slight improvement but their method is inherently limited to few (2-3) of *specific* local representations and to tree-structured networks. Clearly, to take advantage of the plethora of dependency patterns captured by different copula families, we would like to have greater flexibility.

Unfortunately, selection of the right copula family, or dependence pattern, can be hard even for just two random variables. Typical approaches (e.g., [Huard et al., 2006, Fermanian, 2005, Hering and Hofert, 2010, Justel et al., 1997, Genest and Rivest, 1993]) require costly computations such as maximum likelihood estimation, Bayesian integration, simulation, etc. (see Section 3 for details). While such methods can be used to perform model selection for a distribution with few variables, they are impractical when faced with a large number of local model selection tasks that underlie global structure learning. In this work we introduce HELM: a method for **H**ighly **E**fficient **L**earning of **M**ixed copula networks.

Intuitively, for the task of model selection, the maximum likelihood density defined by a particular copula family is in fact a nuisance parameter, and we are only interested in detecting the dependency pattern of the copula. Further, since most copulas have a functional form with few parameters (or even just one), identifying between different copulas only requires a crude view of the distribution. Building on this intuition, we build a copula-to-multinomial mapping that is independent of a particular domain. Then, when faced with the model selection task given training samples, we use a comparison of the empirical multinomial signature to the precomputed mapping in order to choose the most promising copula family. Appealingly, for the building block task of choosing a copula family for two variables, our approach is effective, highly efficient, and comes with finite sample guarantees.

With this model selection building block in hand, we are still faced with the task of learning the *global* structure of the model, which in turn requires costly maximum likelihood computations. Fortunately, the same mechanism we use for selection suggests a highly efficient and effective proxy to the exact computation, when learning tree networks. Further, the method also gives rise to a natural heuristic generalization that allows us to highly efficiently learn networks with a general structure.

We demonstrate the benefit of our HELM approach for learning expressive networks that combine a varied set of copulas for several sizeable real-life datasets. Specifically, we show that our procedure is not only accurate in terms of identifying the best copula family, but also leads to learned probabilistic graphical models that generalize well. Importantly, this favorable performance comes with dramatic runtime speedups that facilitate learning of models in domains where maximum likelihood structure learning is computationally impractical.

2 BACKGROUND

In this section we briefly describe copulas, their relationship to Spearman’s ρ_s measure of association, and the copula network construction.

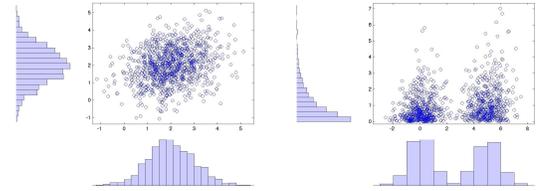

Figure 1: Samples from the bivariate Gaussian copula with $\rho = 0.25$. (left) with Gaussian marginals; (right) with a mixture of Gaussian and Gamma marginals.

Copulas

A copula function joins univariate marginals into a joint real-valued multivariate distributions. Formally, let U_1, \dots, U_n be random variables marginally uniformly distributed on $[0, 1]$. A copula function $C : [0, 1]^n \rightarrow [0, 1]$ is a joint distribution $C_\theta(u_1, \dots, u_n) = P(U_1 \leq u_1, \dots, U_n \leq u_n)$, where θ are the parameters of the copula distribution function.

Now let $\mathcal{X} = \{X_1, \dots, X_n\}$ be an arbitrary set of real-valued random variables. Sklar [1959] states that for *any* CDF $F_{\mathcal{X}}(\mathbf{x})$, there exists a copula C such that

$$F_{\mathcal{X}}(\mathbf{x}) = C(F_1(x_1), \dots, F_n(x_n)).$$

When $F_i(x_i)$ are continuous, C is uniquely defined.

The constructive converse is of particular interest from a modeling perspective: Since $F_i(X_i) \sim U([0, 1])$, *any* copula function taking *any* marginals $\{F_i(X_i)\}$ defines a valid joint cumulative distribution with marginals $\{F_i(X_i)\}$. Thus, copulas are “distribution generating” functions that allow us to separate the choice of the univariate marginals and that of the dependence.

To derive the joint *density* $f(\mathbf{x}) = \frac{\partial^n F(\mathbf{x})}{\partial x_1 \dots \partial x_n}$ from the copula construction, assuming F has n -order partial derivatives (true almost everywhere when F is continuous), and using the chain rule, we have

$$\begin{aligned} f(\mathbf{x}) &= \frac{\partial^n C(F_1(x_1), \dots, F_n(x_n))}{\partial F_1(x_1) \dots \partial F_n(x_n)} \prod_i f_i(x_i) \\ &\equiv c(F_1(x_1), \dots, F_n(x_n)) \prod_i f_i(x_i), \end{aligned}$$

where we use $c(F_1(x_1), \dots, F_n(x_n))$ to denote the *copula density function*.

Example 2.1.: The extremely popular Gaussian copula is defined as

$$C_{\Sigma}(\{U_i\}) = \Phi_{\Sigma}(\Phi^{-1}(U_1), \dots, \Phi^{-1}(U_N)), \quad (1)$$

where Φ is the standard Gaussian, and Φ_{Σ} is a zero mean Gaussian with correlation matrix Σ .

Copulas and Spearman’s Rho

Copulas are intimately connected to many dependence concepts such as Spearman’s ρ_s measure of association

$$\rho_s(X_1, X_2) = \frac{\text{cov}(F_{X_1}, F_{X_2})}{\text{STD}(F_{X_1})\text{STD}(F_{X_2})},$$

which is simply Pearson’s correlation applied to the cumulative distributions of X_1 and X_2 . For the copula associated with the joint $F_{X_1, X_2}(x_1, x_2)$, we have

$$\rho_s(X_1, X_2) = \rho_s(C) \equiv 12 \int \int C(u, v) dudv - 3.$$

Thus, Spearman’s ρ_s is monotonic in the copula cumulative distribution function associated with the joint distribution of X_1 and X_2 . See [Nelsen, 2007, Joe, 1997] for an in-depth exploration of the framework of copulas and its relationship to dependence measures.

Copula Networks

Similarly to a standard Bayesian network [Pearl, 1988], a copula network uses a directed acyclic graph \mathcal{G} to encode the independencies $I(\mathcal{G}) = \{(X_i \perp \text{NonDesc}_i \mid \mathbf{Pa}_i)\}$, where \mathbf{Pa}_i are the parents of X_i in \mathcal{G} , and NonDesc_i are its non-descendants. $I(\mathcal{G})$ implies a decomposition of the joint density into a product of local conditional densities of each variable given its parents: $f_{\mathcal{X}}(X_1, \dots, X_n) = \prod_i f_i(X_i \mid \mathbf{Pa}_i)$.

In copula networks, the local densities are defined via the copula ratio

$$f_i(X_i \mid \mathbf{Pa}_i) = \frac{c_{\theta}(F_i(X_i), \{F_j(X_j)\}_{j \in \mathbf{Pa}_i})}{c_{\theta}(\{F_j(X_j)\}_{j \in \mathbf{Pa}_i})} f_i(X_i). \quad (2)$$

Appealingly, for copulas the denominator can be easily computed from the numerator without the need for integration. Thus, the representation relies solely on the estimation of joint copulas. See [Elidan, 2010] for more details on the construction and its merits.

3 RELATED WORKS

Broadly speaking, methods for performing copula model selection can be split into three groups. Most commonly, model selection is carried out via (penalized) maximum likelihood estimation, which can be costly due to the need to evaluate the maximum likelihood parameters. In fact, as will be demonstrated in Section 7, even when the maximum likelihood parameters have a simple closed form, the actual computation of the maximum likelihood value can be time consuming in the context of structure learning, where this task is repeated numerous times. A second group of works relies on a measure of deviation between the copula, or some of its statistical properties, from the empirical estimators. Genest and Rivest [1993], for example, use the deviation of Kendall’s τ estimates from the population values to select between Archimedean copulas. Unfortunately,

for most copulas, characterizing the Kendall distribution requires simulation and can be computationally demanding [Hering and Hofert, 2010]. Another example first employs Rosenblatt’s transformation, followed by a deviation measurement relative to the uniform distribution [Justel et al., 1997], a process that can also be computationally intensive.

Fermanian [2005] suggests an alternative in the form of a goodness-of-fit test that is based on kernel density estimation. This, however, still requires tedious numerical integration. Finally, Huard et al. [2006] presents a Bayesian approach that, like our method, is quite generic as it avoids estimation of the maximum likelihood parameters. Posterior computations, however, still require costly integration over the support of Kendall’s τ values. In contrast to all of these works, our HELM method uses extremely simple statistics that are easily computed for any copula. As demonstrated in Section 7, this leads to effective performance while offering dramatic speedups.

4 EXPRESSIVE TREE NETWORKS

Our goal is to efficiently learn the structure of copula-based probabilistic graphical models while allowing for different copula families within the same model. We start by considering in this section the building block task of performing selection for bivariate copulas, and show how this building block can be used to learn tree structured networks. Then, after deriving in Section 5 finite sample guarantees for the bivariate case, in Section 6 we propose an extension for learning general networks.

4.1 MULTINOMIAL-BASED SELECTION

Recall that, intuitively, for the purpose of choosing a particular dependence pattern, the distribution is a nuisance parameter and it may be possible to forgo precise estimation. As an example, Figure 2(top) shows the grid frequency of samples from the bivariate Clayton and Gumbel copulas with $\rho_s = 0.5$. The greater emphasis of the Clayton copula on the lower tail is evident as is the converse for the Gumbel copula. Thus, it is possible to choose between the copulas based on simple statistics. Motivated by this example, our selection procedure involves three steps:

1. Precompute a *multinomial signature* for each copula family under consideration.
2. Given a set of training instances, compute an empirical multinomial signature.
3. Choose the copula whose multinomial signature is closest (in some sense) to the empirical one.

We now briefly describe the details involved in each of these three stages.

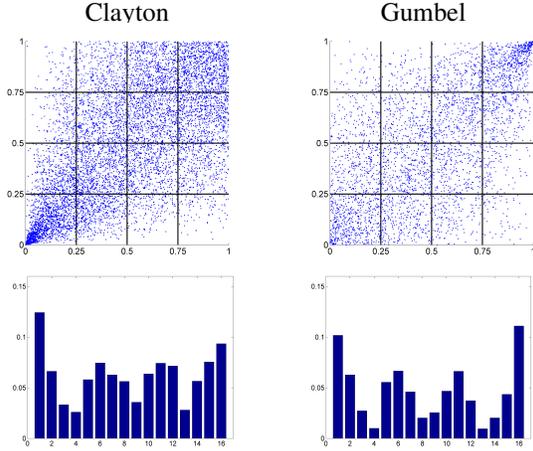

Figure 2: An example of the multinomial mapping for $\rho_s = 0.5$. **(top)** shows the distribution for the Clayton and Gumbel families, overlaid with a 4×4 grid. **(bottom)** shows the corresponding *multinomial signatures* defined by this grid for the two copula families.

Precomputing The Multinomial Signatures

We start by recalling the monotonic relationship, within a copula family, between Spearman’s ρ_s and the copula parameter. This allows us to use the notation C_{ρ_s} to refer to a particular instance of the copula family $C_{\theta(\rho_s)}$. To define the copula-to-multinomial mapping, for a copula family C_{ρ_s} , we partition the unit cube into N partitions $\{A_1, \dots, A_N\}$ and define a multinomial random variable X via

$$P_{C_{\rho_s}}(X = i) = \int_{A_i} c_{\rho_s}(u, v) du dv,$$

where c_{ρ_s} is the corresponding copula density. This mapping defines an N -valued multinomial representation of the copula which we denote by $\pi(c_{\rho_s})$. In principle, computing $P(X = i)$ requires integration. However, for copulas the cumulative distribution function is explicit and, if each A_i is chosen as a rectangular region, then $P(X = i)$ can be readily computed.

For simplicity, we use a generic partition into equal $K \times K$ squares is illustrated in Figure 2(top) for $K = 4$. Finally, since we map the copula to a crude coarsening as it is, in practice we compute the above only for $\rho_s \in \{-1, -0.95, \dots, 0.95, 1\}$, and use interpolation to define the mapping for intermediary values. This also ensures robustness to small fluctuations in the ρ_s estimate. We use $\pi(c_{\rho_s})$ to denote the resulting multinomial distribution.

Choosing A Copula Family

Given a set of M observations for two random variables X, Y , our task is now to compute the empirical multinomial signature and compare it to the template ones in order to choose the closest copula family. Let \mathcal{C} be the set of

candidate copula families from which we wish to choose the most appropriate copula. Omitting the explicit dependence on the data for readability, we use $\hat{\pi}$ and $\hat{\rho}_s$ to denote the empirical multinomial frequency over the $K \times K$ grid and the empirical Spearman’s ρ_s estimate, respectively. We choose the copula family \tilde{C} as the one that minimizes the distance between the empirical and template signatures.¹ That is:

$$\tilde{C} = \operatorname{argmin}_{C_{\rho}} d(\hat{\pi} \| \pi(c_{\hat{\rho}_s})), \quad (3)$$

where $d(\cdot \| \cdot)$ is a divergence measure between distributions. Several possible choices for this measure come to mind. The KL [Kullback and Leibler, 1951] distance is the divergence of choice between distributions, but can be sensitive to small probabilities which can occur in some of the multinomial grid cells. The L1-norm measure is less sensitive to outliers but does not measure relative deviation. In Section 5 we explore the theoretical properties of both choices, and in Section 7 we demonstrate their empirical merit.

4.2 LEARNING A TREE NETWORK

We now turn to our goal of learning the structure of a high-dimensional tree copula networks. Consider a tree structured model over N variables [Kirshner, 2007, Elidan, 2012] where the joint density can be written as

$$f_{\mathcal{X}}(x_1, \dots, x_n) = \prod_{(i,j) \in T} c_{ij}(F_i(x_i), F_j(x_k)) \prod_i f_i(x_i),$$

where c_{ij} is the copula associated with the edge (i, j) in the network. Learning the optimal tree structure can be easily carried out using a maximum spanning tree algorithm once the merit of each the $O(N^2)$ candidate edges has been computed. However, even if we have already made the choice of the copula family for each pair of variables, we still need to estimate the maximum likelihood parameters of the copula, and then compute the maximum likelihood score. That is, taking the log of the density, for each pair of variables in the network X_i and X_j , we need to compute

$$\text{Score}(i, j) \equiv \sum_{m=1}^M \log c_{\hat{\theta}}(F_{X_i}(x_i[m]), F_{X_j}(x_j[m])), \quad (4)$$

where the sum is over instances and $\hat{\theta}$ are the maximum likelihood parameters. As we report in Section 7, the overall computations for the entire network can be demanding.

To overcome this difficulty, we again note that the precise bivariate distribution, defined via $\hat{\theta}$, is a nuisance parameter. In fact, all that we need is a proxy to the above score that will reasonably *rank* candidate edges.² Recalling that

¹In the unlikely case that more than one copula minimizes this measure, we randomly choose between the minimizing copulas.

²We note that the ρ_s -based proxy of Elidan [2012] cannot be used since it assumes the same copula for all edges.

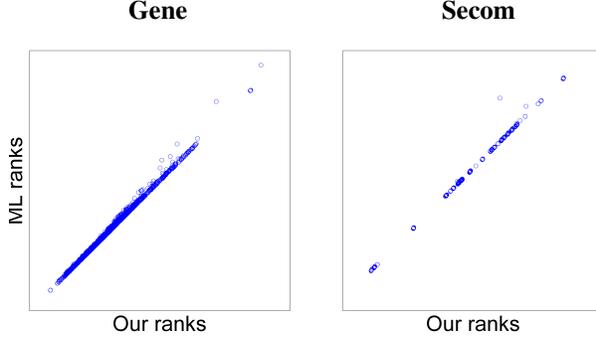

Figure 3: Edge score ranks using maximum likelihood (y-axis) vs. our multinomial proxy score (x-axis) for two of the real-life datasets used in Section 7.

our multinomial mapping roughly approximates the density, it is natural to use the implied multinomial likelihood as a proxy score. Concretely, using $C_{i,j}$ to denote the chosen copula for the variable pair X_i and X_j , instead of Eq. (4), we use

$$\text{Score}^{\text{Mult}}(i, j) = \sum_k \hat{\pi}_{i,j}[k] \log \pi(c_{i,j})[k], \quad (5)$$

where $\hat{\pi}_{i,j}$ is the empirical multinomial distribution induced by X_i and X_j .

To gauge the quality of this proxy score, Figure 3 compares the ranks of Eq. (5) and Eq. (4) for pairs of variables in two large datasets that we use in our experimental evaluation, **Gene** and **Secom** (see Section 7 for details). It is easy to see that our proxy score is near perfect for the purpose of ranking the benefit of candidate edges. Importantly, computation of $\hat{\pi}$ is linear in the (small) number of cells of the multinomial signature. Consequently, computation of our proxy score is significantly faster than the computation of the likelihood score. As we shall see in Section 7, this results in dramatic speedups of the learning procedure.

5 FINITE SAMPLE BOUNDS

Before describing how our approach can be extended to general structures, in this section we consider the theoretical properties of our building block copula selection method. Clearly, as K is increased in the multinomial mapping, we capture the density at an increasingly better granularity and, assuming continuity, asymptotic recovery follows from standard considerations. In fact, even for fixed small partitions such as $K = 4$, most standard copula families will disagree on some of the $K \times K$ multinomial bins, and asymptotic recovery can be easily guaranteed. We are more interested, however, in providing finite sample guarantees for our algorithm, both when using the Kullback-Leibler divergence and the L1-norm in Eq. (3). To the best of our knowledge ours are the first finite-sample bounds in the context of copula model selection.

We assume ρ_s is known (or has been measured) and omit it from the notation for clarity. Let \mathcal{C} be a finite copula family hypothesis class of cardinality $|\mathcal{C}| = L$ and let \mathcal{D} be a set of M i.i.d training instances sampled from $C^* \in \mathcal{C}$. Denote by $\hat{\pi}$ the empirical multinomial signature of \mathcal{D} and by $\tilde{\mathcal{C}}(\mathcal{D})$ the copula family chosen by our algorithm. The probability of mistakenly identifying the copula family is:

$$\mathbf{err}(\mathcal{D}) = P_{C^*}(\tilde{\mathcal{C}}(\mathcal{D}) \neq C^*),$$

where we use P_{C^*} as a shorthand for $P_{\mathcal{D} \sim C^*}$. We will now bound number of instances needed to ensure that the error is below a constant $\mathbf{err}(\mathcal{D}) \leq \alpha$.

5.1 KULLBACK-LEIBLER DIVERGENCE

Assume that the data was generated by a specific copula family $C_0 \in \mathcal{C}$. We will later allow C_0 to be any copula in \mathcal{C} . We start by observing that deciding between C_0 and some other $C_j \in \mathcal{C}$ based on the KL distance from $\hat{\pi}$ is equivalent to a hypothesis test:

$$\mathcal{H}_0 : \hat{\pi} \sim C_0 \quad \mathcal{H}_1 : \hat{\pi} \sim C_j,$$

where, using the likelihood ratio test, the rejection region is defined via $\lambda(C_0, C_1; \mathcal{D}) = \frac{P_{\pi(C_j)}(\mathcal{D})}{P_{\pi(C_0)}(\mathcal{D})} > 1$. Thus, classification error can be cast in terms of type I error, giving rise to a finite sample bound:

Lemma 5.1.: *Assume $\mathcal{D} \sim C_0$ or equivalently $\hat{\pi} \sim \pi(c_0)$. There exists a constant $\delta_0(j)$ such that for any $\alpha > 0$ and $C_j \in \mathcal{C}$, if $M \geq \log\left(\frac{1}{\alpha}\right) \frac{1}{\delta_0(j)}$ then*

$$P_{C_0}(d_{KL}(\hat{\pi} \parallel \pi(c_j)) \leq d_{KL}(\hat{\pi} \parallel \pi(c_0))) \leq \alpha$$

Proof: By Sanov's theorem [Cover and Thomas, 1991] we have that the type I error is $2^{-Md_{KL}(\pi_0 \parallel \pi(c_0))}$, where π_0 is the closest multinomial to $\pi(c_0)$ that is in the rejection region of the above test. π_0 is given explicitly by:

$$\pi_0[k] = \frac{\pi(c_0)[k]^\lambda \pi(c_j)[k]^{1-\lambda}}{\sum_{k'} \pi(c_0)[k']^\lambda \pi(c_j)[k']^{1-\lambda}}, \quad \lambda \in \mathbb{R},$$

where $[k]$ is the k 'th multinomial component, and λ is chosen so that $d_{KL}(\pi_0 \parallel \pi(c_0)) - d_{KL}(\pi_0 \parallel \pi(c_j)) = 0$. Taking $\delta_0(j)$ to be $d_{KL}(\hat{\pi} \parallel \pi(c_j))$ (see Cover and Thomas [1991] for details on how $\lambda, \delta_0(j)$ can be computed) we get the desired result. Note that π_0 does not depend on α . ■

Defining $\delta_0 = \min_{j \neq 0} \delta_0(j)$, we then have:

Corollary 5.2.: *Let $\mathcal{D} \sim C_0$. If $M \geq \log_2\left(\frac{L-1}{\alpha}\right) \frac{1}{\delta_0}$, then the classification error is bounded from above by α .*

Proof: Using the union bound we have:

$$\begin{aligned} P_{C_0}(\exists j : d(\hat{\pi} \parallel \pi(c_j)) \leq d(\hat{\pi} \parallel \pi(c_0))) \\ &\leq \sum_{C_j \in \mathcal{C}} P_{C_0}(d(\hat{\pi} \parallel \pi(c_j)) \leq d(\hat{\pi} \parallel \pi(c_0))) \\ &\leq \sum_{C_j \in \mathcal{C}, j \neq 0} \frac{\alpha}{L-1} = \alpha \end{aligned}$$

where, for compactness $d() \equiv d_{KL}()$. The second inequality follows from the above lemma by using $\alpha = \frac{\alpha}{L-1}$ so that $M \geq \log\left(\frac{L-1}{\alpha}\right) \frac{1}{\delta_0(j)}$ for all j . ■

Finally, we can drop the assumption that the specific generating copula family is known and, appealingly, get a bound that grows logarithmically with $\frac{1}{\alpha}$:

Theorem 5.3. : Define $\delta_C = \min_{i: C_i \in \mathcal{C}} \delta_i$. If $M \geq \log_2\left(\frac{L(L-1)}{\alpha}\right) \frac{1}{\delta_C}$ then the misclassification error is bounded from above by α .

5.2 L_1 DISTANCE

We now develop parallel bounds for the case of the L_1 -norm. Denote by $\pi(c_i)[k]$ the k -th component of the multinomial defined by C_i , and define $\delta_0(i)[k] = |\pi(c_0)[k] - \pi(c_i)[k]|$ for $C_0, C_i \in \mathcal{C}$.

Lemma 5.4.: Let $\mathcal{D} \sim C_0$, and let $\delta_0 = \min_{i \neq 0, k} \delta_0(i)[k]$. If the number of samples satisfies $M \geq \log\left(\frac{2(L-1)K^2}{\alpha}\right) \frac{1}{\delta_0^2}$, then the probability of a classification error is bounded from above by α .

Proof: For compactness define $\Delta_i[k] = |\hat{\pi}[k] - \pi(c_i)[k]|$. Then, since $\hat{\pi} \sim \pi(c_0)$, and using simple union bounds, the probability of misclassification is:

$$\begin{aligned} P_{C_0}\left(\exists i \neq 0 : \sum_k \Delta_i[k] \leq \sum_k \Delta_0[k]\right) \\ \leq \sum_{i \neq 0} P_{C_0}\left(\sum_k \Delta_i[k] \leq \sum_k \Delta_0[k]\right) \\ \leq \sum_{i \neq 0, k} P_{C_0}(\Delta_i[k] \leq \Delta_0[k]) \end{aligned}$$

Next, by definition $\Delta_i[k] \leq \Delta_0[k] \Leftrightarrow \Delta_0[k] \geq \delta_0(i)[k]$. Also, since $\mathcal{D} \sim C_0$, we have $E(\hat{\pi}[k]) = \pi(c_0)[k]$. Using Hoeffding's inequality we then have:

$$\begin{aligned} P_{C_0}\left(\Delta_i[k] \leq \Delta_0[k]\right) &= P_{C_0}\left(\Delta_0[k] \geq \delta_0(i)[k]\right) \\ &\leq 2e^{-2M\delta_0^2}. \end{aligned}$$

If we now choose the number of samples to be $M \geq \log\left(\frac{2(L-1)K^2}{\alpha}\right) \frac{1}{\delta_0^2}$, the result easily follows. ■

Now, using a similar argument to the KL case, we have

Theorem 5.5. : Define $\delta_C = \min_i \delta_i$. For all α , if $M \geq \log_2\left(\frac{L(L-1)K^2}{\alpha}\right) \frac{1}{\delta_C^2}$, then the misclassification error is bounded from above by α .

As an example consider sample data that is distributed according to AMH copula with Spearman's rho equals 0.6. Assuming the copula hypothesis class consists of AMH, Clayton, Gumbel and Plackett copulas. Then using $k = 2$, it is easily verified that $\delta_0 = 0.0713$. Thus, according to 5.4, in order to bound the classification error by $\alpha = 0.05$, at least 1217 samples are needed.

6 LEARNING GENERAL NETWORKS

We now show how our structure learning approach of Section 4 can be adapted to the more elaborate task of learning a copula graphical model with a general structure. As is commonly done, due to the super-exponential nature of the search space, we learn the structure via a greedy search procedure that involves local modifications to the structure (e.g., add/delete/reverse an edge). Similarly to the case of trees, we start by generalizing the local copula selection building block and then explain how this can be used when learning a global structure.

6.1 CHOOSING THE COPULA

Recall that in order to choose a copula family in the bivariate case, we first evaluate the empirical measure of association $\hat{\rho}_s$, as well as the bivariate statistics of the data, and then choose the copula family signature that is closest to the empirical distribution for $\hat{\rho}_s$. In a nutshell, we will choose a copula family for more than two variables by aggregating bivariate distances.

Before doing so, however, we need to evaluate $\hat{\rho}$. For the Gaussian copula, our path is obvious since each bivariate marginal is characterized by its own dependence parameters $\Sigma_{i,j}$, and the corresponding measure of association $\hat{\rho}_{i,j}$ can be computed as before. However, the situation is quite different for other copula families. For example, all bivariate marginals of an n -dimensional Archimedean copula have the *same* dependence parameter so that we require $\hat{\rho}_{i,j} = \hat{\rho}$ for all i, j . Thus, a natural choice in the common case of a *one parameter* family is to estimate $\hat{\rho}$ using

$$\hat{\rho} = \sum_{X_i, X_j, i < j} \binom{n}{2}^{-1} \hat{\rho}_{X_i, X_j}.$$

Note that this is one of the standard generalizations of Spearman's rho [Schmid and Schmidt, 2007]. Then, with $\hat{\rho}_{i,j} = \hat{\rho}$ in hand, we select the copula family that minimizes the sum of distances between the empirical and template multinomials signatures, similarly to Eq. (3):

$$\tilde{C} = \operatorname{argmin}_{C_{\hat{\rho}}} \sum_{X_i, X_j, i < j} d(\hat{\pi} \| \pi(c_{\hat{\rho}_{i,j}})).$$

6.2 EVALUATING THE STRUCTURE SCORE

As in bivariate case, after choosing the copula family, we still face the challenge of comparing the benefit of different candidate structural changes. Concretely, using Eq. (2), we we need to evaluate the conditional likelihood score:

$$\begin{aligned} \operatorname{Score}(i, \mathbf{Pa}_i) &\equiv \\ &\sum_{m=1}^M \log \frac{c_{\hat{\theta}}(F_i(x_i[m]), \{F_j(x_j[m])\}_{j \in \mathbf{Pa}_i})}{c_{\theta}(\{F_j(x_j[m])\}_{j \in \mathbf{Pa}_i})}, \end{aligned}$$

Costly ML

Figure 4: Copula family selection performance for synthetically generated data with 1000 samples. Methods compared are our HELM, that of Huard [Huard et al., 2006], and time consuming ML estimation. Each confusion matrix shows the percentage of the predicted family (columns) given the generating family (rows).

where $\hat{\theta}$ are the maximum likelihood parameters of the copula associated with X_i and its parents.

Once again, we face the bottleneck of maximum likelihood estimation. Whenever an analytically simple relationship between $\hat{\rho}$ (or Kendall’s τ) and $\hat{\theta}$ exists, we use the heuristic proposed by [P.Embrecchts and M.Hofert, 2010] and simply invert the average association measure described above. For other copula families (e.g. Ali-Mikhail), we resort to a standard optimization procedure such as conjugate gradient. Note that even in this case, we perform costly estimation *only* for the chosen copula family, and are thus still significantly more efficient than a full maximum likelihood selection and estimation procedure.

6.3 ADJUSTING THE SCALE OF THE SCORE

To learn a structure that allows for several parents for each variable, all family scores must obviously lie on the same scale. However, the proxy score we use in the case of a single parent is based on a discrete multinomial likelihood (Eq. (5)), while for multiple parents we use a real-valued conditional likelihood (Eq. (6)). Thus, to rank candidate structural changes, we must somehow calibrate these scores relative to each other.

Fortunately, as is clearly evident in Figure 3, our single parent *proxy* scores are almost linearly correlated to the *exact* maximum likelihood scores. Consequently, all that is required in order to accurately approximate the needed scores is to recover this linear transformation via straightforward regression. Concretely, we randomly choose few (e.g. 10%) of the variables pairs, and solve the following regression problem:

$$\hat{\beta} = \operatorname{argmin}_{\beta} \sum_{i,j} (\operatorname{Score}(i,j) - \beta_0 - \beta_1 \operatorname{Score}^{\text{Mult}}(i,j))^2$$

We then use $\hat{\beta}$ to calibrate our bivariate scores:

$$\widetilde{\operatorname{Score}}(i,j) = \beta_0 + \beta_1 \cdot \operatorname{Score}^{\text{Mult}}(i,j).$$

To summarize: starting with the empty graph G_{\emptyset} , we rank

the different $O(N^2)$ candidate edges using our multinomial approximation score. Next, we calibrate these scores using the regression coefficients β . These calibrated score are then used together with the multi-parent scores to guide the greedy structure learning procedure.

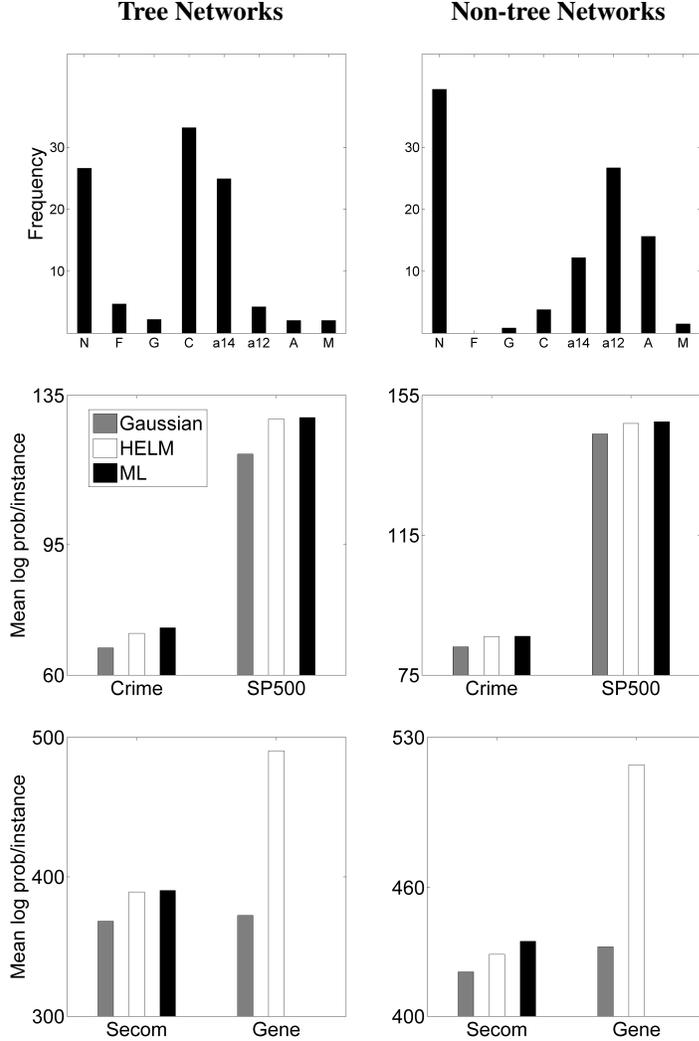

7 EXPERIMENTAL EVALUATION

We now evaluate the ability of our **HELM** approach to efficiently learn expressive copula networks that generalize well. We start by evaluating the merit of the **HELM** model selection building block in the case where the generating distribution is known. We then demonstrate the power of **HELM** when learning high-dimensional structures for sizeable real-life domains.

7.1 COPULA MODEL SELECTION

To evaluate our **HELM** copula model selection building block, we synthetically generate i.i.d. instances from different copula families and attempt to identify the generating family from the samples. We compare our **HELM** approach to the standard maximum likelihood (**ML**) approach (using an inversion of the empirical Kendall tau or Spearman’s rho for fast estimation where possible), and to a Bayesian approach from the copula community suggested by **Huard** [Huard et al., 2006].

Similarly to Huard et al. [2006], we consider a collection of copula families that exhibit varied dependence patterns: Normal (**N**), Frank (**F**), Gumbel (**G**), Clayton (**C**), Ali-Mikhail-Haq (**A**), and Farlie-Gumbel-Morgenstern (**M**) (see [Joe, 1997, Nelsen, 2007] for details of these copulas). For each family, we precompute its multinomial signature as described in Section 4. To cover a wide range of dependence levels, we generate the synthetic data as follows: for values of Spearman’s ρ_s ranging from 0.25 to 0.95, we randomly choose a copula family C , and generate $M = 1000$ i.i.d samples from C_{ρ_s} . We repeat this 1000 times for each value of ρ_s and use the different methods to predict the generating copula family.

Tree Networks

Figure 5: Comparison of copula networks learned using the different methods for tree and non-tree networks. **(left top)** shows the distribution of the chosen copula families when learning using standard maximum likelihood (**ML**) for the **Secom** dataset. **(left middle/bottom)** summarizes the average test log-probability per instance performance of our method (white bars), **ML** (black bars) and the Gaussian copula baseline (gray bar). **(right)** detailed generalization performance along with standard deviation across random folds (in parentheses) and speedup factor of our method relative to **ML**.

In Figure 4 we report average results in the form of confusion matrices that show the distribution of the predicted copula family (columns) for each generating copula family (rows). Results for our approach are with $K = 8$ and using KL (results were qualitatively similar using $K = 4$ and the L_1 distance). As can be seen, **HELM** surpasses **Huard** on average and is not far beyond the much slower **ML**. This is to be expected since we intentionally took a crude but efficient view of the distribution, a crucial step toward the goal of performing global structure learning.

The above competitiveness comes with substantial computational advantages. A single model selection task when using **ML** took 1.08×10^{-2} seconds on average. Using **HELM** this took only 1.1545×10^{-4} seconds on average,

a two orders of magnitude speedup. Advantages are even greater for $K = 4$ since **HELM** is quadratic in K . In this case, **HELM** is close to 200 faster than **ML**, while suffering negligible decrease in predictive performance. Finally, while **Huard** does reasonably well in terms of predictive performance, this comes at an enormous computational cost, taking an average of 0.28 seconds, or 4 orders of magnitude slower than **HELM**.

7.2 LEARNING EXPRESSIVE NETWORKS

We now evaluate the merit of **HELM** for learning expressive copula networks for real-life domains that benefit from a rich mix of local representations. We consider four real-

life datasets that are quite sizable in the context of structure learning of non-Gaussian real-valued models:

- **Crime** (UCI repository). 1994 instances of **100** census variables ranging from household size to fraction of children born out of marriage, for 1994 U.S. communities.
- **Secom** (UCI repository). 1567 instances of **362** variables collected from sensors during a semi-conductor manufacturing process, corresponding to key factors that effect downstream yield.
- **SP500**. End of day changes of the **500** Standard and Poor’s index stocks (variables) over a period of close to 2000 trading days (samples).
- **Gene**. A compendium of gene expression. We focus on **999** genes (variables) that have at most one missing experiment, resulting in 2000 samples.

For each domain, we learn a copula network model using **HELM** as well as using standard maximum likelihood (using fast inversion of ρ_s or τ_K where possible). In both cases, we allow for a mix of Gaussian, Frank, Gumbel, Clayton, arch12, arch14, Ali-Mikhail and FGM copulas. To make comparison to the costly **ML** feasible, we learn networks with up to two parents. For the univariate marginals for both methods, we use a standard kernel-based approach [Parzen, 1962] with the common Gaussian kernel (see, for example, [Bowman and Azzalini, 1997] for details). As an additional baseline, we also consider learning only with a Gaussian copula, which is the strongest of all single family baselines. Finally, we note that due to its significant computational demands, the Bayesian method of **Huard** could not be used in these experiments.

We start by qualitatively demonstrating the real-life need for expressive modeling, or for the combination of different local representations within the same model. As an example Figure 5(left top) shows the distribution of the copula families chosen when learning a mixed model using the **ML** method for the **Secom** dataset. Obviously, the learned model is a rich one.

Quantitatively, Figure 5(left middle/bottom) shows that a mixed **ML** model (black bar) also leads to better generalization relative to the best single family baseline (gray bar) in terms of test set log-probability per instance. Also shown is the performance of **HELM** (white bar). As can be seen, **HELM** is competitive with the costly **ML** method. The table on the right includes the average test performance results along with standard deviations (in parentheses) across 10 folds. Importantly, note that the improvement over the single family baseline is significant since the scale of improvement is in bits per instances. Thus, an improvement of, for example, 10 bits per instance is equivalent to each test instance being on average 2^{10} more likely.

Recall that our goal was not simply to learn competitive expressive networks but to do so highly efficiently so as to facilitate scaling up of structure learning. Speed up factors of **HELM** relative to **ML** are reported in the right-hand column of the tables in Figure 5. As can be seen, the runtime improvements are dramatic at over two orders of magnitudes when learning tree networks. To make these numbers concrete, for example, using **HELM** to learn a mixed tree for the **SP500** domain took less than a minute, while for **ML** the average runtime was nearly 5 hours. For the **Gene** data set with 1000 variables, although learning a mixed network with **HELM** took only around 4.5 minutes, **ML** did not terminate after two days. A substantial runtime improvement is also evident for more general structures. For example, learning using **HELM** took around an hour and a half for **SP500**, while learning using **ML** took over three days. Dramatically, although **HELM** was able to learn a mixed **Gene** network model in less than two hours, learning a model for this domain using **ML** proved impractical, and did not terminate within a week.

8 SUMMARY

We presented **HELM**, an algorithm for efficiently learning copula networks that allows for a rich mix of varied copula families within the *same* model. We demonstrated the substantial computational advantages of using our multinomial signature based approach when learning complex models for several varied sizeable real-life domains.

Our contribution is three fold. First, we presented a straightforward but powerful copula model selection building block that, even in the simple bivariate case, is competitive with maximum likelihood and other estimation approaches while offering dramatic runtime improvements. We further derive finite-sample guarantees for this building block. To the best of our knowledge, these are the first such guarantees in the context of copula model selection.

Second, we showed how our building block gives rise accurate and efficient *ranking* of candidate structures, resulting in highly efficient global structure learning. Third, the computational advantages allows us to scale up structure learning and easily cope with domains that are prohibitive if tackled using standard procedures. Indeed, to the best of our knowledge, ours is the first structure learning method that allows for a mix of local real-valued representations and that has been applied to domains of this size.

Abstract

We investigate the geometrical structure of probabilistic generative dimensionality reduction models using the tools of Riemannian geometry. We explicitly define a distribution over the natural metric given by the models. We provide the necessary algorithms to compute expected metric tensors where the distribution over mappings is given by a Gaussian process. We treat the corresponding latent variable model as a Riemannian manifold and we use the expectation of the metric under the Gaussian process prior to define interpolating paths and measure distance between latent points. We show how distances that respect the expected metric lead to more appropriate generation of new data.

1 MOTIVATION

One way of representing a high dimensional data set is to relate it to a lower dimensional set of *latent variables* through a set of (potentially nonlinear) functions. If the i th data point and the j th feature is represented by $y_{i,j}$, it might be related to a q dimensional vector of latent variables $\mathbf{x}_{i,:}$ as

$$y_{i,j} = f_j(\mathbf{x}_{i,:}) + \epsilon_i,$$

where $f_j(\cdot)$ is a nonlinear function mapping to the j th feature of the data set and ϵ_i is a noise corruption of the underlying function. A manifold derived from a finite data set can never be precisely determined across the entire input range of \mathbf{x} . We consider posterior distributions defined over $f_j(\cdot)$ and we focus on the uncertainty defined over the local metric of the manifold itself. This allows us to define distances that are based on metrics that take account of the uncertainty with which the manifold is defined. We use these metrics to define distances between points in the latent space that respect these metrics.

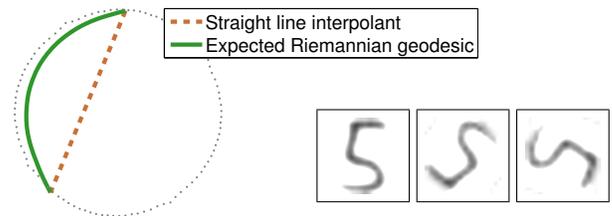

Figure 1: The latent space from a GP-LVM that was trained over a dataset of artificially rotated digits. Black dots represent the latent points. The dashed brown line show the commonly used straight-line interpolant, and the green curve is the suggested expected Riemannian geodesic. This figure is best viewed in colour.

When the mappings $f_j(\cdot)$ are nonlinear, the latent variable model (LVM) can potentially capture non-linearities on the data and thereby provide an even lower dimensional representation as well as a more useful view of the data. While this line of thinking is popular, it is not without its practical issues. As an illustrative example, Fig. 1 shows the latent representation of a set of artificially rotated images obtained through a Gaussian process latent variable model (GP-LVM). It is clear from the display that the latent representation captures the underlying periodic structure of the process which generated the data (a rotation). If we want to analyse the data in the latent space, e.g. by interpolating latent points, our current tools are insufficient. As can be seen, fitting a straight line in the latent space between the two-points leads to a solution that does not interpolate well in the data space: the interpolant goes through regions where the data does not reside, regions where the actual functions, $f_j(\cdot)$, cannot be well determined.

This observation raises several related questions about the choice of interpolant: 1) what is the natural choice of interpolant in the latent space? And, 2) if the natural interpolant is not a straight line, are Euclidean distances still meaningful? We answer these questions for the GP-LVM, though our approach is applicable to other generative models as

well. We consider here a metric which reflects the intrinsic properties of the original data and recovers some information loss due to the nonlinear mapping performed by the model. We find that for smooth LVMs the metric from the observation space can be brought back to the latent space in the form of a random Riemannian metric. We then provide algorithms for computing distances and shortest paths (geodesics) under the expected Riemannian metric. With this the natural interpolant becomes a curve, which follows the trend of the data.

Overview In Section 2 we introduce the concepts of Riemannian geometry, the tool on which we rely on later on in the paper. Section 3 provides an overview of the state of the art in probabilistic dimensionality reduction, introducing the class of models to which the proposed methodology can be extended. In Section 4 we use the probabilistic nature of the generative LVMs to explicitly provide distributions over the metric tensor; first, we provide the general expressions, then we specialise these to the GP-LVM as an example. Finally, we show how to compute shortest paths (geodesics) over the latent space. Experimental results are provided in Section 5, and the paper is concluded with a discussion in Section 6.

2 CONCEPTS OF RIEMANNIAN GEOMETRY

We study latent variable models (LVMs) as embeddings of uncertain surfaces (or manifolds) into the observation space. From a machine learning point of view, we can interpret this embedded manifold as the underlying support of the data distribution. To this end, we review the basic ideas of differential geometry, which study surfaces through local linear models.

Gauss' study [1827] of curved surfaces are among the first examples of (deterministic) LVMs. He noted that a q -dimensional surface embedded in a p -dimensional Euclidean space¹ is well-described through a mapping $f : \mathbb{R}^q \rightarrow \mathbb{R}^p$. The q -dimensional representation of the surface is known as the *chart* (in machine learning terminology, this corresponds to the *latent space*). In general, the mapping f between the chart and the embedding space is not *isometric*, e.g. the Euclidean length of a straight line l in the chart does not match the length of the embedded curve $f(l)$ as measured in the embedding space. Intuitively, the chart provides a distorted view of the surface (see Fig. 2 for an illustration). To rectify this view, Gauss noted that the

¹Historically, Gauss considered the case of two-dimensional surfaces embedded in \mathbb{R}^3 , while the extension to higher dimensional *manifolds* is due to Bernhard Riemann.

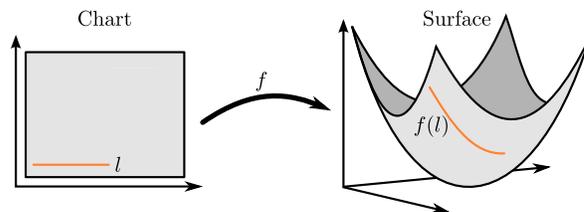

Figure 2: An illustration of the standard surface model; f maps the chart into the embedding space.

length of a curve is

$$\text{Length}(f(l)) = \int_0^1 \left\| \frac{\partial f(l(t))}{\partial t} \right\| dt = \int_0^1 \left\| \mathbf{J} \frac{\partial l(t)}{\partial t} \right\| dt, \quad (1)$$

where \mathbf{J} denotes the Jacobian of f , i.e.

$$[\mathbf{J}]_{i,j} = \frac{\partial f_i}{\partial l_j}. \quad (2)$$

Measurements on the surface can, thus, be computed in the chart locally, and integrated to provide global measures. This gives rise to the definition of a *local* inner product, known as a *Riemannian metric*.

Definition (Riemannian Metric). A Riemannian metric \mathbf{G} on a manifold \mathcal{M} is symmetric and positive definite matrix which defines a smoothly varying inner product

$$\langle \mathbf{a}, \mathbf{b} \rangle_x = \mathbf{a}^\top \mathbf{J}^\top \mathbf{J} \mathbf{b} = \mathbf{a}^\top \mathbf{G}(x) \mathbf{b} \quad (3)$$

in the tangent space $T_x \mathcal{M}$, for each point $x \in \mathcal{M}$ and $\mathbf{a}, \mathbf{b} \in T_x \mathcal{M}$. The matrix \mathbf{G} is called the *metric tensor*.

Remark The Riemannian metric need not be restricted to $\mathbf{G} = \mathbf{J}^\top \mathbf{J}$ and can be any smoothly changing symmetric positive definite matrix [do Carmo, 1992]. We restrict ourselves to the more simple definition as it suffices for our purposes, but note that the more general approach has been used in machine learning, e.g. in *metric learning* [Haugberg et al., 2012] and *information geometry* [Amari and Nagaoka, 2000].

From this definition, Eq. 1 reduces to

$$\text{Length}(\gamma) = \int_0^1 \sqrt{\langle \gamma'(t), \gamma'(t) \rangle_{\gamma(t)}} dt \quad (4)$$

for a general curve $\gamma : [0, 1] \rightarrow \mathbb{R}^p$.

Definition (Geodesic curve). Given two points $\mathbf{x}_1, \mathbf{x}_2 \in \mathcal{M}$, a *geodesic* is a length-minimising curve connecting the points

$$\gamma_g = \arg \min_{\gamma} \text{Length}(\gamma), \quad \gamma(0) = \mathbf{x}_1, \gamma(1) = \mathbf{x}_2. \quad (5)$$

It can be shown [do Carmo, 1992] that geodesics satisfy the following second order ordinary differential equation

$$\gamma'' = -\frac{1}{2}\mathbf{G}^{-1}\left[\frac{\partial \text{vec } \mathbf{G}}{\partial \gamma}\right]^\top (\gamma' \otimes \gamma'), \quad (6)$$

where $\text{vec } \mathbf{G}$ stacks the columns of \mathbf{G} and \otimes denotes the Kronecker product. The Picard-Lindelöf theorem [Tenenbaum and Pollard, 1963] then implies that geodesics exist and are locally unique given a starting point and an initial velocity.

3 PROBABILISTIC DIMENSIONALITY REDUCTION

Nonlinear dimensionality reduction methods [Lee and Verleysen, 2007] provide a flexible data representation which can provide a more faithful model of the observed multivariate datasets than the linear ones. One approach is to perform probabilistic nonlinear dimensionality reduction defining a model that introduces a set of unobserved (or latent) variables \mathbf{X} that can be related to the observed ones \mathbf{Y} in order to define a joint distribution over both. These models are known as latent variable models (LVMs). The latent space is dominated by a prior distribution $p(\mathbf{X})$ which induces a distribution over \mathbf{Y} under the assumption of a probabilistic mapping

$$y_{i,j} = f_j(\mathbf{x}_i) + \epsilon_i, \quad (7)$$

where \mathbf{x}_i is the latent point associated with the i^{th} observation \mathbf{y}_i , j is the index of the features of \mathbf{Y} , and ϵ_i is a noise term, accounts for both noise in the data as well as for inaccuracies in the model. The noise is typically chosen as Gaussian distributed $\epsilon \sim \mathcal{N}(0, \beta^{-1})$, where β is the precision.

One of the advantages of this approach is that it accommodates dimensionality reduction in an intuitive manner, if we assume that the dimensionality of the latent space is significantly lower than that of the observation space. In this case, the reduced dimensionality provides us with both implicit regularisation and a low-dimensional representation of the data, which can be used for visualisation (and, therefore, for data exploration [Vellido et al., 2011]) if the dimension is low enough.

If the mapping $f = W$ is taken to be linear:

$$y_{i,j} = \mathbf{w}_j^\top \mathbf{x}_i + \epsilon_i, \quad (8)$$

and the prior $p(\mathbf{X})$ to be Gaussian, this model is known as probabilistic principal component analysis [Tipping and Bishop, 1999]. The conditional probability of the data given the latent space can be written as

$$p(\mathbf{y}_i | \mathbf{x}_i, \mathbf{W}, \beta) = \mathcal{N}(\mathbf{y}_i | \mathbf{W}\mathbf{x}_i, \beta^{-1}\mathbf{I}). \quad (9)$$

With a further assumption of independence across data points, the marginal likelihood of the data is

$$p(\mathbf{Y}) = \int \prod_{i=1}^N p(\mathbf{y}_i | \mathbf{x}_i, \mathbf{W}, \beta) p(\mathbf{x}_i) d\mathbf{X}. \quad (10)$$

In general, this approach can be applied to both linear and nonlinear dimensionality reduction models, leading to the definition of, for instance, Factor Analysis [Bartholomew, 1987], Generative Topographic Mapping (GTM) [Bishop et al., 1998], or Gaussian Process-LVM (GP-LVM) [Lawrence, 2005] to name a few.

One example that generalises from the linear case to the nonlinear one is the GTM, in which the noise model is taken to be a linear combinations of a set of M basis functions

$$y_{i,j} = \sum_{m=1}^M \mathbf{w}_j^\top \phi_m(\mathbf{x}_i) + \epsilon_i. \quad (11)$$

This model can be seen as a mixture of distributions (usually Gaussian radial basis distributions) whose centres are constrained to lay on an intrinsically low-dimensional space. These centres can be interpreted as data prototypes or cluster centroids that can be further agglomerated in a full blown clustering procedure. In this manner, GTM mixes the functionalities of Self-Organising Maps and mixture models by providing both data visualisation over the latent space and data clustering [Olier and Vellido, 2008]. If the prior over the latent space is chosen to be Gaussian, this model leads, in a similar way of probabilistic PCA, to a Gaussian conditional distribution of the data

$$p(\mathbf{y}_i | \mathbf{x}_i, \mathbf{W}, \beta) = \mathcal{N}\left(\mathbf{y}_i \left| \sum_{m=1}^M \mathbf{w}_j^\top \phi_m(\mathbf{x}_i), \beta^{-1}\mathbf{I} \right.\right). \quad (12)$$

In the classic approach the latent variables are marginalised and the parameters are optimised by maximising the model likelihood. An alternative (and equivalent) approach proposes to marginalise the parameters and optimise the latent variables, leading to Gaussian Process Latent Variables Model (GP-LVM).

In terms of applications, Grochow et al. [2004] animate human poses using *style-based inverse kinematics* based on a GP-LVM model. The animation is performed under a prior towards small Euclidean motions in the latent space, i.e. under the same assumptions as those leading to a straight-line interpolant. As the Euclidean metric does not match that of the observation space, this prior is difficult to interpret. In a related application, Urtasun et al. [2005] track the pose of a person in a video sequence with a similar prior and, hence, similar considerations hold. Recently, Gonczarek and Tomczak [2014] track human poses in images under a Brownian motion prior in the latent space. Again, this relies on a meaningful metric in the latent space.

In all of the above application, it is beneficial if the metric in the latent space is related to that of the observation metric.

4 METRICS FOR PROBABILISTIC LVMs

The common approach to estimate local metrics rely on assumptions over the neighbourhoods defined in the observed space (see e.g. [Hastie and Tibshirani, 1996, Ramanan and Baker, 2011]). This might be less efficient in presence of high dimensional noise, because the induced distances may not be reliable. One way to deal with this problem is to define a noise model (7) and to assume a global belief over the geometry of the data. This way, the resulting models have the advantage of providing an intrinsic local metric which is able to deal with noise.

In this paper we only consider smooth generative models for manifold learning. This contrasts with prior approaches such as [Bregler and Omohundro, 1994, Tenenbaum, 1997, Tenenbaum et al., 2000] that use metrics which vary discretely across the space (see also [Lawrence, 2012] for relations to Gaussian models).

We define here the local metric tensor for generative LVMs. We then illustrate the specific case of GP-LVM, providing an algorithm to compute shortest path.

4.1 THE DISTRIBUTION OF THE NATURAL METRIC

When the mapping f in Eq. 7 is differentiable, it can be interpreted as the mapping between the *chart* (or *latent space*) and the embedding space (c.f. Section 2). Then it is possible to explicitly compute the natural Riemannian metric of the given model.

Let \mathbf{J} be the Jacobian (as in Eq. 2), then the tensor

$$\mathbf{G} = \mathbf{J}^\top \mathbf{J}$$

defines a local inner product structure over the latent space according to Eq. 3.

In the case of LVMs where the conditional probability over the Jacobian follow a Gaussian distribution, this naturally induces a distribution over the local metric tensor \mathbf{G} . Assuming independent rows of \mathbf{J}

$$p(\mathbf{J} | \mathbf{X}, \mathbf{f}, \beta) = \prod_{j=1}^p \mathcal{N}(\boldsymbol{\mu}_{J(j,:)}, \boldsymbol{\Sigma}_J), \quad (13)$$

the resulting random variable follow a non-central Wishart distribution [Anderson, 1946]:

$$\mathbf{G} = \mathcal{W}_q(p, \boldsymbol{\Sigma}_J, \mathbb{E}[\mathbf{J}^\top] \mathbb{E}[\mathbf{J}]), \quad (14)$$

where p represents the number of degrees of freedom; the quantity $\boldsymbol{\Sigma}_J^{-1} \mathbb{E}[\mathbf{J}^\top] \mathbb{E}[\mathbf{J}]$ is know as the non-centrality ma-

trix and it is equal to zero in the central Wishart distribution. The Wishart distribution is a multivariate generalisation of the Gamma distribution.

4.2 GP-LVM LOCAL METRIC

A Gaussian Process (GP) is used to describe distributions over functions and it is defined as a collection of random variables, any finite number of which have a joint Gaussian distribution [Rasmussen and Williams, 2006]. Given a vector $\mathbf{x} \in \mathbb{R}^q$, a GP determined by its mean function and its covariance function is denoted $f(\mathbf{x}) \sim \mathcal{GP}(m(\mathbf{x}), k(\mathbf{x}, \mathbf{x}'))$. From this, it is possible to generate a random vector \mathbf{f} which is Gaussian distributed with covariance matrix given by $(\mathbf{K})_{i,j} = k(\mathbf{x}_i, \mathbf{x}_j)$.

Gaussian Processes have been used in probabilistic nonlinear dimensionality reduction to define a prior distribution over the mapping f (in Eq. 7), leading to the formulation of GP-LVM. This way, the likelihood of the data \mathbf{Y} given \mathbf{X} is computed by marginalising the mapping and optimising the latent variables:

$$p(\mathbf{Y} | \mathbf{X}, \mathbf{f}, \beta) = \prod_{j=1}^p \mathcal{N}(\mathbf{y}_{:,j}, \mathbf{K} + \beta^{-1} \mathbf{I}) = \prod_{j=1}^p \mathcal{N}(\mathbf{y}_{:,j}, \tilde{\mathbf{K}}). \quad (15)$$

To follow the notation introduced in Section 3, the noise model is defined by

$$y_{i,j} = \mathbf{K}_{(\mathbf{x}_i, \mathbf{x})} \mathbf{K} \mathbf{Y}_{:,j} + \epsilon_i, \quad (16)$$

Due to the linear nature of the differential operator, the derivative of a Gaussian process is again a Gaussian process ([Rasmussen and Williams, 2006] §9.4), as long as the covariance function is differentiable. This property allows inference and predictions about derivatives of a Gaussian Process, therefore the Jacobian \mathbf{J} of the GP-LVM mapping can be computed over continuum for every latent point \mathbf{x}_* and we denote with $\frac{\partial \mathbf{y}_*}{\partial x^{(i)}}$ the partial derivative of $\mathbf{y}(x_*)$ with respect to the i^{th} component in the latent space. We call $\mathbf{J}^\top = \frac{\partial \mathbf{y}_*}{\partial \mathbf{x}} = \left[\frac{\partial \mathbf{y}_*}{\partial x^{(1)}}; \dots; \frac{\partial \mathbf{y}_*}{\partial x^{(q)}} \right]$, where $\frac{\partial \mathbf{y}_*}{\partial \mathbf{x}}$ is a $q \times p$ matrix whose columns are multivariate normal distributions. We now consider the jointly Gaussian random variables

$$\left[\begin{array}{c} \mathbf{Y} \\ \frac{\partial \mathbf{y}_*}{\partial \mathbf{x}} \end{array} \right] \sim \mathcal{N} \left(\mathbf{0}, \left[\begin{array}{cc} \tilde{\mathbf{K}}_{\mathbf{x}, \mathbf{x}} & \partial \tilde{\mathbf{K}}_{\mathbf{x}, *} \\ \partial \tilde{\mathbf{K}}_{\mathbf{x}, *}^\top & \partial^2 \tilde{\mathbf{K}}_{*, *} \end{array} \right] \right), \quad (17)$$

where $\partial \mathbf{K}_{*, \mathbf{x}}, \partial^2 \mathbf{K}_{*, *}$ are a matrices given by

$$(\partial \mathbf{K}_{*, *})_{n,l} = \frac{\partial k(\mathbf{x}_n, \mathbf{x}_*)}{\partial x^{(l)}}, \quad n = 1, \dots, N, \quad l = 1, \dots, q \quad (18)$$

$$(\partial^2 \mathbf{K}_{*, *})_{i,l} = \frac{\partial^2 k(\mathbf{x}_*, \mathbf{x}_*)}{\partial x^{(i)} \partial x^{(l)}}. \quad i = 1, \dots, q, \quad l = 1, \dots, q \quad (19)$$

The GP-LVM model provides an explicit mapping from the latent space to the observed space. This mapping defines

the support of the observed data \mathbf{Y} as a q dimensional manifold embedded into \mathbb{R}^p . If the covariance function of the model is continuous and differentiable, the Jacobian of the GP-LVM mapping is well-defined and the natural metric follows Eq. 14.

It follows from Eq. 17 and the properties of the GPs that the distribution of the Jacobian of the GP-LVM mapping is the product of p independent Gaussian distributions (one for each dimension of the dataset) with mean $\boldsymbol{\mu}_{J(j,:)}$ and covariance $\boldsymbol{\Sigma}_J$. For a every latent point \mathbf{x}_* the Jacobian takes the following form:

$$p(\mathbf{J} \mid \mathbf{Y}, \mathbf{X}, \mathbf{x}_*) = \prod_{j=1}^p \mathcal{N}(\boldsymbol{\mu}_{J(j,:)}, \boldsymbol{\Sigma}_J) \quad (20)$$

$$= \prod_{j=1}^p \mathcal{N}(\partial \mathbf{K}_{\mathbf{x}_*,*}^\top \tilde{\mathbf{K}}_{\mathbf{x}_*,\mathbf{x}}^{-1} \mathbf{Y}_{:,j}, \partial^2 \mathbf{K}_{*,*} - \partial \mathbf{K}_{\mathbf{x}_*,*}^\top \tilde{\mathbf{K}}_{\mathbf{x}_*,\mathbf{x}}^{-1} \partial \mathbf{K}_{\mathbf{x}_*,*}),$$

which (c.f. Eq. 14) gives a distribution over the metric tensor \mathbf{G}

$$\mathbf{G} = \mathcal{W}_q(p, \boldsymbol{\Sigma}_J, \mathbb{E}[\mathbf{J}^\top] \mathbb{E}[\mathbf{J}]). \quad (21)$$

From this distribution, the expected metric tensor can be computed as

$$\mathbb{E}[\mathbf{J}^\top \mathbf{J}] = \mathbb{E}[\mathbf{J}^\top] \mathbb{E}[\mathbf{J}] + p \boldsymbol{\Sigma}_J. \quad (22)$$

Note that the expectation of the metric tensor includes a covariance term. This implies that the metric tensor expands as the uncertainty over the mapping increases. Hence, curve lengths also increases when going through uncertain regions, and as a consequence geodesics will tend to avoid these regions.

The metric tensor defines the local geometric properties of the GP-LVM model and it can be used as a tool to data exploration. One way to visualise the tensor metric is through the differential volume of the high dimensional parallelepiped spanned by GP-LVM; this, for a latent dimension $q = 2$ is known as magnification factor and it has been introduced by [Bishop et al., 1997] for generative topographic mapping (and self organising maps). Its explicit formulation for GP-LVM is given by

$$\text{MF} = \sqrt{\det(\mathbb{E}[\mathbf{J}^\top \mathbf{J}])}. \quad (23)$$

An example of the magnification factor is shown in Fig. 3.

4.3 COMPUTING GEODESICS

Given a latent space endowed with an expected Riemannian metric, we now consider how to compute geodesics (shortest paths) between given points. Once a geodesic is computed its length can be evaluated through numerical integration of Eq. 4.

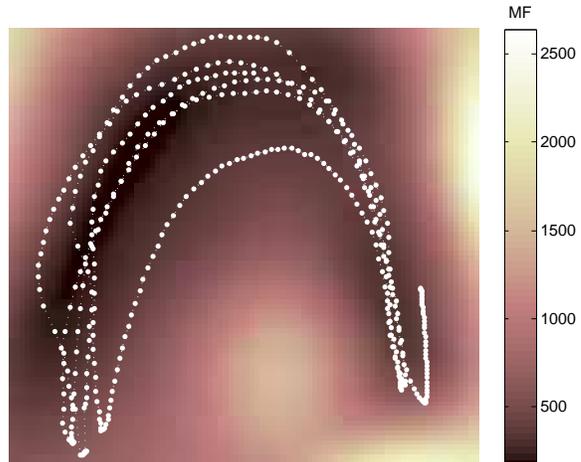

Figure 3: GP-LVM latent space for the motion capture data (see section 5 for details). White dots denote latent points \mathbf{x}_n and the background colour is proportional to the magnification factor (23).

The obvious solution to the shortest path problem is to discretise the latent space and compute shortest paths on the resulting graph using e.g. Dijkstra’s algorithm [Cormen et al., 1990]. The computational complexity of this approach, however, grows exponentially with the dimensionality of the latent space and the approach quickly becomes infeasible. Further, this approach will also introduce discretisation errors due to the finite size of the graph.

Instead we solve the geodesic differential equation (6) numerically. This scales more gracefully as it only involves a discretisation of the geodesic curve which is always one-dimensional independently of the dimension of the latent space. The 2nd order ODE in (6) can be rewritten in a standard way as a system of 1st order ODEs, which we can solve using a four-stage implicit Runge-Kutta method [Kierzenka and Shampine, 2001]². This gives a smooth solution which is fifth order accurate. Alternatively, such equations can be solved by repeated Gaussian process regression [Hennig and Hauberg, 2014].

To evaluate Eq. 6 we need the derivative of the expected metric:

$$\frac{\partial \text{vec} \mathbb{E}[\mathbf{G}(\mathbf{x})]}{\partial \mathbf{x}} = \frac{\partial \text{vec}(\mathbb{E}[\mathbf{J}^\top] \mathbb{E}[\mathbf{J}] + p \cdot \text{cov}(\mathbf{J}, \mathbf{J}))}{\partial \mathbf{x}}. \quad (24)$$

For the GP-LVM this reduces to computing the derivatives of the covariance function k . Given two vectors $\mathbf{x}_1, \mathbf{x}_2 \in \mathbb{R}^q$, a widely used covariance function is the *squared exponential* (or *RBF*) kernel

$$k(\mathbf{x}_1, \mathbf{x}_2) = \alpha \exp\left(-\frac{\omega}{2} \|\mathbf{x}_1 - \mathbf{x}_2\|_2^2\right). \quad (25)$$

²We use an off-the-shelf numerical solver (bvp5c in Matlab[®]); runnig times and computational cost are provided in the reference.

We choose here the *RBF* as an illustrative example, but our approach apply to any other kernel that leads to a differentiable mapping. This function is differentiable in \mathbf{x} and will be used here (and in Section 5) to provide a specific algorithm. We explicitly compute Eq. 18 and 19 for the squared exponential kernel to have an explicit form of Eq. 20:

$$(\partial \mathbf{K}_{\mathbf{x}_1, \mathbf{x}_2})_{1,j} = -\omega(x_1^{(j)} - x_2^{(j)}) k(\mathbf{x}_1, \mathbf{x}_2) \quad (26)$$

$$(\partial^2 \mathbf{K}_{\mathbf{x}_1, \mathbf{x}_2})_{i,l} = \quad (27)$$

$$= \begin{cases} \omega(x_1^{(i)} - x_2^{(i)})(x_1^{(l)} - x_2^{(l)}) k(\mathbf{x}_1, \mathbf{x}_2), & i \neq l \\ \omega(\omega(x_1^{(i)} - x_2^{(i)})^2 - 1) k(\mathbf{x}_1, \mathbf{x}_2), & i = l \end{cases}$$

Due to symmetry, the upper triangular of the Hessian matrix is sufficient to the computation. Note that, for our choice of kernel, the Hessian is diagonal and constant for $\mathbf{x}_1 = \mathbf{x}_2$, which is the case of $\partial^2 \mathbf{K}_{*,*}$, so there is no need to compute its derivative (which appears in the expression of $\partial \text{vec } \mathbf{G}$).

5 EXPERIMENTS AND RESULTS

Section 1 shows a first motivating example: a single image of a hand-written digit is rotated from 0 to 360 degrees to produce 200 rotated images. We then estimate³ a GP-LVM model with a $q = 2$ dimensional latent space; the latent space is shown in Fig. 1. We interpolate two points using either a straight line or a geodesic, and reconstruct images along these paths. The results in Fig. 4 show the poor reconstruction of the straight-line interpolator. The core problem with this interpolator is that it goes through regions with little data support, meaning the resulting reconstruction will be similar to the average of the entire data set.

In the next two sections we consider experiments on real data, but our results are similar to the synthetic digit experiment. First, we consider images of rotating objects (Section 5.1), and then motion capture data (Section 5.2).

5.1 IMAGES OF ROTATING OBJECTS

We consider images from the COIL data set [Nene et al., 1996], which consist of images from a fixed camera depicting 100 different objects on a motorised turntable against a black background. Each image is acquired after a 5 degree rotation of the turntable, giving a total of 72 images per object. Here we consider the images of object 74 (a rubber duck), but similar results are attained for other objects.

We estimate a $q = 2$ dimensional latent space using GP-LVM, and interpolate two latent points using either a straight line or a geodesic. Reconstructed images along the

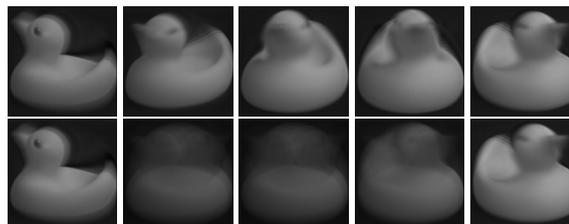

Figure 5: COIL image reconstruction. Inference after sampling over the latent space following the geodesic (top row) and the Euclidean straight line (bottom row).

interpolated paths are shown in Fig. 5. It is clear that the geodesic gives a better interpolation as it avoids regions with high uncertainty.

To measure the quality of the different interpolators we reconstruct 50 images equidistantly along each interpolating path and measure the distance to the nearest neighbour in the training data. This is shown in Fig. 6, which, for reference, also shows the average reconstruction error of the latent representations of the training data,

$$\text{Avg. training error} = \frac{1}{N} \sum_{n=1}^N \|\mathbb{E}[f(\mathbf{x}_n)] - \mathbf{y}_n\|. \quad (28)$$

It is clear that the straight line interpolator performs poorly away from the end-points, while the geodesic provides errors which are comparable to the average error of the latent representation of the training data.

5.2 HUMAN MOTION CAPTURE

We next consider human motion capture data from the *CMU Motion Capture Database*⁴. Specifically, we study motion 16 from subject 22, which is a repetitive *jumping jack* motion. Each time instance of this data consist of a human pose as acquired by a marker-based motion capture system; see Fig. 9 for example data. We represent each

pose by the three-dimensional joint positions, i.e. as a vector $\mathbf{y}_{n,:} \in \mathbb{R}^{3P}$, where P denotes number of joint positions.

We estimate a GP-LVM using dynamics [Damianou et al., 2011] as is common for this type of data [Wang et al., 2008]. The resulting latent space is shown in Fig. 7, and the metric tensor is shown in Fig. 3. As can be seen, the latent points $\mathbf{x}_{n,:}$ follow a periodic pattern as expected for this motion, and the metric tensor is generally smaller in regions of high data density.

We pick two latent extremal points of the motion (\mathbf{x}_1 and \mathbf{x}_T) and interpolate them using the Euclidean straight line and the expected Riemannian geodesic. Fig. 7 show the interpolants: again, the geodesic follow the trend of the data while the straight line goes through regions with high model uncertainty. Reconstructed poses along the interpolants are shown in Fig. 10 and 11. A comparison with the intermediate poses ($\mathbf{x}_2 \dots \mathbf{x}_{T-1}$) in the training sequence (see Fig. 9) show that the geodesic interpolant is a more truthful reconstruction compared to that of the straight line.

To measure the quality of the reconstruction we note that the length of the subject’s limbs should stay constant throughout the sequence. Our representation does, however, not enforce this constraint. Fig. 8 show the length of the subjects forearm for the two reconstructions along with the correct length. The straight line interpolant drastically changes the limb lengths, while the geodesic matches the ground truth well. Similar observations have been made for other limbs.

6 DISCUSSION AND FUTURE WORK

When the mapping between a latent space and the observation space is not isometric (the common case for nonlinear mappings), a Euclidean distance measure in the latent space does not match that of the original observation space. In fact, the distance measures in the latent and observation spaces can be arbitrarily different. This makes it difficult to

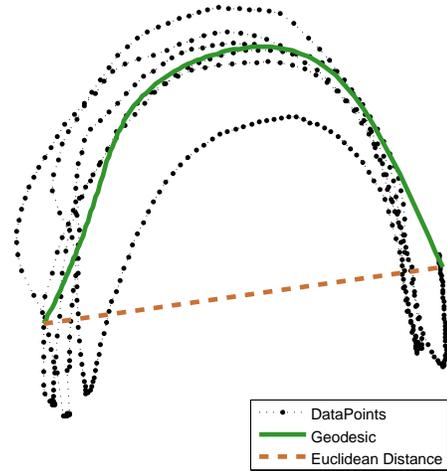

Figure 7: GP-LVM latent space for the motion capture data. White dots denote latent points \mathbf{x}_n and the background colour is proportional to the magnification factor (23). The blue curve denotes the geodesic interpolant, while the dashed red curve is the straight-line interpolant. This figure is best viewed in colour.

perform any meaningful statistical operation directly in the latent space as the used metric is difficult to interpret.

We solve this issue by carrying the metric from the observation space into the latent space in the form of a *random Riemannian metric*. This gives a distribution over a smoothly changing local metric at each point in the latent space. We then provide an expression for the *expected* local metric and show how shortest paths (geodesics) can be computed numerically under the resulting metric. These geodesics provide natural generalisations of straight-lines and are, thus, suitable for interpolation under the new metric.

For the GP-LVM model the expected metric depends on the uncertainty of the model, such that distances become longer in regions of high uncertainty. This effectively forces geodesic curves to avoid uncertain regions in the latent space, which is the desired behaviour for most applications. It is worth noting that a similar analysis for the GTM does *not* provide a metric with this capacity as the uncertainty is constant in this model.

The idea of considering the expected metric is practical as it turns the latent space into a Riemannian manifold. This opens up to many applications as statistical operations are reasonably well-understood in these spaces. E.g. tracking can be performed in the latent space through a Riemannian Kalman filter [Hauberg et al., 2013], classification can be done using the geodesic distance, etc.

It is, however, potentially misleading to only consider the expectation of the metric rather than the entire distributions

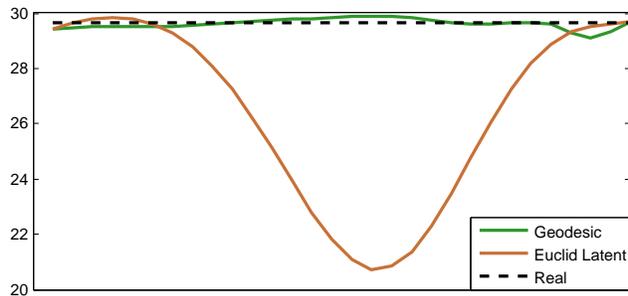

Figure 8: Length, in centimetres, of the subjects forearm during latent space interpolation. The blue curve is according to the geodesic interpolant, and the red dashed curve is according to the straight-line interpolant. For reference, the black dots show the true length.

of metrics. Although, if the latent dimension is much lower than the data dimension, it can be shown that the distribution of the metric concentrates around its mean. But in general *random Riemannian manifolds* are mathematically less well-understood, e.g. it is known that geodesics are almost surely not length minimising curves under a random metric [LaGatta and Wehr, 2014]. We are suggesting that manifolds derived from data are necessarily uncertain, and there is much to gain from further consideration of these spaces, which then naturally lead to distributions over geodesics, distances, angles, curvature and so forth.

In this paper we have only considered how geometry can be used to understand an already estimated LVM, but it is also worth considering if this geometry can be used when estimating the LVM. E.g. it is worth investigating if a prior on the curvature of the latent manifold is an effective way to influence learning.

Abstract

We study the problem of an advertising agent who needs to intelligently distribute her budget across a sequence of online keyword bidding auctions. We assume the closing price of each auction is governed by the same unknown distribution, and study the problem of making provably optimal bidding decisions. Learning the distribution is done under censored observations, i.e. the closing price of an auction is revealed only if the bid we place is above it. We consider three algorithms, namely ϵ -First, Greedy Product-Limit (GPL) and LuekerLearn, respectively, and we show that these algorithms provably achieve Hannan-consistency. In particular, we show that the regret bound of ϵ -First is at most $O(T^{\frac{2}{3}})$ with high probability. For the other two algorithms, we first prove that, by using a censored data distribution estimator proposed by Zeng [19], the empirical distribution of the closing market price converges in probability to its true distribution with a $O(\frac{1}{\sqrt{t}})$ rate, where t is the number of updates. Based on this result, we prove that both GPL and LuekerLearn achieve $O(\sqrt{T})$ regret bound with high probability. This in fact provides an affirmative answer to the research question raised in [1]. We also evaluate the abovementioned algorithms using real bidding data, and show that although GPL achieves the best performance on average (up to 90% of the optimal solution), its long running time may limit its suitability in practice. By contrast, LuekerLearn and ϵ -First proposed in this paper achieve up to 85% of the optimal, but with an exponential reduction in computational complexity (a saving up to 95%, compared to GPL).

1 INTRODUCTION

Sponsored search is the most significant example of monetisation of Internet activities. This multi-billion dollar industry poses many challenging research problems for both advertisers and search engines. One of the most well-studied, but nonetheless still open, problems is the optimisation of marketing campaigns for an advertiser, or an autonomous agent acting on her behalf¹, with a fixed budget. This fundamental problem has been studied in a number of stylised models, yet many of the questions arising in real sponsored search auctions remain unanswered. In this paper, we focus on one such question—bidding when prices are not known but must be learnt to choose the right bidding strategy.

In this work, we follow a stochastic market price model that was used in [1, 7]. In particular, we take the point of view of an advertising agent with a specified budget for a given time horizon, who wants to find a bidding strategy that maximises the number of clicks. We consider a model with a single keyword and a single slot. Each time a user searches for the keyword, an auction is run to decide which of the interested agents is assigned the ad slot on the search results page. The winner is the agent with the highest bid who pays the *market price* which is determined by the second highest bid: i.e., the slot is sold in the style of a second-price auction. In practice, other factors affecting allocation of the slot include randomisation used by the search engine and advertiser/keyword-specific “quality scores” that adjust advertisers’ bids. Given these factors and the lack of information about bids and strategies of the other advertisers, an advertising agent cannot easily take into account her own effect on the market price, and so instead views the price as a random variable.

The key challenge of this stochastic model is that the distribution of the market price is not known in ad-

¹We will interchangeably use the terms agent and advertiser within this paper.

vance. Thus, to select the right bidding strategy, the agent needs to learn that distribution. This learning problem is further complicated by “censored observations” [1, 7]: the agent observes the market price only when she wins the auction; otherwise she just learns that the market price is above her bid. Although existing methods, designed for budget-limited online optimisation, can provably achieve asymptotically optimal performance for the case with no censorship [2, 18], they fail within the settings studied here. In particular, due to the censored observations, these methods cannot reproduce efficient estimation of the distribution of the market price, as they use conventional empirical estimation techniques [9, 16].

To combat this, Amin *et al.* (2012) proposed Greedy Product-Limit (GPL) and LuekerLearn, two methods that use the Kaplan–Meier estimator [9], designed for estimating the distribution of censored data, and achieve good performance in experiments with real bidding data. However, no theoretical performance analysis has been provided. Against this background, this paper addresses this gap by providing theoretical justification for these algorithms and a novel one that we develop for this setting. Our results prove asymptotic optimality of the algorithms, guaranteeing good performance as the number of auctions increases. We first look at ϵ –First, an algorithm inspired by a class of methods designed for multi-armed bandits [5, 18], tailored to our settings. In particular, this algorithm uses the first ϵ fraction of the auctions to estimate the market price distribution. Based on this estimate, it then solves a Markov decision process (MDP) in order to determine the optimal bidding policy. We prove that this algorithm achieves Hannan–consistency (i.e., sub-linear regret bound). Put differently, we show that the regret (i.e., the difference between the performance of a particular algorithm and that of an optimal solution) of the algorithm is at most $O(T^{\frac{2}{3}})$ with high probability, where T is the number of auctions. Note that the Hannan–consistency property (i.e., the sub-linear $O(T^{\frac{2}{3}})$ regret bound) guarantees that the average regret (i.e., the total regret divided by the number of auctions) converges to 0 as the number of auctions is increased, and thus, the bidding behaviour of a Hannan–consistent algorithm becomes more similar to that of the optimal solution (due to the decreasing performance gap defined by the average regret).

In addition to ϵ –First, we also provide an affirmative answer to the conjectures posed in [1]. That is, we show that, by replacing the Kaplan–Meier estimator with a novel censored data distribution estimator proposed by Zeng [19], GPL and LuekerLearn, the algorithms studied by Amin *et al.*, do indeed achieve sub-linear regret bounds, and thus, are also Hannan–consistent. In particular, we show that, by using Zeng’s estimator, the empirical distribution of the clos-

ing market price converges in probability to its true distribution with a $O(\frac{1}{\sqrt{t}})$ rate, where t is the number of updates. Relying on this result, we prove that GPL achieves $O(\sqrt{T})$ regret bound with high probability. On the other hand, LuekerLearn achieves $O(\sqrt{T} + \ln T)$ regret bound, also with high probability. Given this, our work extends the state of the art as follows:

- We provide a theoretical regret analysis for ϵ –First, GPL and LuekerLearn, and we show that they achieve Hannan–consistency.
- We compare the performance of each algorithm through extensive empirical evaluations, using real bidding data from Microsoft adCenter. In particular, we demonstrate that, although GPL typically outperforms the other algorithms, it requires significantly higher computational complexity, which could limit its suitability in practice. On the other hand, both ϵ –First and LuekerLearn can achieve performance close to that of GPL (typically within 10%), but with a much lower computational cost (with up to 50 times speed-up in computation time).

The remainder of the paper is organised as follows. In the next section we review related work. The model we study is presented in Section 3. We review existing and new algorithms for learning and bidding in Section 4. Our main contribution — theoretical guarantees — are derived in Section 5. Numerical evaluation using real-world data sets is presented in Section 6, and Section 7 concludes.

2 RELATED WORK

Bid optimisation in sponsored search auctions is a topic of considerable research in the autonomous agents community [4, 8, 10, 12, 14]. One of the first papers on the topic offers heuristic algorithms for prediction and bidding that were shown to work in practice [10]. Moreover, Feldman *et al.* [6] prove that simple randomised strategies for optimising a budget across multiple keywords achieve good performance. In that work, cost per click and number of clicks for each bid are known to the bidder. Berg *et al.* [3] compare bidding algorithms such as equating return-on-investment (ROI) and knapsack-based solutions based on the predictions they require (e.g., number of clicks and cost per click) and evaluate them in a simulated bidding environment of the Trading Agent Competition in Ad Auctions [8]. Unlike all the above papers, our focus is on bidding with online *learning*—in order to make bidding decisions, we need to learn the distribution of the market price.

The two papers closest to our work that combine learning and bidding in ad auctions are [1] and [20]. In par-

ticular, our work can be seen as a continuation of the research started by Amin *et al.* [1] who compared various algorithms for prediction and bidding. We adopt the same model, but focus on theoretical guarantees of the algorithms considered in [1] as well as that of our proposed ε -First algorithm. Zhou and Naroditskiy [20] address the keyword bidding problem when multiple slots are available, but do not provide theoretical guarantees for their proposed algorithm.

Furthermore, two very recent related works are [18] and [2]. Both works propose general frameworks for studying multi-armed bandit problems with supply (or budget) constraints. Although bidding in repeated auctions is a problem that can be modeled in these frameworks, they do not address the one-sided censored observations issue, which is the main challenge addressed here. It is worth noting that we can still apply these models to our settings by combining them with the censored data solutions described in Section 4. However, since they are designed for more generic problems, they do not exploit the domain-specific features of our problem, and thus, they provide weaker performance guarantees. Nevertheless, they may form a strong basis for our future work.

Finally, it is worth to note that our problem can also be formalised as a Markov decision process (MDP) (see Section 3 for more details), and thus, it shows similarities to the domain of reinforcement learning [15, 17]. However, as existing RL methods do not take into account censored data, it is not trivial how to incorporate them into our settings. Given this, we ignore the large literature of RL, as we argue that they are out of scope of our paper. Nevertheless, a possible future work would be to find an efficient way to combine RL techniques with censored data estimation.

3 MODEL DESCRIPTION

Our model consists of a sequence of T single slot second-price auctions, where the bidder (or agent) has to repeatedly place her bid in order to win a single keyword at each time step $t \in \{1, \dots, T\}$. We refer to T auctions as a bidding *period* and use B to denote the budget for the period. That is, the total cost spent on the auctions cannot exceed this budget. At each time step t , we assume that the market price x_t of the keyword is an independent and identically distributed (i.i.d.) random variable drawn from an unknown, but fixed, distribution with probability distribution function p . We assume that p has a finite support $[0, C]$ for some sufficiently large $C > 0$. This assumption is reasonable, as the market price is typically less than a couple of dollars. In our model, if a particular bid of the agent at time step t is higher than x_t , the agent wins the auction, and the budget is decreased by x_t . Otherwise, the agent does not win, and the budget

remains the same. More formally, let b_t and B_t denote the agent’s bid, and the residual budget (i.e., the remaining budget) at time step t , respectively. Note that $B_1 = B$. Given this, we have

$$B_{t+1} = B_t - x_t$$

if $b_t \geq x_t$, and

$$B_{t+1} = B_t$$

otherwise. Note that the agent cannot place a bid that is higher than the current residual budget. That is, $b_t \leq B_t$ for each time step t . We assume that both b_t and x_t are discrete values chosen/drawn from \mathbb{Z}^+ . This assumption is reasonable, as the bids and market prices can be regarded as multiplications of the smallest unit of currency allowed for bidding.

Now, our goal is to find a bidding policy that maximises the number of wins over the time interval $\{1, \dots, T\}$. It is worth to note that if $B \geq CT$, we can achieve the optimal solution by repeatedly bidding with C . In particular, since bidding C always guarantees winning, if our budget is larger than CT , we can always win at each time step. Given this, we now only focus on the nontrivial case, and thus, we from hereafter assume that

$$B < CT \tag{1}$$

Given this condition, our problem can be formalised as follows. Let A denote a bidding policy that places bid $b^A(B_t, t)$ at each time step t , where B_t is the residual budget at that time step. In addition, let $G^A(B, T)$ denote the expected total number of wins of policy A with respect to total budget B and time limit T :

$$G^A(B, T) = \mathbb{E} \left[\sum_{t=1}^T I\{b^A(B_t, t) \geq x_t\} \right], \tag{2}$$

where $I\{\cdot\}$ is the indicator function. Note that $b^A(B_t, t) \leq B_t$ and

$$B_{t+1} = \begin{cases} B_t - x_t, & \text{if } b^A(B_t, t) \geq x_t \\ B_t, & \text{otherwise.} \end{cases}$$

We aim to find an optimal policy

$$A^* = \arg \max_A G^A(B, T)$$

that maximises the expected total number of wins. For the sake of simplicity, we denote the expected performance of A^* with $G^*(B, T)$. It is known that if we have exact information about the distribution function p , we can calculate A^* using a Markov decision process (MDP) formulation [1, 15]. In particular, let $F(b) = P(X > b)$ denote the survival function of the market price² (i.e., the probability that the market

²The problem of estimating the distribution of censored data first appeared in the survival analysis literature [9, 13]. Hence the name of the survival function.

price is higher than bid b). Suppose that the optimal policy A^* chooses bid $b^*(B', t)$ if the budget is B' at time step t . It can be shown that A^* has to satisfy the following set of Bellman equations [15]:

$$\begin{aligned}
 b^*(B', t) &= \arg \max_{b(B', t)} \left\{ \sum_{\sigma=1}^{b(B', t)} p(\sigma) [1 + G^*(B' - \sigma, T - t)] \right. \\
 &\quad \left. + F(b(B', t))G^*(B', T - t) \right\} \\
 G^*(B', T - t + 1) &= \sum_{\sigma=1}^{b^*(B', t)} p(\sigma) [1 + G^*(B' - \sigma, T - t)] \\
 &\quad + F(b^*(B', t))G^*(B', T - t)
 \end{aligned}$$

for each $t \in \{1, \dots, T\}$ and $0 \leq B' \leq B$. That is, $b^*(B', t)$ denotes the optimal bid (i.e., the one that maximises the expected number of future wins) at time step t and budget B' , while the second equation implies that the optimal number of wins at time step t and budget B' can be achieved by taking the optimal bid and continuing with the optimal policy A^* (for more details, see e.g. [1, 15]). Note that $G^*(B', 0) = 0$ for any $0 \leq B' \leq B$. Given this, we can recursively solve the Bellman equations given above, and thus, determine the optimal bid for each time step t in order to calculate the optimal solution $G^*(B, T)$. Hereafter we may refer to A^* as the optimal stochastic solution, as opposed to the deterministic approach, that additionally has full information about the sequence of market prices x_t , which A^* typically does not have (see Section 4.3 for more details).

Since p is unknown for us, A^* cannot be determined in an exact manner. This implies that A^* represents a theoretical optimum value, which is unachievable in general. Nevertheless, for any algorithm A , we can define the regret for A as the difference between the total number of wins of A and that of the theoretical optimum A^* . More precisely, letting R^A denote the regret, we have

$$R^A(B, T) = G^*(B, T) - G^A(B, T)$$

Thus, our objective is to derive algorithms for learning p and bidding that minimise this regret.

4 ALGORITHMS

Given the problem definition, we now turn to the description of the algorithms that we study within this paper. In particular, we investigate three algorithms: (i) ε -First, (ii) GPL and (iii) LuekerLearn. These algorithms are described in the next sections.

4.1 The ε -First Algorithm

Algorithm 1 The ε -First Algorithm

- 1: **Inputs:** $T > 0, B > 0, 0 < \varepsilon < 1$;
 - 2: **Exploration phase:**
 - 3: **for** $t = 1 \rightarrow \varepsilon T$ **do**
 - 4: randomly choose bid b_t from uniform distribution over $[1, \frac{B}{\varepsilon T}]$;
 - 5: observe $o_t = \min\{x_t, b_t\}$;
 - 6: **end for**
 - 7: **Exploitation phase:**
 - 8: use Suzukawa's estimator to calculate \hat{p} ;
 - 9: solve the Bellman equations given in Equation 4;
 - 10: **for** $t = \varepsilon T \rightarrow T$ **do**
 - 11: place the bid $b^+(B_t, t)$ accordingly to the solution of the Bellman equations;
 - 12: **end for**
-

As mentioned earlier, the key challenge of finding an optimal solution for the budget-limited auction problem is that we do not know the distribution function p of the market price in advance. Given this, we need to learn (or estimate) this distribution from the observed sequence of market prices x_1, x_2, \dots, x_T . This naturally lends itself to the idea of ε -First, which first estimates the distribution of the market price and then optimises the bidding policy. In particular, it uses an ε fraction of the total number of auctions T within a period to estimate the market price distribution function p . Following this, in the rest of $(1 - \varepsilon)T$ auctions, we solve the budget-limited auction problem with the estimated market price distribution function \hat{p} learnt from the learning phase. Hereafter we refer to the former phase as *exploration*, while to the latter as *exploitation*, respectively. In what follows, we describe these phases in more detail (the pseudo code is depicted in Algorithm 1).

We start with the description of the exploration phase. Within this phase, our goal is to accurately estimate the market price distribution. To do so, we can use the first ε proportion of the total auctions T . Now, recall that we can only observe x_t when it is not higher than the chosen bid b_t . That is, the sequence of x_t is (right) censored by the sequence of b_t . In particular, at each time step, we can only observe the value of $o_t = \min\{x_t, b_t\}$. This, indeed, makes the estimation of p a challenging problem. Note that [1] used the product-limit, or Kaplan-Meier (KM), estimator to address this challenge [9]. However, it is well known that the KM estimator has a negative bias [13]. To overcome this issue, we consider a modification of the KM estimator, an estimation technique proposed by [16], for estimating functionals of the distribution p . This method is proven to be unbiased, and thus, we can use McDiarmid's inequality to guarantee the $O(t^{-1})$ convergence rate of the \hat{p}_t estimate. This convergence rate provides the basis for the performance analysis of ε -First (see Section 5 for more details).

Suzukawa's method can be adopted to the estimation

of the market price distribution as follows. It relies on the assumption that we know the distribution from which the bids b_t are drawn. Let S denote the survival function of this bid distribution, and $o_t = \min\{x_t, b_t\}$ denote the observed value at t . Let $\varphi_b(x)$ be a function defined as

$$\begin{aligned}\varphi_b(x) &= 1 \quad \text{if } x \leq b \\ \varphi_b(x) &= 0 \quad \text{otherwise.}\end{aligned}$$

In addition, let $\delta_t = I\{x_t \leq b_t\}$ denote the indicator function whether the market price does not exceed the bid at time step t . Given this, Suzukawa's estimation for the market price's cumulative probability function P is formalised as:

$$\hat{P}_t(b) = \frac{1}{t} \sum_{i=1}^t \frac{\delta_i \varphi_b(o_i)}{S^-(o_i)} \quad (3)$$

where $S^-(o_i) = \lim_{x>0, x \rightarrow 0} S(o_i - x)$ and $\hat{P}_t(b)$ is the estimate of $P(b)$ after t observations. Using techniques similar to those from [16], we can easily derive that $\hat{P}_t(b)$ is indeed an unbiased estimator of $P(b)$.

Based on this, ε -First places the bids within the exploration phase as follows. For each $t \leq \varepsilon T$, ε -First uniformly chooses a bid b_t from $[1, \frac{B}{\varepsilon T}]$ (Algorithm 1, lines 4 – 5). This guarantees that the total cost spent within the exploration phase will not exceed the total budget B . When the exploration ends, let \hat{p} and \hat{F} denote Suzukawa's KM estimation of the market price distribution function p , and the survival function, respectively (line 8). Next, we will describe how ε -First uses these estimates to tackle the budget-limited auction problem.

We now turn to the description of the exploitation phase. Let $B_{\varepsilon T}$ denote the residual budget after the exploration phase ends. In order to determine the bids at each time step, ε -First solves the following Bellman equations:

$$\begin{aligned}b^+(B', t) &= \arg \max_{b(B', t)} \left\{ \sum_{\sigma=1}^{b(B', t)} \hat{p}(\sigma) [1 + G^+(B' - \sigma, T - t)] \right. \\ &\quad \left. + \hat{F}(b(B', t)) G^+(B', T - t) \right\} \\ G^+(B', T - t + 1) &= \sum_{\sigma=1}^{b^+(B', t)} \hat{p}(\sigma) [1 + G^+(B' - \sigma, T - t)] \\ &\quad + \hat{F}(b^+(B', t)) G^+(B', T - t) \quad (4)\end{aligned}$$

for each $\varepsilon T \leq t \leq T$ and $0 \leq B' \leq B_{\varepsilon T}$, where $b^+(B', t)$ is the chosen bid of ε -First at time step t and budget B' . Recall that $G^+(B', 0) = 0$ for any $0 \leq B' \leq B$. These together allow us to (recursively)

Algorithm 2 The GPL Algorithm

- 1: **Inputs:** $T > 0$, $B > 0$, \hat{p}_1 is uniform;
 - 2: **for** $t = 1 \rightarrow T$ **do**
 - 3: solve the Bellman equations given in Equation 5 for \hat{p}_t ;
 - 4: place a bid $b^+(B_t, t)$ according to the solution of the Bellman equations;
 - 5: use Zeng's estimator to update \hat{p}_{t+1} ;
 - 6: **end for**
-

evaluate each value of $b^+(B', t)$, and thus, the bidding policy within the exploitation phase of ε -First (Algorithm 1, lines 9 – 12).

The intuition behind ε -First is that by properly setting the value of ε , we can quickly estimate the distribution of the market price with sufficient accuracy. Thus, the solution of the Bellman equations within the exploitation phase is close to the optimal solution, resulting in a good overall bidding performance (see Section 5 for more details).

4.2 The GPL Algorithm

The GPL algorithm, introduced by [1], can be described as follows. For each time step t , it uses an MDP model to determine the current optimal policy, given the current estimate \hat{p}_t of the market price distribution function p . That is, it solves a set of Bellman equations, similar to the exploitation phase of ε -First, but with a different \hat{p}_t at each time step. According to this optimal policy, it then chooses the next bid, and observes the censored value o_t . Based on this observation, GPL uses a novel censored data distribution estimator, proposed by [19], to update the estimation of the market price distribution function, \hat{p}_{t+1} , for the next time step. Note that here we replace the KM estimator, which is used in [1], with Zeng's method (for a brief description of Zeng's method and further explanations, see Section 5). The above mentioned steps are repeated until $t = T$ (see Algorithm 2 for the pseudo code). More formally, suppose that the residual budget at time step t is B_t . In addition, let \hat{F}_t denote the estimate of the survival function at t . GPL solves the following equations:

$$\begin{aligned}b^+(B', \tau) &= \arg \max_{b(B', \tau)} \left\{ \sum_{\sigma=1}^{b(B', \tau)} \hat{p}_t(\sigma) [1 + G^+(B' - \sigma, \right. \\ &\quad \left. T - \tau)] + \hat{F}_t(b(B', \tau)) G^+(B', T - \tau) \right\} \\ G^+(B', T - \tau) &= \sum_{\sigma=1}^{b^+(B', \tau)} \hat{p}_t(\sigma) [1 + G^+(B' - \sigma, \\ &\quad T - \tau - 1)] + \hat{F}_t(b^+(B', \tau)) G^+(B', T - \tau - 1)\end{aligned}$$

where $t \leq \tau \leq T-1$ and $0 \leq B' \leq B_t$. In addition, we have $G^+(B', 0) = 0$ for all $0 \leq B' \leq B_t$. For the sake of simplicity, we set \hat{p}_1 to be a uniform distribution in $(0, B]$. Given the solutions, GPL then places bid $b^+(B_t, t)$ at each time step t (Algorithm 2, lines 2–6).

4.3 The LuekerLearn Algorithm

Similar to GPL, this algorithm was also described in [1], and is based on the algorithm proposed by Lueker for the online stochastic knapsack problem [11]. In particular, within the online stochastic knapsack problem, an item with profit r_t and weight x_t arrives into the system at each time step t such that the pair $\{r_t, x_t\}$ is drawn from a *fixed* and *known* joint distribution. At each time step, we have to decide whether to put the arrived item into a knapsack with the total capacity B such that the total weight of the chosen items cannot exceed this capacity. Our goal is to maximise the total profit of the chosen items. It is easy to see that within our settings, if the market price distribution p is known in advance, the budget-limited auction problem can be reduced to the online stochastic knapsack problem by setting $r_t = 1$ for each t . Given this, Lueker’s algorithm, originally designed for the online stochastic knapsack problem, can be adopted to the budget-limited auction with full knowledge of p as follows (for more details, see [11]). At each time step $1 \leq t \leq T$, Lueker’s algorithm chooses a bid $b^+(B_t, t)$ that satisfies

$$b^+(B_t, t) = \max \{b\} \quad \text{s.t.} \quad \sum_{\sigma=0}^b p(\sigma)\sigma \leq \frac{B_t}{T-t+1} \quad (5)$$

where B_t is the current residual budget. The efficiency of this algorithm is guaranteed by the following:

Proposition 1 (Theorem 2 from [11]) *Suppose that we have full information about the market price distribution p . Consider the optimal deterministic solution, that has the full information about the sequence of market prices $\{x_t\}$ as well (i.e., it knows the value of each x_t in advance). Given this, the difference between the performance of Lueker’s algorithm and that of the optimal deterministic solution is at most $O(\ln T)$.*

The proof can be found in [11]. However, since neither the sequence of $\{x_t\}$ nor p is known in advance, we combine Lueker’s algorithm with Zeng’s estimator (instead of the KM estimator) in order to learn the market price distribution and determine an efficient bid at the same time. This leads to the LuekerLearn algorithm (see Algorithm 3), that places a bid $b^+(B_t, t)$ as follows:

Algorithm 3 The LuekerLearn Algorithm

- 1: **Inputs:** $T > 0, B > 0, \hat{p}_1$ is uniform;
 - 2: **for** $t = 1 \rightarrow T$ **do**
 - 3: place a bid $b^+(B_t, t)$ according to Equation 6;
 - 4: use Zeng’s estimator to update \hat{p}_{t+1} ;
 - 5: **end for**
-

$$b^+(B_t, t) = \max \{b\} \quad \text{s.t.} \quad \sum_{\sigma}^b \hat{p}_t(\sigma)\sigma \leq \frac{B_t}{T-t+1} \quad (6)$$

where \hat{p}_t is the estimate of p at time step $1 \leq t \leq T$, and $b^+(B_T, T) = B_T$. Based on the censored observation o_t , it then updates the estimation of p (i.e., \hat{p}_{t+1}), using the Zeng’s estimator (Algorithm 3, lines 2–5). The intuition of the algorithm is that as the estimate \hat{p}_t gets more accurate over time, the algorithm converges to the original algorithm provided by Lueker. Since Proposition 1 guarantees the efficiency of the latter, LuekerLearn can also achieve low regret bounds, as we will prove later in this work.

5 PERFORMANCE ANALYSIS

Within this section, we analyse the performance of the aforementioned algorithms. In particular, we derive performance regret bounds for each of the algorithms. We also show that these regret bounds imply the fact that the algorithms converge to the theoretical optimal solution with high probability. We start with ε -First:

Theorem 2 *Let $T \geq 8(-\ln \frac{\beta}{2})$ for some $0 < \beta < 1$. For any $0 < \varepsilon < 1$ and $B > \varepsilon CT$, and $T > C$ where C is the support of the market price, the regret of the modified version of ε -First where Suzukawa’s method is used for the estimation of the market price distribution, is at most $C\varepsilon T + \sqrt{\frac{8(-\ln \frac{\beta}{2})T}{\varepsilon}}$ with probability of at least $(1-\beta)$. In addition, by setting $\varepsilon = \left(\frac{-2 \ln \frac{\beta}{2}}{C^2 T}\right)^{\frac{1}{3}}$, the regret bound can be refined to $3\left(-2 \ln \frac{\beta}{2}\right)^{\frac{1}{3}} C^{\frac{1}{3}} T^{\frac{2}{3}}$.*

Note that the condition $B > \varepsilon CT$ guarantees that within the exploration phase, the bids are uniformly sampled from the entire interval $[1, C]$, since the algorithm samples from the $[1, \frac{B}{\varepsilon T}]$. This condition guarantees that Suzukawa’s estimator can fully cover the interval $[1, C]$. In addition, the $O(C^{\frac{1}{3}} T^{\frac{2}{3}})$ regret bound is weak if the $C < T$ condition does not hold. In particular, by fixing T and increasing C , we will get a regret bound that is worse than $O(T)$. Nevertheless, this regret bound achieves Hannan consistency (i.e., sub-linear in T) if $C < T$.

It is also worth to note that since we only consider the case $B \sim O(T)$, $O(T^{\frac{2}{3}})$ regret bound is equiva-

lent to $O(B^{\frac{2}{3}})$, as $T^{\frac{2}{3}} > \frac{B^{\frac{3}{2}}}{C^{\frac{3}{2}}}$. Given the results for ε -First, we now turn to the analysis of GPL and LuekerLearn. If we consider the sequence of the bids as random variables, then the consistency and the zero bias property of KM estimators such as Suzukawa’s require independency between the bids and the market price³. However, since in both GPL and LuekerLearn we choose the current bid based on the empirical distribution which is built by using the previous observations, it is easy to see that the current bid is not independent from the sequence of the previous market prices. Thus, the consistency (and the convergence rate) of the empirical distribution might not be guaranteed if the standard KM or Suzukawa’s estimator is used within GPL and LuekerLearn (for more details, see, e.g., [13, 16]). This implies that neither GPL or LuekerLearn can achieve Hannan-consistency if we use their versions proposed in [1] without any modifications. To overcome this issue, we replace the KM estimator within GPL and LuekerLearn with a novel censored data estimator proposed by Zeng [19]. Due to its complexity and the space limitations, the detailed description of Zeng’s estimator is omitted (for more details, see [19]). However, we sketch it as follows.

Zeng’s method assumes that there is an underlying set of (known) variables \mathbf{L} that describes the dependency between the two sequences of chosen bids and market prices. Furthermore, suppose that \mathbf{L} is sufficient enough such that for each t , x_t (i.e., the market price) is independent from b_t (i.e., the chosen bid value), conditional to the value of \mathbf{L} at time step t , denoted with \mathbf{L}_t . In addition, this method requires that either x_t or b_t follows Cox’s proportional model; that is, at least one of the following conditions must hold:

$$p(x_t | \mathbf{L}_t = \mathbf{l}) \sim \lambda_x \exp \{ \beta' \mathbf{l} \} \quad (7)$$

$$p(b_t | \mathbf{L}_t = \mathbf{l}) \sim \lambda_b \exp \{ \gamma' \mathbf{l} \} \quad (8)$$

for some unknown λ_x , λ_b random variables, and some (unknown) parameters β and γ , respectively. Let \hat{P}_t denote Zeng’s estimate of the market price P after t time steps. Zeng proved that $\sqrt{t}(\hat{P}_t - P)$ is a Donsker-class empirical process. Based on this result, we state the following:

Theorem 3 *The abovementioned assumptions hold for both GPL and LuekerLearn. Given this, by using Zeng’s estimation method, the estimate \hat{P}_t of the market price distribution converges in probability to the true distribution P with rate $O(\frac{1}{\sqrt{t}})$ in both GPL and LuekerLearn.*

This theorem implies the following statements:

³In fact, it is sufficient to guarantee that the covariance between the bids and the market price is 0.

Theorem 4 *There exists a constant $K > 0$ that only depends on the market price distribution p , such that the regret of GPL, combined with Zeng’s estimator, is at most $O(2K\sqrt{T})$ with high probability.*

Similarly, we have the following theorem for LuekerLearn:

Theorem 5 *There exists a constant $K > 0$ that only depends on the market price distribution p , such that the regret of LuekerLearn, combined with Zeng’s estimator, is at most $O(2K(\sqrt{T} + \ln T))$ with high probability.*

Similarly to the case of ε -First, here we can also transform the regret bounds of GPL and LuekerLearn to $O(2K\sqrt{B})$ and $O(2K(\sqrt{B} + \ln B))$, respectively.

Note that Theorems 4 and 5 imply that GPL converges faster to the optimal solution than LuekerLearn, as T tends to infinity. This is due to the additional $\ln T$ term within the regret bound of LuekerLearn. The reason behind this is that LuekerLearn in fact converges with rate $O(\ln T)$ towards GPL. Hence an additional, $O(\ln T)$, gap is needed here. Also note that by using Zeng’s method in ε -First, we would get worse results, compared to Theorem 2, as with the approach from Suzukawa, we could derive exact constant coefficient values for the regret bound, while Zeng’s method only provides asymptotic regret bounds. In addition, since in both Theorems 4 and 5, the value of K is typically hard to be identified, the results of these theorems are in fact focussing on the asymptotic behaviour of the algorithms (i.e., both algorithms are Hannan consistent), and do not address whether the bounds are tight.

6 NUMERICAL EVALUATION

While we have so far developed theoretical upper bounds for the performance regret of the algorithms, we now turn to practical aspects and examine their performance in a realistic setting, as it might be the case that regret bound for ε -First is not tight, and thus, it might perform better than $O(T^{\frac{2}{3}})$ in many cases, as we will demonstrate later within this section. Given this, in this section, we aim to investigate whether the algorithms achieve high performance when applied to practical sponsored search auction problems. To do so, we first describe our parameter settings in Section 6.1. We then continue with the numerical results of the algorithms’ performance in Section 6.2.

6.1 Parameter Settings

To investigate the performance of the algorithms, we use the same dataset as [1], taken from a real-world

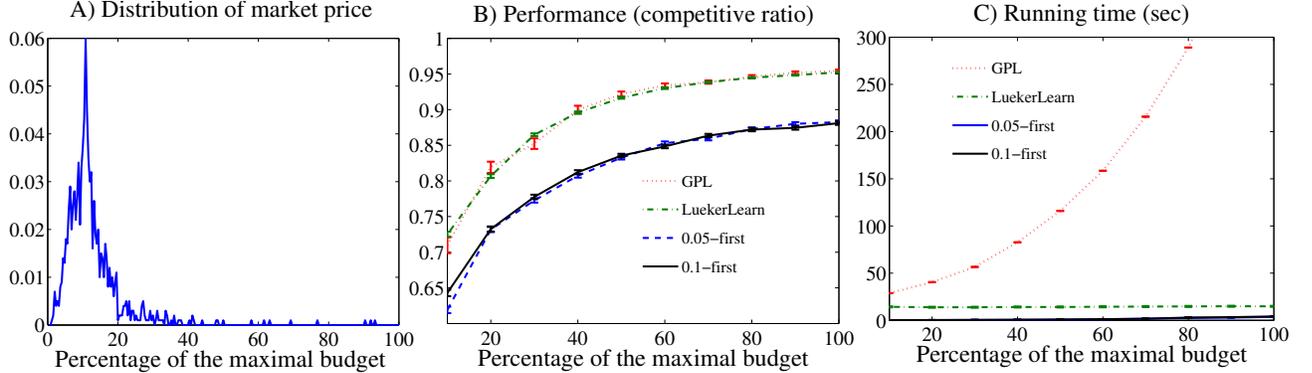

Figure 1: Numerical results on a subset of keywords with single distribution peaks, and with budgets ranging from 10% to 100% of the maximal budget $B_k(T)$: A) A typical single-peaked distribution of the market price. B) The performance of the algorithms, measured in competitive ratio against the optimal solution. C) Computational cost of the algorithms.

sponsored search auction database. Given this, we follow the parameter settings described there. In particular, for each experiment, we use $U = 10$ periods, each of which comprises $T = 100$ auctions and the budget is refilled at the beginning of each period. For a fair comparison to the results of Amin *et al.*, the maximal budget $B_k(T)$ for keyword k is also selected in the same way they do. In particular, we set $B_k(T)$ such that $G^*(B_k(T), T) = fT$ for $f = 0.1$ (i.e., 10%) and $T = 100$. This setting aims to satisfy that, on average, we can win 10% of the auctions. Within each experiment, we vary the budget from $\frac{B_k(T)}{10}$ up to $B_k(T)$ with a step of $\frac{B_k(T)}{10}$. Each experiment was repeated 100 times (for more details of the parameter settings, see [1]). Within our experiments, we run ε -First with $\varepsilon = 0.05$ and $\varepsilon = 0.1$, respectively, as these values are typically more efficient than other value settings⁴.

6.2 Numerical Results

Given the description of the parameter settings above, we now investigate the numerical results in more detail. In particular, we observed that the real distribution of the market price can typically be distinguished into two groups. In the first group, the market price usually concentrates at low values, creating a single-peaked distribution (see Figure 1A). Within the second group, the market price is typically more scattered, causing multiple peaks within the distribution (see Figure 2A). The performance efficiency of the algorithms also vary between these distribution groups. Therefore, we distinguish these two cases, and separately examine the performance of the algorithms

⁴Note that all the numerical tests appearing in this paper are performed on a personal computer, Intel® Xeon® CPU W3520 @2.67GHz with 12GB RAM and under Windows 7 operating system. The code was written and tested on Matlab R2012a.

within these cases. In particular, Figure 1 depicts the numerical results for the single-peaked case, and Figure 2 depicts the results for the multi-peaked case, respectively (here, the second group typically contains two peaks, as is also shown in Figure 2).

We first evaluate the single-peaked case (Figure 1). As mentioned earlier, Figure 1A shows the distribution of the market price. In addition, Figure 1B plots the performance of the algorithm, compared against that of the optimal stochastic solution described in Section 3. Here, the optimal stochastic solution also uses an MDP model to determine the optimal bidding policy, but assuming full knowledge of the distribution of market prices. Figure 1C depicts the running time of each algorithm. As can be seen from the figures, GPL and LuekerLearn provide similar performance, and both outperform the two versions of ε -First, 0.05-First and 0.1-First, by up to 10%. The reason for this is that since the market price is typically concentrated at low values, all the algorithms can quickly learn this. This allows GPL and LuekerLearn to use small bids to refine the estimation of the market price distribution at small values, and thus, to bid more efficiently. In contrast, as ε -First stops learning after the exploration phase, its estimation at the small values is not as accurate as the others'. Given this, ε -First bids suboptimally in more time steps, compared to the other two. Nevertheless, note that ε -First can still achieve by up to 88% of the optimal solution.

On the other hand, the running time of GPL is significantly larger, compared to that of the others (Figure 1C). In particular, GPL typically needs more than 500 seconds to evaluate the case of maximal budget $B_k(T)$, while ε -First algorithms only need less than 10 seconds. The reason for this is that GPL recomputes the MDP for the optimal decision at each step, after updating its price distribution. This is

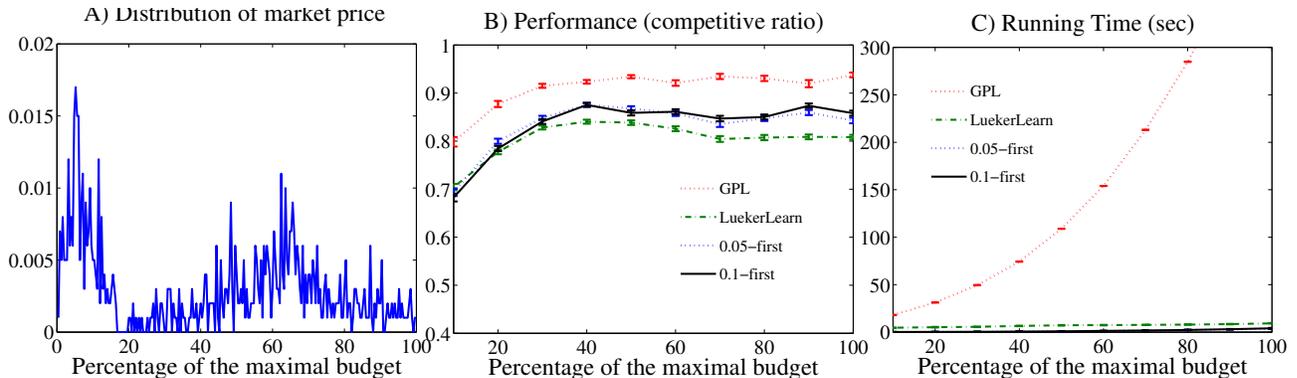

Figure 2: Numerical results on a subset of keywords with more than one distribution peaks, and with budgets ranging from 10% to 100% of the maximal budget $B_k(T)$: A) A typical two-peaked distribution of the market price. B) The performance of the algorithms, measured in competitive ratio against the optimal solution. C) Computational cost of the algorithms.

computationally expensive, especially for large budgets. By contrast, the ε -First algorithms only compute the MDP once, at the end of the exploration phase. Thus, despite its best competitive ratio performance, the running time of GPL would limit its suitability for real-time deployment. LuekerLearn also needs approximately 15 seconds to solve this problem instance. Given this, for single-peaked distributions, LuekerLearn yields the best trade-off between efficiency and computational cost, as it achieves similar performance to that of the GPL (33 times faster), and is almost as fast as the ε -First algorithms.

Within the case of distributions with multiple peaks (in this case, we consider the two-peaked version), we can see that GPL still provides the best performance (see Figure 2B). However, in this setting, ε -First outperforms LuekerLearn by approximately 5%. The reason behind this is that due to multiple peaks, LuekerLearn starts to deviate between the peaks, as it makes more observations (see [1] for more details). This implies that LuekerLearn makes more suboptimal bids, as placing bids at the first peak is typically more desirable, as opposed to the bids close to the second peak. On the other hand, due to its restricted learning phase, ε -First typically learns the values around the first peak, and thus, can act more efficiently, compared to LuekerLearn. Nevertheless, both ε -First and LuekerLearn still achieve good performance, as both typically provide at least 80% of the optimal solution's.

In terms of computational cost, GPL still requires the highest running time (more than 600 seconds for the case of maximal budget $B_k(T)$). By contrast, both ε -First and LuekerLearn require at most 10 seconds. Note that ε -First is typically two times faster than LuekerLearn. Therefore, in the two-peaked case, ε -First is clearly the best choice for the budget-limited

auction problem, as it provides good performance (above 85% of the optimal solution), and achieves by far the lowest computational cost.

7 CONCLUSIONS

We studied the online bid optimisation problem in budget-limited sponsored search auctions, where the market price is drawn from a fixed, but unknown distribution, and is censored by the value of our current bid. Although existing algorithms have been shown to achieve good performance in practice, no theoretical performance analysis has been provided for this problem. Given this, we proposed ε -First, and we show that it provably achieves $O(T^{\frac{2}{3}})$ regret bound with high probability, where T is the number of total auctions. We also provided an affirmative answer to the research question raised in [1], which conjectures that GPL, a state-of-the-art algorithm for the budget-limited sponsored search auction problem, can achieve asymptotically optimal performance. In particular, we proved that GPL achieves $O(\sqrt{T})$ regret bound with high probability. We also showed in the paper that the regret bound of LuekerLearn, another state-of-the-art algorithm, is $O(\sqrt{T} + \ln T)$, also with high probability. In addition, we compared the performance of the algorithms on real-world data, and observed that, although GPL provides the highest performance, it is by far the most computationally expensive algorithm, and its running time would make it infeasible for real time deployment. On the other hand, LuekerLearn would be the best choice in the case of single-peaked distributions, as it provides the best trade-off between efficiency and computational cost. For the two-peaked distribution case, we showed that ε -First outperforms LuekerLearn with a reduced running time.

Abstract

In high-dimensional classification or regression problems, the expected gradient outerproduct (EGOP) of the unknown regression function f , namely $\mathbb{E}_X (\nabla f(X) \cdot \nabla f(X)^\top)$, is known to recover those directions $v \in \mathbb{R}^d$ most relevant to predicting the output Y .

However, just as in gradient estimation, optimal estimators of the EGOP can be expensive in practice. We show that a simple rough estimator, much cheaper in practice, suffices to obtain significant improvements on real-world nonparametric classification and regression tasks. Furthermore, we prove that, despite its simplicity, this rough estimator remains statistically consistent under mild conditions.

1 INTRODUCTION

In high-dimensional nonparametric classification or regression problems, the output Y might not depend equally on all input variables in $X = (X^i)_{i=1}^d$. To be more precise, let $Y \approx f(X)$ for some unknown smooth f , it is often the case that f varies most along a few *relevant* coordinates, and varies little along most coordinates. This observation has given rise to many practical variable selection methods.

The usual assumption in variable selection is that $f(X) = g(PX)$, where $P \in \{0, 1\}^{k \times d}$ projects X down to $k < d$ relevant coordinates. This assumption is generalized in *multi-index* regression (see e.g. [7, 9, 2, 12]) by letting $P \in \mathbb{R}^{k \times d}$ project X down to a k -dimensional subspace of \mathbb{R}^d . In other words, while f might vary significantly along all coordinates of X , it actually only depends on an unknown k -dimensional subspace.

Recovering this relevant subspace (sometimes called *effective dimension reduction* [7]) gives rise to the expected gra-

dient outerproduct (EGOP):

$$\mathbb{E}_X G(X) \triangleq \mathbb{E}_X (\nabla f(X) \cdot \nabla f(X)^\top).$$

The EGOP recovers the average variation of f in all directions: the directional derivative at x along $v \in \mathbb{R}^d$ is given by $f'_v(x) = \nabla f(x)^\top v$, in other words $\mathbb{E}_X |f'_v(X)|^2 = \mathbb{E}_X (v^\top G(X) v) = v^\top (\mathbb{E}_X G(X)) v$.

It follows that, if f does not vary along v , v must be in the null-space of the EGOP matrix $\mathbb{E}_X G(X)$, since $\mathbb{E}_X |f'_v(X)|^2 = 0$. In fact, it is not hard to show that, under mild conditions (f continuously differentiable on a compact space \mathcal{X}), the column space of $\mathbb{E}_X G(X)$ is exactly the *relevant* subspace defined by P ([11]).

Interestingly, the EGOP is useful beyond the above multi-index motivation: even if there is no clearly relevant dimension-reduction P , as is likely in practice, one can expect that f does not vary equally in all directions. Instead of dimension-reduction, we might rather weight any direction $v \in \mathbb{R}^d$ according to its relevance as captured by the average variation of f along v (encoded in the EGOP). The weighting approach will be the main use of EGOP considered in this work.

The EGOP can be estimated in various sophisticated ways, which can however be prohibitively expensive. For instance an optimal way of estimating $\nabla f(x)$, and hence the EGOP, is to estimate the slope of a linear approximation to f locally at each $x = X_i$ in an n -sample $\{(X_i, Y_i)\}_{i=1}^n$. Local linear fits can however be prohibitively expensive since it involves multiplying and inverting large-dimensional matrices at all X_i . This can render the approach impractical although it is otherwise well motivated.

The main message of this work is that the EGOP need not be estimated optimally, but just well enough to use towards improving classification or regression, our practical end-goal.

The cheaper estimator considered here is as follows. Let f_n denote an initial estimate of f (we use a kernel estimate);

*Both authors contributed equally to this work

for the i -th coordinate of $\nabla f(x)$, we use the rough estimate

$$\Delta_{t,i} f_n(x) = (f_n(x + te_i) - f_n(x - te_i))/2t, t > 0.$$

Let $G_n(x)$ be the outer-product of the resulting gradient estimate $\hat{\nabla} f_n(x)$, the EGOP is estimated as $\mathbb{E}_n G_n(X)$, the empirical average of G_n . The exact procedure is given in Section 3.1.

We first show that this estimator is sound: despite being a rough approximation, it remains a statistically consistent estimate of the EGOP under very general distributional conditions. The main consistency result and key difficulties (having to do with interdependencies in the estimate) are discussed in Section 4.

More importantly, we show through extensive experiments that preprocessing data with this cheaper EGOP estimate can significantly improve the performance of nonparametric classification and regression procedures in real-world applications. This is described in Section 5.

In the next Section 2, we start with an overview of relevant work, followed by Section 3 describing the estimator and our theoretical setup.

2 SUMMARY OF RELEVANT WORK

The recent work of [6] considers estimating the coordinates f'_i of ∇f in a similar fashion as in the present work. However [6] is only concerned with a variable selection setting where each coordinate i of X is to be weighted by an estimate of $\mathbb{E}_X |f'_i(X)|$, which is their quantity of interest. This work addresses the more general approach of estimating the EGOP, its consistency and applicability.

Multiple methods have been developed for multi-index regression analysis, some using the so-called *inverse regression* approach (e.g. [7]), and many of them incorporating the estimation of derivative functionals of the unknown f . These approaches can already be found in early work such as [9], and typically estimate ∇f as the slope of local linear approximations of f .

Recent works of [11, 8] draw a clearer link between the various approaches to multi-index regression, and in particular relate the EGOP to the *covariance*-type matrices estimated in inverse regression. Furthermore, [8] proposes an alternative to estimating local linear slopes: their method estimates ∇f via a regularized least-squares objective over an RKHS. This is however still expensive since the least-square solution involves inverting an $n \times n$ feature matrix. In contrast our less sophisticated approach will take time in the order of n times the time to estimate f_n (f_n in practice could be a fast kernel regressor employing fast range-search methods).

The main use of the EGOP in the context of multi-index regression (as in the above cited work) is to recover the

relevant subspace given by P in the model $f(x) = g(Px)$. The data can then be projected to the estimated subspace before projection.

While we do not argue for a particular way to use the EGOP to preprocess data, our experiments focus on the following use: let VDV^\top be a spectral decomposition of the estimated EGOP, transform the input x as $D^{1/2}V^\top x$. Thus we do not rely on the multi-index model holding, but rather on a more general model where P might be a full-dimensional rotation (i.e. all directions are relevant), but g varies more in some coordinate than in others. The diagonal element $D_{i,i}$ recovers $\mathbb{E}_X (g'_i(X))^2$ where g'_i denotes coordinate i of ∇g , while V^\top recovers P .

3 SETUP AND DEFINITIONS

We consider a regression or classification setting where the input X belongs to a space $\mathcal{X} \subset \mathbb{R}^d$, of bounded diameter 1. The output Y is real. We are interested in the unknown *regression function* $f(x) \triangleq \mathbb{E}[Y|X = x]$ (in the case of classification with $Y \in \{0, 1\}$, this is just the probability of 1 given x).

For a vector $x \in \mathbb{R}^d$, let $\|x\|$ denote the Euclidean norm, while for a matrix A , let $\|A\|_2$ denote the spectral norm, i.e. the largest singular value $\sigma_{\max}(A)$.

We use $A \circ B$ to denote the entry-wise product of matrices A and B .

3.1 ESTIMATING THE EGOP

We let μ denote the marginal of $P_{X,Y}$ on \mathcal{X} and we let μ_n denote its empirical counterpart on a random sample $\mathbf{X} = \{X_i\}_{i=1}^n$. Given a labeled sample $(\mathbf{X}, \mathbf{Y}) = \{(X_i, Y_i)\}_{i=1}^n$ from $P_{X,Y}^n$, we estimate the EGOP as follows.

We consider a simple kernel estimator defined below, using a Kernel K satisfying the following admissibility conditions:

Definition 1 (Admissible Kernel). $K : \mathbb{R}_+ \mapsto \mathbb{R}_+$ is non-increasing, $K > 0$ on $[0, 1)$, and $K(1) = 0$.

Using such an admissible kernel K , and a bandwidth $h > 0$, we consider the regression estimate $f_{n,h}(x) = \sum_i \omega_i(x) Y_i$ where

$$\omega_i(x) = \frac{K(\|x - X_i\|/h)}{\sum_j K(\|x - X_j\|/h)} \text{ if } B(x, h) \cap \mathbf{X} \neq \emptyset,$$

$$\omega_i(x) = \frac{1}{n} \text{ otherwise.}$$

For any dimension $i \in [d]$, and $t > 0$, we first define

$$\Delta_{t,i} f_{n,h}(x) \triangleq \frac{f_{n,h}(x + te_i) - f_{n,h}(x - te_i)}{2t}.$$

This is a rough estimate of the line-derivative along coordinate i . However, for a robust estimate we also need to ensure that enough sample points contribute to the estimate. To this end, given a confidence parameter $0 < \delta < 1$ (this definition for δ is assumed in the rest of this work), define $A_{n,i}(X)$ as the event that

$$\min_{s \in \{-t, t\}} \mu_n(B(X + se_i, h/2)) \geq \frac{2d \ln 2n + \ln(4/\delta)}{n}.$$

The gradient estimate is then given by the vector

$$\hat{\nabla} f_{n,h}(x) = (\Delta_{t,i} f_{n,h}(x) \cdot \mathbf{1}_{A_{n,i}(x)})_{i \in [d]}.$$

Note that, in practice we can just replace $A_{n,i}(X)$ with the event that the balls $B(X + se_i, h)$, $s \in \{-t, t\}$, contain samples.

Finally, define $G_n(x)$ as the outer-product of $\hat{\nabla} f_{n,h}(x)$, we estimate $\mathbb{E}_X G(X)$ as

$$\mathbb{E}_n G_n(X) \triangleq \frac{1}{n} \sum_{i=1}^n \hat{\nabla} f_{n,h}(X_i) \cdot \hat{\nabla} f_{n,h}(X_i)^\top.$$

3.2 DISTRIBUTIONAL QUANTITIES AND ASSUMPTIONS

For the analysis, our assumptions are quite general. In fact we could simply assume, as is common, that μ has lower-bounded density on a compact support \mathcal{X} , and that f is continuously differentiable; all the assumptions below will then hold. We list these more general detailed assumptions to better understand the minimal distributional requirements for consistency of our EGOP estimator.

A1 (Noise). Let $\eta(X) \triangleq Y - f(X)$. We assume the following general noise model: $\forall \delta > 0$ there exists $c > 0$ such that $\sup_{x \in X} \mathbb{P}_{Y|X=x}(|\eta(x)| > c) \leq \delta$. We denote by $C_Y(\delta)$ the infimum over all such c . For instance, suppose $\eta(X)$ has exponentially decreasing tail, then $\forall \delta > 0$, $C_Y(\delta) \leq O(\ln 1/\delta)$.

Last the variance of $(Y|X = x)$ is upper-bounded by a constant σ_Y^2 uniformly over $x \in X$. The next assumption is standard for nonparametric regression/classification.

A2 (Bounded Gradient). Define the τ -envelope of \mathcal{X} as $\mathcal{X} + B(0, \tau) \triangleq \{z \in B(x, \tau), x \in \mathcal{X}\}$. We assume there exists τ such that f is continuously differentiable on the τ -envelope $\mathcal{X} + B(0, \tau)$. Furthermore, for all $x \in \mathcal{X} + B(0, \tau)$, we have $\|\nabla f(x)\| \leq R$ for some $R > 0$, and ∇f is uniformly continuous on $\mathcal{X} + B(0, \tau)$ (this is automatically the case if the support \mathcal{X} is compact).

The next assumption generalizes common smoothness assumptions: it is typically required for gradient estimation that the gradient itself be Hölder continuous (or that f be

second-order smooth). These usual assumptions imply the more general assumptions below.

A3 (Modulus of continuity of ∇f). Let $\epsilon_{t,i} = \sup_{x \in \mathcal{X}, s \in [-t, t]} |f'_i(x) - f'_i(x + se_i)|$. We assume $\epsilon_{t,i} \xrightarrow{t \rightarrow 0} 0$ which is for instance the case when ∇f is uniformly continuous on an envelope $\mathcal{X} + B(0, \tau)$.

The next two assumptions capture some needed regularity conditions on the marginal μ . To enable local approximations of $\nabla f(x)$ over \mathcal{X} , the marginal μ should not concentrate on the boundary of \mathcal{X} . This is captured in the following assumption.

A4 (Boundary of \mathcal{X}). Define the (t, i) -boundary of \mathcal{X} as $\partial_{t,i}(\mathcal{X}) = \{x : \{x + te_i, x - te_i\} \not\subseteq \mathcal{X}\}$. Define the vector $\mu_{\partial_t} = (\mu(\delta_{t,i}(\mathcal{X})))_{i \in [d]}$. We assume that $\mu_{\partial_t} \xrightarrow{t \rightarrow 0} \mathbf{0}$. This is for instance the case if μ has a continuous density on \mathcal{X} .

Finally we assume that μ has mass everywhere, so that for samples X in dense regions, $X \pm te_i$ is also likely to be in a dense region.

A5 (Full-dimensionality of μ). For all $x \in \mathcal{X}$ and $h > 0$, we have $\mu(B(x, h)) \geq C_\mu h^d$. This is for instance the case if μ has a lower-bounded density on \mathcal{X} .

4 CONSISTENCY OF THE ESTIMATOR $\mathbb{E}_n G_n(X)$ OF $\mathbb{E}_X G(X)$

We establish consistency by bounding $\|\mathbb{E}_n G_n(X) - \mathbb{E}_X G(X)\|_2$ for finite sample size n . The main technical difficulties in establishing the main result below have to do with the fact that each gradient approximation $\Delta_{t,h} f_{n,h}(X)$ at a sample point X depends on all other samples in \mathbf{X} . These inter-dependencies are circumvented by proceeding in steps which consider related quantities that are less sample-dependent.

Theorem 1 (Main). *Assume A1, A2 and A5. Let $t < \tau$ and suppose $h \geq (\log^2(n/\delta)/n)^{1/d}$. There exist $C = C(\mu, K(\cdot))$ and $N = N(\mu)$ such that the following holds with probability at least $1 - 2\delta$. Define $A(n) = \sqrt{Cd} \cdot \log(n/\delta) \cdot C_Y^2(\delta/2n) \cdot \sigma_Y^2 / \log^2(n/\delta)$. Suppose $n \geq N$, we have:*

$$\begin{aligned} \|\mathbb{E}_n G_n(X) - \mathbb{E}_X G(X)\|_2 &\leq \frac{6R^2}{\sqrt{n}} \left(\sqrt{\ln d} + \sqrt{\ln \frac{1}{\delta}} \right) + \\ &\left(3R + \|\epsilon_t\| + \sqrt{d} \left(\frac{hR + C_Y(\delta/n)}{t} \right) \right) \cdot \left[\|\epsilon_t\| + \right. \\ &\left. \frac{\sqrt{d}}{t} \sqrt{\frac{A(n)}{nh^d} + 2h^2 R^2} + R \left(\sqrt{\frac{d \ln \frac{d}{2n}}{2n}} + \|\mu_{\partial_t}\| \right) \right] \end{aligned}$$

Proof. Start with the decomposition

$$\begin{aligned} \|\mathbb{E}_n G_n(X) - \mathbb{E}_X G(X)\|_2 &\leq \|\mathbb{E}_n G(X) - \mathbb{E}_X G(X)\|_2 \\ &\quad + \|\mathbb{E}_n G_n(X) - \mathbb{E}_n G(X)\|_2. \end{aligned} \quad (1)$$

The two terms of the r.h.s. are bounded separately in Lemma 2 and 12. \square

Remark. Under the additional assumptions A3 and A4, the theorem implies consistency for $t \xrightarrow{n \rightarrow \infty} 0$, $h \xrightarrow{n \rightarrow \infty} 0$, $h/t^2 \xrightarrow{n \rightarrow \infty} 0$, and $(n/\log n)h^d t^4 \xrightarrow{n \rightarrow \infty} \infty$, this is satisfied for many settings, for example $t \propto h^{1/4}$, $h \propto (1/n)^{1/(2(d+1))}$.

The bound on the first term of (1) is a direct result of the below concentration bound for random matrices:

Lemma 1. [10, 3]. Consider a random matrix $A \in \mathbb{R}^{d \times d}$ with bounded spectral norm $\|A\|_2 \leq M$. Let A_1, A_2, \dots, A_n be i.i.d. copies of A . With probability at least $1 - \delta$, we have

$$\left\| \frac{1}{n} \sum_{i=1}^n A_i - \mathbb{E}A \right\|_2 \leq \frac{6M}{\sqrt{n}} \left(\sqrt{\ln d} + \sqrt{\ln \frac{1}{\delta}} \right).$$

We apply the above concentration to the i.i.d. matrices $G(X), X \in \mathbf{X}$, using the fact that $\|G(X)\|_2 = \|\nabla f(X)\|_2 \leq R$.

Lemma 2. Assume A2. With probability at least $1 - \delta$ over the i.i.d sample $\mathbf{X} \triangleq \{X_i\}_{i=1}^n$, we have

$$\|\mathbb{E}_n G(X) - \mathbb{E}_X G(X)\|_2 \leq \frac{6R^2}{\sqrt{n}} \left(\sqrt{\ln d} + \sqrt{\ln \frac{1}{\delta}} \right).$$

The next Lemma provides an initial bound on the second term of (1).

Lemma 3. Fix the sample (\mathbf{X}, \mathbf{Y}) . We have:

$$\begin{aligned} \|\mathbb{E}_n G_n(X) - \mathbb{E}_n G(X)\|_2 &\leq \mathbb{E}_n \|\nabla f(X) - \hat{\nabla} f_{n,h}(X)\| \\ &\quad \cdot \max_{x \in \mathbf{X}} \|\nabla f(x) + \hat{\nabla} f_{n,h}(x)\|. \end{aligned} \quad (2)$$

Proof. We have by a triangle inequality $\|\mathbb{E}_n G_n(X) - \mathbb{E}_n G(X)\|_2$ is bounded by:

$$\mathbb{E}_n \left\| \left(\hat{\nabla} f_{n,h}(X) \cdot \hat{\nabla} f_{n,h}(X)^\top - \nabla f(X) \cdot \nabla f(X)^\top \right) \right\|_2.$$

To bound the r.h.s above, we use the fact that, for vectors a, b , we have

$$aa^\top - bb^\top = \frac{1}{2}(a-b)(b+a)^\top + \frac{1}{2}(b+a)(a-b)^\top,$$

implying that

$$\begin{aligned} \|aa^\top - bb^\top\|_2 &\leq \frac{1}{2} \|(a-b)(b+a)^\top\|_2 \\ &\quad + \frac{1}{2} \|(b+a)(a-b)^\top\|_2 \\ &= \|(b+a)(a-b)^\top\|_2 \end{aligned}$$

since the spectral norm is invariant under matrix transposition.

We therefore have that $\|\mathbb{E}_n G_n(X) - \mathbb{E}_n G(X)\|_2$ is at most

$$\begin{aligned} \mathbb{E}_n \left\| (\nabla f(X) - \hat{\nabla} f_{n,h}(X)) \cdot (\nabla f(X) + \hat{\nabla} f_{n,h}(X))^\top \right\|_2 \\ = \mathbb{E}_n \|\nabla f(X) - \hat{\nabla} f_{n,h}(X)\| \cdot \|\nabla f(X) + \hat{\nabla} f_{n,h}(X)\| \\ \leq \mathbb{E}_n \|\nabla f(X) - \hat{\nabla} f_{n,h}(X)\| \cdot \max_{x \in \mathbf{X}} \|\nabla f(x) + \hat{\nabla} f_{n,h}(x)\|. \end{aligned}$$

\square

Thus the matrix estimation problem is reduced to that of an average gradient estimation. The two terms of (2) are bounded in the following two subsections. These sections thus contain the bulk of the analysis. All omitted proofs are found in the supplementary.

4.1 BOUND ON $\mathbb{E}_n \|\nabla f(X) - \hat{\nabla} f_{n,h}(X)\|$

The analysis of this section relies on a series of approximations. In particular we relate the vector $\hat{\nabla} f_{n,h}(x)$ to the vector

$$\hat{\nabla} f(x) \triangleq (\Delta_{t,i} f(x) \cdot \mathbf{1}_{A_{n,i}(x)})_{i \in [d]}.$$

In other words we start with the decomposition:

$$\begin{aligned} \mathbb{E}_n \|\nabla f(X) - \hat{\nabla} f_{n,h}(X)\| &\leq \mathbb{E}_n \|\nabla f(X) - \hat{\nabla} f(X)\| \\ &\quad + \mathbb{E}_n \|\hat{\nabla} f(X) - \hat{\nabla} f_{n,h}(X)\|. \end{aligned} \quad (3)$$

We bound each term separately in the following subsections.

4.1.1 Bounding $\mathbb{E}_n \|\nabla f(X) - \hat{\nabla} f(X)\|$

We need to introduce vectors $\mathbf{I}_n(x) \triangleq (\mathbf{1}_{A_{n,i}(x)})_{i \in [d]}$, and $\overline{\mathbf{I}_n(x)} \triangleq (\mathbf{1}_{\bar{A}_{n,d}(x)})_{i \in [d]}$. We then have:

$$\begin{aligned} \mathbb{E}_n \|\nabla f(X) - \hat{\nabla} f(X)\| &\leq \mathbb{E}_n \|\nabla f(X) \circ \overline{\mathbf{I}_n(X)}\| \\ &\quad + \mathbb{E}_n \|\nabla f(X) \circ \mathbf{I}_n(X) - \hat{\nabla} f(X)\|. \end{aligned} \quad (4)$$

The following lemma bounds the first term of (4).

Lemma 4. Assume A2 and A5. Suppose $h \geq (\log^2(n/\delta)/n)^{1/d}$. With probability at least $1 - \delta$ over the

sample of \mathbf{X} :

$$\mathbb{E}_n \left\| \nabla f(X) \circ \overline{\mathbf{I}_n(X)} \right\| \leq R \cdot \left(\sqrt{\frac{d \ln \frac{d}{\delta}}{2n}} + \|\mu_{\partial_t}\| \right).$$

The second term of (4) is bounded in the next lemma.

Lemma 5. *Fix the sample \mathbf{X} . We have $\max_{X \in \mathbf{X}} \|\nabla f(X) \circ \mathbf{I}_n(X) - \hat{\nabla} f(X)\| \leq \|\epsilon_t\|$.*

The last two lemmas can then be combined using equation (4) into the final bound of this subsection.

Lemma 6. *Assume A2 and A5. Suppose $h \geq (\log^2(n/\delta)/n)^{1/d}$. With probability at least $1 - \delta$ over the sample \mathbf{X} :*

$$\mathbb{E}_n \|\nabla f(X) - \hat{\nabla} f(X)\| \leq R \cdot \left(\sqrt{\frac{d \ln \frac{d}{\delta}}{2n}} + \|\mu_{\partial_t}\| \right) + \|\epsilon_t\|.$$

4.1.2 Bounding $\mathbb{E}_n \|\hat{\nabla} f(X) - \hat{\nabla} f_{n,h}(X)\|$

We need to consider bias and variance functionals of estimates $f_{n,h}(x)$. To this end we introduce the expected estimate $\tilde{f}_{n,h}(x) = \mathbb{E}_{\mathbf{Y}|\mathbf{X}} f_{n,h}(x) = \sum_{i=1}^n w_i(x) f(X_i)$.

The following lemma bounds the bias of estimates $f_{n,h}$. The proof relies on standard ideas.

Lemma 7 (Bias of $f_{n,h}$). *Assume A2. Let $t < \tau$. We have for all $X \in \mathbf{X}$, all $i \in [d]$, and $s \in \{-t, t\}$:*

$$|\tilde{f}_{n,h}(X + se_i) - f(X + se_i)| \cdot \mathbf{1}_{A_{n,i}(x)} \leq hR.$$

The following lemma bounds the variance of estimates $f_{n,h}$ averaged over the sample \mathbf{X} . To obtain a high probability bound, we rely on results of Lemma 7 in [6]. However in [6], the variance of the estimator if evaluated at a point, therefore requiring local density assumptions. The present lemma has no such local density requirements given that we are interested in an average quantity over a collection of points.

Lemma 8 (Average Variance). *Assume A1. There exist $C = C(\mu, K(\cdot))$, such that the following holds with probability at least $1 - 2\delta$ over the choice of the sample (\mathbf{X}, \mathbf{Y}) . Define $A(n) = \sqrt{Cd \cdot \ln(n/\delta)} \cdot C_Y^2(\delta/2n) \cdot \sigma_Y^2$, for all $i \in [d]$, and all $s \in \{-t, t\}$:*

$$\mathbb{E}_n | \tilde{f}_{n,h}(X + se_i) - f_{n,h}(X + se_i) |^2 \cdot \mathbf{1}_{A_{n,i}(X)} \leq \frac{A(n)}{nh^d}$$

The main bound of this subsection is given in the next lemma which combines the above bias and variance results.

Lemma 9. *Assume A1 and A2. There exist $C = C(\mu, K(\cdot))$, such that the following holds with probability at least $1 - 2\delta$ over the choice of (\mathbf{X}, \mathbf{Y}) . Define $A(n) = \sqrt{Cd \cdot \ln(n/\delta)} \cdot C_Y^2(\delta/2n) \cdot \sigma_Y^2$:*

$$\mathbb{E}_n \|\hat{\nabla} f(X) - \hat{\nabla} f_{n,h}(X)\| \leq \frac{\sqrt{d}}{t} \sqrt{\frac{A(n)}{nh^d}} + 2R^2h^2.$$

Proof. In what follows, we first apply Jensen's inequality, and the fact that $(a+b)^2 \leq 2a^2 + 2b^2$. We have:

$$\begin{aligned} & \mathbb{E}_n \|\hat{\nabla} f(X) - \hat{\nabla} f_{n,h}(X)\| \\ &= \mathbb{E}_n \left(\sum_{i \in [d]} |\Delta_{t,i} f_{n,h}(X) - \Delta_{t,i} f(X)|^2 \cdot \mathbf{1}_{A_{n,i}(X)} \right)^{1/2} \\ &\leq \left(\sum_{i \in [d]} \mathbb{E}_n |\Delta_{t,i} f_{n,h}(X) - \Delta_{t,i} f(X)|^2 \cdot \mathbf{1}_{A_{n,i}(X)} \right)^{1/2} \\ &\leq \frac{\sqrt{d}}{2t} \left(\max_{i \in [d], s \in \{-t, t\}} 4\mathbb{E}_n |f_{n,h}(\tilde{X}) - f(\tilde{X})|^2 \cdot \mathbf{1}_{A_{n,i}(X)} \right)^{1/2} \end{aligned} \quad (5)$$

where $\tilde{X} = X + se_i$. Next, use the fact that for any $s \in \{-t, t\}$, we have the following decomposition into variance and bias terms

$$\begin{aligned} & |f_{n,h}(X + se_i) - f(X + se_i)|^2 \\ &\leq 2|f_{n,h}(X + se_i) - \tilde{f}_{n,h}(X + se_i)|^2 \\ &\quad + 2|\tilde{f}_{n,h}(X + se_i) - f(X + se_i)|^2. \end{aligned}$$

Combine this into (5) to get a bound in terms of the average bias and variance of estimates $f_{n,h}(X + se_i)$. Apply Lemma 7 and 8 and conclude. \square

4.1.3 Main Result of this Section

The following theorem provides the final bound of this section on $\mathbb{E}_n \|\nabla f(X) - \hat{\nabla} f_{n,h}(X)\|$. It follows directly from the decomposition of equation 3 and Lemmas 6 and 9.

Lemma 10. *Assume A1, A2 and A5. Let $t < \tau$ and suppose $h \geq (\log^2(n/\delta)/n)^{1/d}$. With probability at least $1 - 2\delta$ over the choice of the sample (\mathbf{X}, \mathbf{Y}) , we have*

$$\begin{aligned} \mathbb{E}_n \|\nabla f(X) - \hat{\nabla} f_{n,h}(X)\| &\leq \frac{\sqrt{d}}{t} \sqrt{\frac{A(n)}{nh^d}} + 2R^2h^2 \\ &\quad + R \left(\sqrt{\frac{d \ln \frac{d}{\delta}}{2n}} + \|\mu_{\partial_t}\| \right) + \|\epsilon_t\|. \end{aligned}$$

4.2 BOUNDING $\max_{X \in \mathbf{X}} \|\nabla f(X) + \hat{\nabla} f_{n,h}(X)\|$

Lemma 11. *Assume A1 and A2. With probability at least $1 - \delta$, we have*

$$\|\nabla f(X) + \hat{\nabla} f_{n,h}(X)\| \leq 3R + \|\epsilon_t\| + \sqrt{d} \left(\frac{hR + C_Y(\delta/n)}{t} \right).$$

Proof. Fix $X \in \mathbf{X}$. We have

$$\begin{aligned} \|\nabla f(X) + \hat{\nabla} f_{n,h}(X)\| &\leq 2\|\nabla f(X)\| \\ &\quad + \|\nabla f(x) - \hat{\nabla} f_{n,h}(X)\| \\ &\leq 2R + \|\nabla f(X) - \hat{\nabla} f(x)\| \\ &\quad + \|\hat{\nabla} f(X) - \hat{\nabla} f_{n,h}(X)\|. \end{aligned} \tag{6}$$

We can bound the second term of (6) above as follows.

$$\begin{aligned} \|\nabla f(X) - \hat{\nabla} f(X)\| &\leq \|\nabla f(X) \circ \mathbf{I}_n(X) - \hat{\nabla} f(X)\| \\ &\quad + \|\nabla f(X) \circ \overline{\mathbf{I}_n(X)}\| \\ &\leq \|\epsilon_t\| + R, \end{aligned}$$

where we just applied Lemma 5.

For the third term of (6), $\|\hat{\nabla} f(x) - \hat{\nabla} f_{n,h}(x)\|$ equals

$$\sqrt{\sum_{i \in [d]} (|\Delta_{t,i} f_{n,h}(x) - \Delta_{t,i} f(x)| \cdot \mathbf{1}_{A_{n,i}(x)})^2}.$$

As in the proof of Lemma 9, we decompose the above summand into bias and variance terms, that is:

$$\begin{aligned} &|\Delta_{t,i} f_{n,h}(x) - \Delta_{t,i} f(x)| \\ &\leq \frac{1}{t} \max_{s \in \{-t, t\}} |\tilde{f}_{n,h}(x + se_i) - f(x + se_i)| \\ &\quad + \frac{1}{t} \max_{s \in \{-t, t\}} |\tilde{f}_{n,h}(x + se_i) - f_{n,h}(x + se_i)|. \end{aligned}$$

By Lemma 7, $|\tilde{f}_{n,h}(x + se_i) - f(x + se_i)| \leq Rh$ for any $s \in \{-t, t\}$.

Next, by definition of $C_Y(\delta/n)$, with probability at least $1 - \delta$, for each $j \in [n]$, Y_j has value within $C_Y(\delta)$ of $f(X_j)$. It follows that $|\tilde{f}_{n,h}(X + se_i) - f_{n,h}(X + se_i)| \leq C_Y(\delta/n)$ for $s \in \{-t, t\}$.

Thus, with probability at least $1 - \delta$, we have

$$\|\hat{\nabla} f(X) - \hat{\nabla} f_{n,h}(X)\| \leq \sqrt{d} \left(\frac{hR + C_Y(\delta/n)}{t} \right).$$

Combine these bounds in (6) and conclude. \square

4.3 FINAL BOUND ON $\|\mathbb{E}_n G_n(X) - \mathbb{E}_n G(X)\|_2$.

We can now combine the results of the last two subsections, namely Lemma 10 and 11, into the next lemma, using the bound of Lemma 3.

Lemma 12. *Assume A1, A2 and A5. Let $t < \tau$ and suppose $h \geq (\log^2(n/\delta)/n)^{1/d}$. With probability at least $1 - 2\delta$ over the choice of the sample (\mathbf{X}, \mathbf{Y}) , we have that $\|\mathbb{E}_n G_n(X) - \mathbb{E}_n G(X)\|_2$ is at most*

$$\begin{aligned} &\left(3R + \|\epsilon_t\| + \sqrt{d} \left(\frac{hR + C_Y(\delta/n)}{t} \right) \right) \\ &\left[\frac{\sqrt{d}}{t} \sqrt{\frac{A(n)}{nh^d} + 2h^2 R^2} + R \left(\sqrt{\frac{d \ln \frac{d}{\delta}}{2n}} + \|\mu_{\partial_t}\| \right) + \|\epsilon_t\| \right]. \end{aligned}$$

5 EXPERIMENTAL EVALUATION

In this section we describe experiments aimed at evaluating the utility of EGOP as a metric estimation technique for regression or classification. We consider a family of non-parametric methods that rely on the notion of distance under a given Mahalanobis metric M , computed as $(x - x')^T M (x - x')$. In this setup, we consider three choices of M : (i) identity, i.e., Euclidean distance in the original space; (ii) the estimated gradient weights (GW) matrix as in [6], i.e., Euclidean distance weighted by the estimated $\Delta_{t,i} f_n$, and (iii) the estimated EGOP matrix $\mathbb{E}_n G_n(X)$. The latter corresponds to Euclidean distance in the original space under linear transform given by $[\mathbb{E}_n G_n(X)]^{1/2}$. Note that a major distinction between the metrics based on GW and EGOP is that the former only scales the Euclidean distance, whereas the latter introduces a rotation.

Each choice of M can define the set of neighbors of an input point x in two ways: (a) k nearest neighbors (k NN) of x for a fixed k , or (b) neighbors with distance $\leq h$ for a fixed h ; we will refer to this as h NN. When the task is regression, the output values of the neighbors are simply averaged; for classification, the class label for x is decided by majority vote among neighbors. Note that h NN corresponds to kernel regression with the boxcar kernel.

Thus, we will consider six methods, based on combinations of the choice of metric M and the definition of neighbors: k NN, k NN-GW, k NN-EGOP, h NN, h NN-GW, and h NN-EGOP.

5.1 SYNTHETIC DATA

We first discuss experiments on synthetic data, the goal of which is to examine the effect of varying the dependence of f on input dimensions on the quality of metric recovered with EGOP and alternative approaches. In these experiments, the output is generated i.i.d. as: $y = \sum_i \sin(c_i x_i)$, where the sum is over the dimensions of $x \in \mathbb{R}^d$, and the profile of c determines the degree to which the value of

x_i affects the output. We used $d = 50$ -dimensional input sampled over a bounded domain, and set $c[1] = 50$ and $c[i] = 0.6 * c[i - 1]$ for $i = 2 : 50$. We consider two cases: (R) the input features are transformed by a random rotation in \mathbb{R}^d , after y has been generated; and (I) the input features are preserved. Under these conditions we evaluate the out of sample regression accuracy with original metric, GW and EGOP-based metrics, for different value of n ; in each experiment, the values of h and t are tuned by cross-validation on the training set.

The first observation from results in Figures 1 is that adapting the metric by either GW or EGOP helps performance across the board. As can be expected, performance of EGOP, however, is not significantly affected by rotation. On the other hand, GW is able to recover a good metric in the no-rotation case, but much less so under rotation. Some insight into the nature of estimated metrics is obtained from the profile of the estimated feature relevance. For GW this consists of values on the diagonal of \mathbf{M} , and for EGOP of the (square roots) of the eigenvalues of \mathbf{M} . Plots in Figure 1 show these profiles (sorted in descending order). It is clear that EGOP is largely invariant to rotation of the features, and is consistently better at recovering the true relative relevance of features corresponding to the c described above.

5.2 REGRESSION EXPERIMENTS

In this section we present results on several real world datasets. The list of data sets with vital statistics (dimensionality and number of training/test points) is found in Table 1. For each data set, we report the results averaged over ten random training/test splits.

As a measure of performance we compute for each experiment the *normalized mean squared error* (nMSE): mean squared error over test set, divided by target variance over that set. This can be interpreted as fraction of variance in the target unexplained by the regressor.

In each experiment the input was normalized by the mean and standard deviation of the training set. For each method, the values of h or k as well as t (the bandwidth used to estimate finite differences for GW and EGOP) were set by two fold cross-validation on the training set.

5.3 CLASSIFICATION EXPERIMENTS

The setup for classification data sets is very similar for regression, except that the task is binary classification, and the labels of the neighbors selected by each prediction method are aggregated by simple majority vote, rather than averaging as in regression. The performance measure of interest here is classification error. As in regression experiments, we normalized the data, tuned all relevant parameters by cross validation on training data, and repeated the entire experimental procedure ten times with random train-

ing/test splits.

In addition to the baselines listed above, in classification experiments we considered another competitor: the popular feature relevance determination method called ReliefF [4, 5]. A highly engineered method that includes heuristics honed over considerable time by practitioners, it has the same general form of assigning weights to features as do GW and EGOP.

5.4 RESULTS

The detailed results are reported in Tables 1 and 2. These correspond to a single value of training set size. Plots in Figures 2 and 3 show a few representative cases for regression and classification, respectively, of performance of different methods as a function of training set size; it is evident from these that while the performance of all methods tends to improve if additional training data are available, the gaps methods persist across the range of training set sizes.

From the results in Tables 1 and 2, we can see that the -EGOP variants dominate the -GW ones, and that both produce gains relative to using the original metric. This is true both for k NN and for kernel regression (h NN) methods, suggesting general utility of EGOP-based metric, not tied to a particular non-parametric mechanism.

We also see that the metrics based on estimated EGOP are competitive with ReliefF, despite the latter benefiting from extensive engineering efforts over the years.

5.5 EXPERIMENTS WITH LOCAL LINEAR REGRESSION

As mentioned earlier in the paper, our estimator for EGOP is an alternative to an estimator based on computing the slope of locally linear regression (LLR) [1] over the training data. We have compared these two estimation methods on a number of data sets, and the results are plotted in Figure 4. In these experiments, the bandwidth of LLR was tuned by a 2-fold cross-validation on the training data.

We observe that despite its simplicity, the accuracy of predictors using EGOP-based metric estimated by our approach is competitive with or even better than the accuracy with EGOP estimated using LLR. As the sample size increases, accuracy of LLR improves. However, the computational expense of LLR-based estimator also grows with the size of data, and in our experiments it became dramatically slower than our estimator of EGOP for the larger data sizes. This confirms the intuition that our estimator is an appealing alternative to LLR-based estimator, offering a good tradeoff of speed and accuracy.

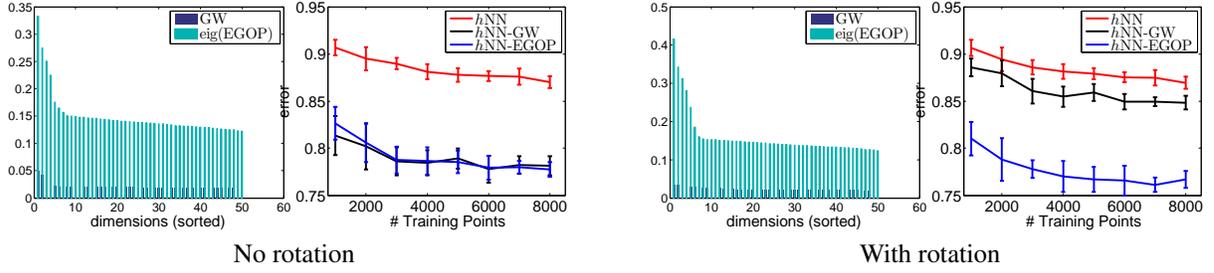

Figure 1: Synthetic data, $d=50$, with and without rotation applied after generating y from x . In each case we show error of h NN with different metrics (left) and the profile of derivatives recovered by GW and EGO. The deterioration of the error performance of the Gradient Weights approach after the feature space is subject to a random rotation is noteworthy. See text for details.

Table 1: Regression results, with ten random runs per data set.

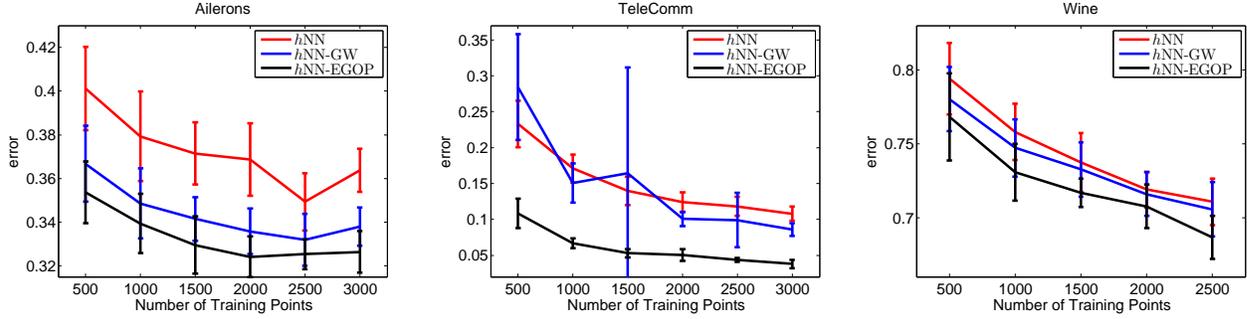

Figure 2: Regression error (nMSE) as a function of training set size for Ailerons, TeleComm, Wine data sets.

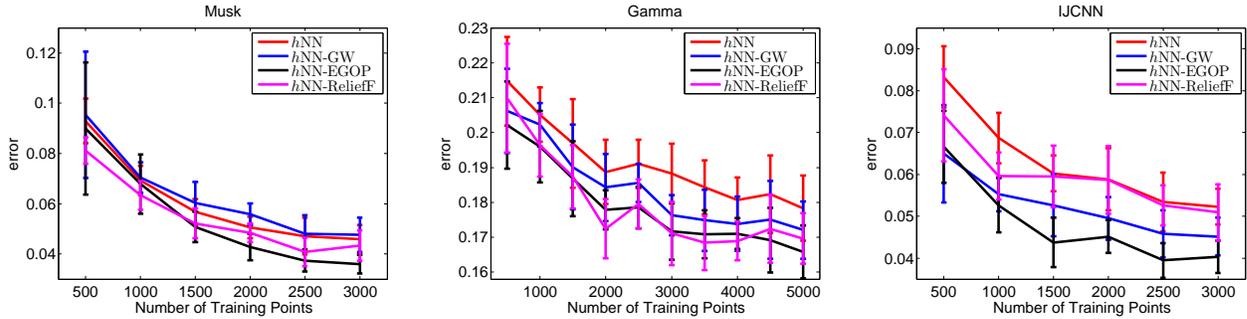

Figure 3: Classification error as a function of training set size for Musk, Gamma, IJCNN data sets.

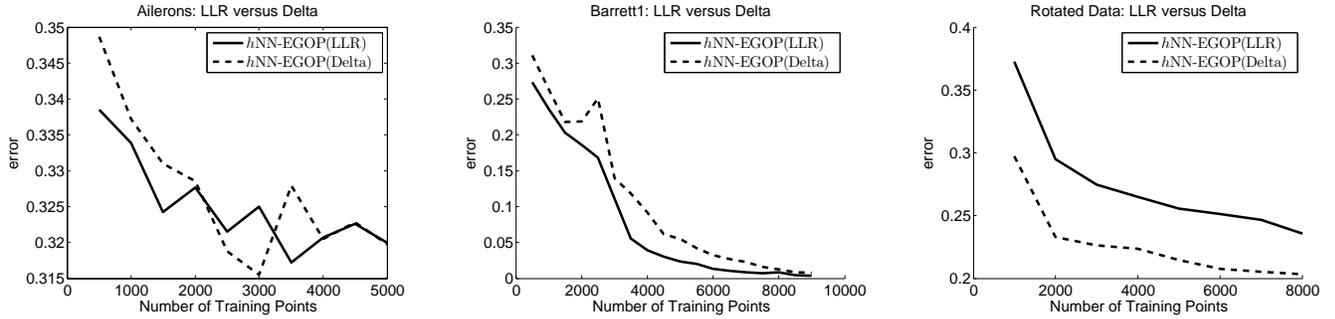

Figure 4: Comparison of EGOP estimated by our proposed method vs. locally linear regression, for Ailerons, Barrett1 and the synthetic (with rotation) data sets (this synthetic dataset is similar to the one used in section 5.1 but with $d = 12$ and $c = [5, 3, 1, .5, .2, .1, .08, .06, .05, .04, .03, .02]$). We also report the following running times (averaged over the ten random runs) for the same using our method and LLR respectively for the highest sample size used in the above real world datasets: Ailerons (128.13s for delta and 347.48s for LLR), Barrett (377.03s for delta and 1650.55s for LLR). Showing that our rough estimator is significantly faster than Local Linear Regression while giving competitive performance. These timings were recorded on an Intel i7 processor with CPU @ 2.40 GHz and 12 GB of RAM.

Venn–Abers Predictors

Vladimir Vovk and Ivan Petej

Egham, Surrey, UK

Abstract

This paper continues study, both theoretical and empirical, of the method of Venn prediction, concentrating on binary prediction problems. Venn predictors produce probability-type predictions for the labels of test objects which are guaranteed to be well calibrated under the standard assumption that the observations are generated independently from the same distribution. We give a simple formalization and proof of this property. We also introduce Venn–Abers predictors, a new class of Venn predictors based on the idea of isotonic regression, and report promising empirical results both for Venn–Abers predictors and for their more computationally efficient simplified version.

1 INTRODUCTION

Venn predictors were introduced in [16] and are discussed in detail in [15], Chapter 6, but to make the paper self-contained we define them in Section 2. This section also states the important property of validity of Venn predictors: they are automatically well calibrated. In some form this property of validity has been known: see, e.g., [15], Theorem 6.6. However, this known version is complicated, whereas our version (Theorem 1 below) is much simpler and the intuition behind it is more transparent. In the same section we show (Theorem 2) that Venn prediction is essentially the only way to achieve our new property of validity.

Section 3 defines a natural class of Venn predictors, which we call Venn–Abers predictors (with the “Abers” part formed by the initial letters of the authors’ surnames of the paper [1] introducing the underlying technique). The latter are defined on top of a wide class of classification algorithms, which we call “scoring classifiers” in this paper; each scoring classifier can be automatically transformed into a Venn–Abers predictor, and we refer to this

transformation as the “Venn–Abers method”. Because of its theoretical guarantees, this method can be used for improving the calibration of probabilistic predictions.

The definition of Venn–Abers predictors was prompted by [8], which demonstrated that the method of calibrating probabilistic predictions introduced by Zadrozny and Elkan in [17] (an adaptation of the isotonic regression procedure of [1]) does not always achieve its goal and sometimes leads to poorly calibrated predictions. Another paper reporting the possibility for the Zadrozny–Elkan method to produce grossly miscalibrated predictions is [7]. The Venn–Abers method is a simple modification of Zadrozny and Elkan’s method; being a special case of Venn prediction, it overcomes the problem of potentially poor calibration.

Theorem 1 in Section 2 says that Venn predictors are perfectly calibrated. The price to pay, however, is that Venn predictors are multiprobabilistic predictors, in the sense of issuing a set of probabilistic predictions instead of a single probabilistic prediction; intuitively, the diameter of this set reflects the uncertainty of our prediction. In Section 5 we explore the efficiency of Venn–Abers predictors empirically using the fundamental log loss function and another popular loss function, square loss. To apply these loss functions, we need, however, probabilistic predictions rather than multiprobabilistic predictions, and in Section 4 we define natural minimax ways of replacing the latter with the former.

In Section 5 we explore the empirical predictive performance of the most natural version of the original Zadrozny–Elkan method, the Venn–Abers method, and the latter’s simplified version, which is not only simpler but also more efficient computationally. We use nine benchmark data sets from the UCI repository [5] and six standard scoring classifiers, and for each combination of a data set and classifier evaluate the predictive performance of each method. Our results show that the Venn–Abers and simplified Venn–Abers methods usually improve the performance of the underlying classifiers, and in our experiments they work better than the original Zadrozny–Elkan

method.

Interestingly, the predictive performance of the simplified Venn–Abers method is slightly better than that of the Venn–Abers method on the chosen data sets and scoring classifiers; for example, in the case of the log loss function, the best performance is achieved by the simplified Venn–Abers methods for seven data sets out of the nine. If these results are confirmed in wider empirical studies, the simplified Venn–Abers method is preferred since it achieves both computational and predictive efficiency.

Our empirical study in Section 5 does not mean that we recommend that the multiprobabilistic predictions output by Venn–Abers (and more generally Venn) predictors be replaced by probabilistic predictions (e.g., using the formulas of Section 4). On the contrary, we believe that the size of a multiprobabilistic prediction carries valuable information about the uncertainty of the prediction. The only purpose of replacing multiprobabilistic by probabilistic predictions is to facilitate comparison of various prediction algorithms using well-established loss functions.

2 VENN PREDICTORS

We consider *observations* $z = (x, y)$ consisting of two components: an *object* $x \in \mathbf{X}$ and its *label* $y \in \mathbf{Y}$. In this paper we are only interested in the binary case and for concreteness set $\mathbf{Y} := \{0, 1\}$. We assume that \mathbf{X} is a measurable space, so that observations are elements of the measurable space that is the Cartesian product $\mathbf{Z} := \mathbf{X} \times \mathbf{Y} = \mathbf{X} \times \{0, 1\}$.

A *Venn taxonomy* A is a measurable function that assigns to each $n \in \{2, 3, \dots\}$ and each sequence $(z_1, \dots, z_n) \in \mathbf{Z}^n$ an equivalence relation \sim on $\{1, \dots, n\}$ which is equivariant in the sense that, for each n and each permutation π of $\{1, \dots, n\}$,

$$(i \sim j \mid z_1, \dots, z_n) \implies (\pi(i) \sim \pi(j) \mid z_{\pi(1)}, \dots, z_{\pi(n)}),$$

where the notation $(i \sim j \mid z_1, \dots, z_n)$ means that i is equivalent to j under the relation assigned by A to (z_1, \dots, z_n) . The measurability of A means that for all n, i , and j the set $\{(z_1, \dots, z_n) \mid (i \sim j \mid z_1, \dots, z_n)\}$ is measurable. Define

$$\begin{aligned} A(j \mid z_1, \dots, z_n) \\ := \{i \in \{1, \dots, n\} \mid (i \sim j \mid z_1, \dots, z_n)\} \end{aligned}$$

to be the equivalence class of j . Let (z_1, \dots, z_l) be a training sequence of observations $z_i = (x_i, y_i)$, $i = 1, \dots, l$, and x be a test object. The *Venn predictor* associated with a given Venn taxonomy A outputs the pair (p_0, p_1) as its prediction for x 's label, where

$$p_y := \frac{|\{i \in A(l+1 \mid z_1, \dots, z_l, (x, y)) \mid y_i = 1\}|}{|A(l+1 \mid z_1, \dots, z_l, (x, y))|}$$

for both $y \in \{0, 1\}$ (notice that the denominator is always positive). Intuitively, p_0 and p_1 are the predicted probabilities that the label of x is 1; of course, the prediction is useful only when $p_0 \approx p_1$. The *probability interval* output by a Venn predictor is defined to be the convex hull $\text{conv}(p_0, p_1)$ of the set $\{p_0, p_1\}$; we will sometimes refer to the pair (p_0, p_1) or the set $\{p_0, p_1\}$ as the *multiprobabilistic prediction*.

Validity of Venn predictors

Let us say that a random variable P taking values in $[0, 1]$ is *perfectly calibrated* for a random variable Y taking values in $\{0, 1\}$ if

$$\mathbb{E}(Y \mid P) = P \quad \text{a.s.} \quad (1)$$

Intuitively, P is the prediction made by a probabilistic predictor for Y , and perfect calibration means that the probabilistic predictor gets the probabilities right, at least on average, for each value of the prediction. A probabilistic predictor for Y whose prediction P satisfies (1) with an approximate equality is said to be well calibrated [4], or unbiased in the small [11, 4]; this terminology will be used only in informal discussions, of course.

A *selector* is a random variable taking values 0 or 1.

Theorem 1. *Let $(X_1, Y_1), \dots, (X_l, Y_l), (X, Y)$ be IID (independent identically distributed) random observations. Fix a Venn predictor V and an $l \in \{1, 2, \dots\}$. Let (P_0, P_1) be the output of V given $(X_1, Y_1, \dots, X_l, Y_l)$ as the training set and X as the test object. There exists a selector S such that P_S is perfectly calibrated for Y .*

Intuitively, at least one of the two probabilities output by the Venn predictor is perfectly calibrated. Therefore, if the two probabilities tend to be close to each other, we expect them (or, say, their average) to be well calibrated.

In the proof of Theorem 1 and later in the paper we will use the notation $\wr a_1, \dots, a_n \wr$ for bags (in other words, multisets); the cardinality of the set $\{a_1, \dots, a_n\}$ might well be smaller than n (because of the removal of all duplicates in the bag). Intuitively, $\wr a_1, \dots, a_n \wr$ is the sequence (a_1, \dots, a_n) with its ordering forgotten. We will sometimes refer to the bag $\wr z_1, \dots, z_l \wr$, where (z_1, \dots, z_l) is the training sequence, as the training set (although technically it is a multiset rather than a set).

Proof of Theorem 1. Take $S := Y$ as the selector. Let us check that (1) is true even if we further condition on the observed bag $\wr (X_1, Y_1), \dots, (X_l, Y_l), (X, Y) \wr$ (so that the remaining randomness consists in generating a random permutation of this bag). We only need to check the equality $\mathbb{E}(Y \mid P = p) = p$, where P is the average of 1s in the equivalence class containing (X, Y) , for the p s which are the percentages of 1s in various equivalence classes (further

conditioning on the observed bag is not reflected in our notation). For each such p , $\mathbb{E}(Y \mid P = p)$ is the average of 1s in the equivalence classes for which the average of 1s is p ; therefore, we indeed have $\mathbb{E}(Y \mid P = p) = p$. \square

The following simple corollary of Theorem 1 gives a weaker property of validity, which is sometimes called “unbiasedness in the large” [11, 4].

Corollary 1. *For any Venn predictor V and any $l = 1, 2, \dots$,*

$$\mathbb{P}(Y = 1) \in \left[\mathbb{E}(\underline{V}(X; X_1, Y_1, \dots, X_l, Y_l)), \mathbb{E}(\overline{V}(X; X_1, Y_1, \dots, X_l, Y_l)) \right], \quad (2)$$

where $(X_1, Y_1), \dots, (X_l, Y_l), (X, Y)$ are IID observations and $[\underline{V}(\dots), \overline{V}(\dots)]$ is the probability interval produced by V for the test object X based on the training sequence $(X_1, Y_1, \dots, X_l, Y_l)$.

Proof. It suffices to notice that, for a selector S such that $P = P_S$ ((P_0, P_1) being the output of V) satisfies the condition of perfect calibration (1),

$$\begin{aligned} \mathbb{P}(Y = 1) &= \mathbb{E}(Y) = \mathbb{E}(\mathbb{E}(Y \mid P_S)) \\ &= \mathbb{E}(P_S) \in [\mathbb{E} \underline{V}, \mathbb{E} \overline{V}], \end{aligned}$$

where the arguments of \underline{V} and \overline{V} are omitted. \square

Unbiasedness in the large (2) is easy to achieve even for probabilistic predictors if we do not care about other measures of quality of our predictions: for example, the probabilistic predictor ignoring the x s and outputting k/l as its prediction, where k is the number of 1s in the training sequence of size l , is unbiased in the large. Unbiasedness in the small (1) is also easy to achieve if we allow multiprobabilistic predictors: consider the multiprobabilistic predictor ignoring the x s and outputting $\{k/(l+1), (k+1)/(l+1)\}$ as its prediction. The problem is how to achieve predictive efficiency (making our prediction as relevant to the test object as possible without overfitting) while maintaining validity.

Our following result, Theorem 2, will say that under mild regularity conditions unbiasedness in the small (1) holds only for Venn predictors (perhaps weakened by adding irrelevant probabilistic predictions) and, therefore, implies all other properties of validity, such as the more complicated one given in [15, Chapter 6].

To state Theorem 2 we need a few further definitions. Let us fix the length l of the training sequence for now. A *multiprobabilistic predictor* is a function that maps each sequence $(z_1, \dots, z_l) \in \mathbf{Z}^l$ to a subset of $[0, 1]$ (not required to be measurable in any sense). Venn predictors are an important example for this paper. Let us say that a multiprobabilistic predictor is *invariant* if it is independent of the ordering of the training set (z_1, \dots, z_l) . An *invariant selector*

for an invariant multiprobabilistic predictor F is a measurable function $f : \mathbf{Z}^{l+1} \rightarrow [0, 1]$ such that $f(z_1, \dots, z_{l+1})$ does not change when z_1, \dots, z_l are permuted and such that $f(z_1, \dots, z_{l+1}) \in F(z_1, \dots, z_l)$ for all (z_1, \dots, z_{l+1}) . (It is natural to consider only invariant predictors and selectors under the IID assumption because of the principle of sufficiency [3, Chap. 2].) We say that an invariant multiprobabilistic predictor F is *invariantly perfectly calibrated* if it has an invariant selector f such that

$$\begin{aligned} \mathbb{E}(Y \mid f(Z_1, \dots, Z_l, (X, Y))) \\ = f(Z_1, \dots, Z_l, (X, Y)) \quad \text{a.s.} \quad (3) \end{aligned}$$

whenever $Z_1, \dots, Z_l, (X, Y)$ are IID observations.

Theorem 2. *If an invariant multiprobabilistic predictor F is invariantly perfectly calibrated, then it contains a Venn predictor V in the sense that both elements of $V(Z_1, \dots, Z_l)$ belong to $F(Z_1, \dots, Z_l)$ almost surely provided Z_1, \dots, Z_l are IID.*

Proof. Let f be an invariant selector of F satisfying the condition (3) of being invariantly perfectly calibrated. By definition,

$$\begin{aligned} \mathbb{E}(Y - f(Z_1, \dots, Z_l, (X, Y)) \mid \\ f(Z_1, \dots, Z_l, (X, Y))) = 0 \quad \text{a.s.}, \end{aligned}$$

which implies

$$\begin{aligned} \mathbb{E}((Y - f(Z_1, \dots, Z_l, (X, Y))) \\ \mathbf{1}_{\{f(Z_1, \dots, Z_l, (X, Y)) \in [a, b]\}}) = 0 \quad \text{a.s.} \quad (4) \end{aligned}$$

for all intervals $[a, b]$ with rational end-points. The expected value in (4) can be obtained in two steps: first we average

$$(y'_{l+1} - f(z'_1, \dots, z'_{l+1})) \mathbf{1}_{\{f(z'_1, \dots, z'_{l+1}) \in [a, b]\}}$$

over the orderings (z'_1, \dots, z'_{l+1}) of each bag $\mathcal{Z}_{z_1, \dots, z_{l+1}}$, where $z_i = (x_i, y_i)$ and $z'_i = (x'_i, y'_i)$, and then we average over the bags $\mathcal{Z}_{z_1, \dots, z_{l+1}}$ generated according to $z_i := Z_i$, $i = 1, \dots, l$, and $z_{l+1} := (X, Y)$. The first operation is discrete: the average over the orderings of $\mathcal{Z}_{z_1, \dots, z_{l+1}}$ is the arithmetic mean of $(y_i - p_i) \mathbf{1}_{\{p_i \in [a, b]\}}$ over $i = 1, \dots, l+1$, where $p_i := f(\dots, z_i)$ and the dots stand for z_1, \dots, z_{i-1} and z_{i+1}, \dots, z_{l+1} arranged in any order (since f is invariant, the order does not matter). By the completeness of the statistic that maps a data sequence of size $l+1$ to the corresponding bag [10, Section 4.3], this average is zero for all $[a, b]$ and almost all bags. Without loss of generality we assume that this holds for all bags.

Define a Venn taxonomy A as follows: given a sequence (z_1, \dots, z_{l+1}) , set $i \sim j$ if $p_i = p_j$ where p is defined as above. It is easy to check that the corresponding Venn predictor satisfies the requirement in Theorem 2. \square

Remark. The invariance assumption in Theorem 2 is essential. Indeed, suppose $l > 1$ and consider the multiprobabilistic predictor whose prediction for the label of the test observation does not depend on the objects and is

$$\begin{cases} \{k/l, (k+1)/l\} & \text{if } y_1 = 0 \\ \{(k-1)/l, k/l\} & \text{if } y_1 = 1, \end{cases}$$

where k is the number of 1s among the labels of the l training observations. This non-invariant predictor is perfectly calibrated (see below) but does not contain a Venn predictor (if it did, such a Venn predictor, being invariant, would always output the one-element multiprobabilistic prediction $\{k/l\}$, which is impossible). Let us check that this non-invariant predictor is indeed perfectly calibrated, even given the union of the training set and the test observation (i.e., given the bag of size $l+1$ obtained from the training sequence by joining the test observation and then forgetting the ordering). Take the selector such that the selected probabilistic predictor is

$$\begin{cases} k/l & \text{for sequences of the form } 0 \dots 0 \\ (k+1)/l & \text{for sequences of the form } 0 \dots 1 \\ (k-1)/l & \text{for sequences of the form } 1 \dots 0 \\ k/l & \text{for sequences of the form } 1 \dots 1. \end{cases}$$

For a binary sequence of labels of length $l+1$ with m 1s the probabilistic prediction P for its last element will be, therefore,

$$\begin{cases} m/l & \text{for sequences of the form } 0 \dots 0 \\ m/l & \text{for sequences of the form } 0 \dots 1 \\ (m-1)/l & \text{for sequences of the form } 1 \dots 0 \\ (m-1)/l & \text{for sequences of the form } 1 \dots 1. \end{cases}$$

The conditional probability that $Y = 1$ (Y being the label of the last element) given $P = p$ (and given m) is

$$\frac{\binom{l-1}{m-1}}{\binom{l}{m}} = \frac{m}{l}$$

when $p = m/l$ and is

$$\frac{\binom{l-1}{m-2}}{\binom{l}{m-1}} = \frac{m-1}{l}$$

when $p = (m-1)/l$; in both cases we have perfect calibration.

3 VENN-ABERS PREDICTORS

We say that a function f is *increasing* if its domain is an ordered set and $t_1 \leq t_2 \Rightarrow f(t_1) \leq f(t_2)$.

Many machine-learning algorithms for classification are in fact *scoring classifiers*: when trained on a training sequence of observations and fed with a test object x , they

output a *prediction score* $s(x)$; we will call $s : \mathbf{X} \rightarrow \mathbb{R}$ the *scoring function* for that training sequence. The actual classification algorithm is obtained by fixing a threshold c and predicting the label of x to be 1 if and only if $s(x) \geq c$ (or if and only if $s(x) > c$). Alternatively, one could apply an increasing function g to $s(x)$ in an attempt to “calibrate” the scores, so that $g(s(x))$ can be used as the predicted probability that the label of x is 1.

Fix a scoring classifier and let (z_1, \dots, z_l) be a training sequence of observations $z_i = (x_i, y_i)$, $i = 1, \dots, l$. The most direct application [17] of the method of isotonic regression [1] to the problem of score calibration is as follows. Train the scoring classifier on the training sequence and compute the score $s(x_i)$ for each training observation (x_i, y_i) , where s is the scoring function for (z_1, \dots, z_l) . Let g be the increasing function on the set $\{s(x_1), \dots, s(x_l)\}$ that maximizes the likelihood

$$\prod_{i=1}^l p_i, \quad \text{where } p_i := \begin{cases} g(s(x_i)) & \text{if } y_i = 1 \\ 1 - g(s(x_i)) & \text{if } y_i = 0. \end{cases} \quad (5)$$

Such a function g is indeed unique [1, Corollary 2.1] and can be easily found using the “pair-adjacent violators algorithm” (PAVA, described in detail in the summary of [1] and in [2, Section 1.2]; see also the proof of Lemma 1 below). We will say that g is the *isotonic calibrator* for $((s(x_1), y_1), \dots, (s(x_l), y_l))$. To predict the label of a test object x , the direct method finds the closest $s(x_i)$ to $s(x)$ and outputs $g(s(x_i))$ as its prediction (in the case of ties our implementation of this method used in Section 5 chooses the smaller $s(x_i)$; however, ties almost never happen in our experiments). We will refer to this as the *direct isotonic regression* (DIR) method.

The direct method is prone to overfitting as the same observations z_1, \dots, z_l are used both for training the scoring classifier and for calibration without taking any precautions. The *Venn-Abers predictor* corresponding to the given scoring classifier is the multiprobabilistic predictor that is defined as follows. Try the two different labels, 0 and 1, for the test object x . Let s_0 be the scoring function for $(z_1, \dots, z_l, (x, 0))$, s_1 be the scoring function for $(z_1, \dots, z_l, (x, 1))$, g_0 be the isotonic calibrator for

$$((s_0(x_1), y_1), \dots, (s_0(x_l), y_l), (s_0(x), 0)), \quad (6)$$

and g_1 be the isotonic calibrator for

$$((s_1(x_1), y_1), \dots, (s_1(x_l), y_l), (s_1(x), 1)). \quad (7)$$

The multiprobabilistic prediction output by the Venn-Abers predictor is (p_0, p_1) , where $p_0 := g_0(s_0(x))$ and $p_1 := g_1(s_1(x))$. (And we can expect p_0 and p_1 to be close to each other unless DIR overfits grossly.) The Venn-Abers predictor is described as Algorithm 1.

The intuition behind Algorithm 1 is that it tries to evaluate the robustness of the DIR prediction. To see how sensitive the scoring function is to the training set we extend

Algorithm 1 Venn–Abers predictor

Input: training sequence (z_1, \dots, z_l) **Input:** test object x **Output:** multiprobabilistic prediction (p_0, p_1) **for** $y \in \{0, 1\}$ **do** set s_y to the scoring function for $(z_1, \dots, z_l, (x, y))$ set g_y to the isotonic calibrator for $(s_y(x_1), y_1), \dots, (s_y(x_l), y_l), (s_y(x), y))$ set $p_y := g_y(s_y(x))$ **end for**

the latter by adding the test object labelled in two different ways. And to see how sensitive the probabilistic prediction is, we again consider the training set extended in two different ways (if it is sensitive, the prediction will be fragile even if the scoring function is robust). For large data sets and inflexible scoring functions, we will have $p_0 \approx p_1$, and both numbers will be close to the DIR prediction. However, even if the data set is very large but the scoring function is very flexible, p_0 can be far from p_1 (the extreme case is where the scoring function is so flexible that it ignores all observations apart from a few that are most similar to the test object, and in this case it does not matter how big the data set is). We rarely know in advance how flexible our scoring function is relative to the size of the data set, and the difference between p_0 and p_1 gives us some indication of this.

The following proposition says that Venn–Abers predictors are Venn predictors and, therefore, inherit all properties of validity of the latter, such as Theorem 1.

Proposition 1. *Venn–Abers predictors are Venn predictors.*

Proof. Fix a Venn–Abers predictor. The corresponding Venn taxonomy is defined as follows: given a sequence

$$(z_1, \dots, z_n) = ((x_1, y_1), \dots, (x_n, y_n)) \in (\mathbf{X} \times \{0, 1\})^n$$

and $i, j \in \{1, \dots, n\}$, we set $i \sim j$ if and only if $g(s(x_i)) = g(s(x_j))$, where s is the scoring function for (z_1, \dots, z_n) and g is the isotonic calibrator for

$$((s(x_1), y_1), \dots, (s(x_n), y_n)).$$

Lemma 1 below shows that the Venn predictor corresponding to this taxonomy gives predictions identical to those given by the original Venn–Abers predictor. This proves the proposition. \square

Lemma 1. *Let g be the isotonic calibrator for*

$$((t_1, y_1), \dots, (t_n, y_n)),$$

where $t_i \in \mathbb{R}$ and $y_i \in \{0, 1\}$, $i = 1, \dots, n$. Any $p \in \{g(t_1), \dots, g(t_n)\}$ is equal to the arithmetic mean of the labels y_i of the t_i , $i = 1, \dots, n$, satisfying $g(t_i) = p$.

Proof. The statement of the lemma immediately follows from the definition of the PAVA [1, summary], which we will reproduce here. Arrange the numbers t_i in the strictly increasing order $t_{(1)} < \dots < t_{(k)}$, where $k \leq n$ is the number of distinct elements among t_i . We would like to find the increasing function g on the set $\{t_{(1)}, \dots, t_{(k)}\} = \{t_1, \dots, t_n\}$ maximizing the likelihood (defined by (5) with t_i in place of $s(x_i)$ and n in place of l). The procedure is recursive. At each step the set $\{t_{(1)}, \dots, t_{(k)}\}$ is partitioned into a number of disjoint cells consisting of adjacent elements of the set; to each cell is assigned a ratio a/N (formally, a pair of integers, with $a \geq 0$ and $N > 0$); the function g defined at this step (perhaps to be redefined at the following steps) is constant on each cell. For $j = 1, \dots, k$, let $a_{(j)}$ be the number of i such that $y_i = 1$ and $t_i = t_{(j)}$, and let $N_{(j)}$ be the number of i such that $t_i = t_{(j)}$. Start from the partition of $\{t_{(1)}, \dots, t_{(k)}\}$ into one-element cells, assign the ratio $a_{(j)}/N_{(j)}$ to $\{t_{(j)}\}$, and set

$$g(t_{(j)}) := \frac{a_{(j)}}{N_{(j)}} \quad (8)$$

(in the notation used in this proof, a/N is a pair of integers whereas $\frac{a}{N}$ is a rational number, the result of the division). If the function g is increasing, we are done. If not, there is a pair C_1, C_2 of adjacent cells (“violators”) such that C_1 is to the left of C_2 and $g(C_1) > g(C_2)$ (where $g(C)$ stands for the common value of $g(t_{(j)})$ for $t_{(j)} \in C$); in this case redefine the partition by merging C_1 and C_2 into one cell C , assigning the ratio $(a_1 + a_2)/(N_1 + N_2)$ to C , where a_1/N_1 and a_2/N_2 are the ratios assigned to C_1 and C_2 , respectively, and setting

$$\begin{aligned} g(t_{(j)}) &:= \frac{N_1}{N_1 + N_2} g(C_1) + \frac{N_2}{N_1 + N_2} g(C_2) \\ &= \frac{a_1 + a_2}{N_1 + N_2} \end{aligned} \quad (9)$$

for all $t_{(j)} \in C$. Repeat the process until g becomes increasing (the number of cells decreases by 1 at each iteration, so the process will terminate in at most k steps). The final function g is the one that maximizes the likelihood. The statement of the lemma follows from this recursive definition: it is true by definition for the initial function (8) and remains true when g is redefined by (9). \square

4 PROBABILISTIC PREDICTORS DERIVED FROM VENN PREDICTORS

In the next section we will compare Venn–Abers predictors with known probabilistic predictors using standard loss functions. Since Venn–Abers predictors output pairs of probabilities rather than point probabilities, we will need to fit them (somewhat artificially) in the standard framework extracting one probability p from p_0 and p_1 .

In this paper we will use two loss functions, log loss and square loss. The *log loss* suffered when predicting $p \in [0, 1]$ whereas the true label is y is

$$\lambda_{\ln}(p, y) := \begin{cases} -\ln(1-p) & \text{if } y = 0 \\ -\ln p & \text{if } y = 1. \end{cases}$$

This is the most fundamental loss function, since the cumulative loss $\sum_{i=1}^n \lambda_{\ln}(p_i, y_i)$ over a test sequence of size n is equal to the minus log of the probability that the predictor assigns to the sequence (this assumes either the batch mode of prediction with independent test observations or the on-line mode of prediction); therefore, a smaller cumulative log loss corresponds to a larger probability. The *square loss* suffered when predicting $p \in [0, 1]$ for the true label y is

$$\lambda_{\text{sq}}(p, y) := (y - p)^2.$$

The main advantage of this loss function is that it is *proper* (see, e.g., [4]): the function $\mathbb{E}_{y \sim B_p} \lambda_{\text{sq}}(q, y)$ of $q \in [0, 1]$, where B_p is the Bernoulli distribution with parameter p , attains its minimum at $q = p$. (Of course, the log loss function is also proper.)

First suppose that our loss function is λ_{\ln} and we are given a multiprobabilistic prediction (p_0, p_1) ; let us find the corresponding minimax probabilistic prediction p . If the true outcome is $y = 0$, our regret for using p instead of the appropriate p_0 is $-\ln(1-p) + \ln(1-p_0)$. If $y = 1$, our regret for using p instead of the appropriate p_1 is $-\ln p + \ln p_1$. The first regret as a function of $p \in [0, 1]$ strictly increases from a nonpositive value to ∞ as p changes from 0 to 1. The second regret as a function of p strictly decreases from ∞ to a nonpositive value as p changes from 0 to 1. Therefore, the minimax regret is the solution to

$$-\ln(1-p) + \ln(1-p_0) = -\ln p + \ln p_1,$$

which is

$$p = \frac{p_1}{1 - p_0 + p_1}. \quad (10)$$

The intuition behind this minimax value of p is that we can interpret the multiprobabilistic prediction (p_0, p_1) as the unnormalized probability distribution P on $\{0, 1\}$ such that $P(\{0\}) = 1 - p_0$ and $P(\{1\}) = p_1$; we then normalize P to get a genuine probability distribution $P' := P/P(\{0, 1\})$, and the p in (10) is equal to $P'(\{1\})$. Of course, it is always true that $p \in \text{conv}(p_0, p_1)$.

In the case of the square loss function, the regret is

$$\begin{cases} p^2 - p_0^2 & \text{if } y = 0 \\ (1-p)^2 - (1-p_1)^2 & \text{if } y = 1 \end{cases}$$

and the two regrets are equal when

$$p := p_1 + p_0^2/2 - p_1^2/2. \quad (11)$$

To see how natural this expression is notice that (11) is equivalent to

$$p = \bar{p} + (p_1 - p_0) \left(\frac{1}{2} - \bar{p} \right),$$

where $\bar{p} := (p_0 + p_1)/2$. Therefore, p is a regularized version of \bar{p} : we move \bar{p} towards the neutral value $1/2$ in the typical (for the Venn–Abers method) case where $p_0 < p_1$. In any case, we always have $p \in \text{conv}(p_0, p_1)$.

The following lemma shows that log loss is never infinite for probabilistic predictors derived from Venn predictors.

Lemma 2. *Neither of the methods discussed in this section (see (10) and (11)) ever produces $p \in \{0, 1\}$ when applied to Venn–Abers predictors.*

Proof. Lemma 1 implies that $p_0 < 1$ and that $p_1 > 0$. It remains to notice that both (10) and (11) produce p in the interior of $\text{conv}(p_0, p_1)$ if $p_0 \neq p_1$ and produce $p = p_0 = p_1$ if $p_0 = p_1$ (and this is true for any sensible averaging method). \square

5 EXPERIMENTAL RESULTS

In this section we compare various calibration methods discussed so far by applying them to six standard scoring classifiers (we will usually omit “scoring” in this section) available within Weka [6], a machine learning tool developed at the University of Waikato, NZ. The standard classifiers are J48 decision trees (abbreviated to J48, or even to J), J48 decision trees with bagging (J48 Bagging, or JB), logistic regression (LR), naïve Bayes (NB), neural networks (NN), and support vector machines calibrated using a sigmoid function as defined by Platt [13] (SVM Platt, or simply SVM). Each of these standard classifiers produces scores in the interval $[0, 1]$, which can then be used as probabilistic predictions; however, in most previous studies these have been found to be inaccurate (see [17] and [9]). We use the scores generated by classifiers as inputs, and by applying the DIR (defined in Section 3), Venn–Abers (VA), and simplified Venn–Abers (SVA, see below) methods we investigate how well we can calibrate the scores and improve them in their role as probabilistic predictions.

In the set of experiments described in this section we do not perform a direct comparison to the method developed by Langford and Zadrozny [9] primarily because, as far as we are aware, the algorithms described in their work are not publicly available.

For the purpose of comparison we use a total of nine datasets with binary labels (encoded as 0 or 1) obtained from the UCI machine learning repository [5]: Australian Credit (which we abbreviate to Australian), Breast Cancer (Breast), Diabetes, Echocardiogram (Echo), Hepatitis, Ionosphere, Labor Relations (Labor), Liver Disorders

Table 1: Log loss (MLE) results obtained using standard Weka classifiers (W) and the three calibration methods (VA, SVA, DIR) applied to the standard classifiers’ outputs for the following Weka classifiers: J48, J48 Bagging, logistic regression (upper part) and naïve Bayes, neural networks, and SVM Platt (lower part). The best results for each pair (classifier, dataset) are in bold.

(Liver), and Congressional Voting (Vote). The datasets vary in size as well as the number and type of attributes in order to give a reasonable range of conditions encountered in practice.

In our comparison we use the two standard loss functions discussed in the previous section. Namely, on a given test sequence of length n we will calculate the *mean log error* (MLE)

$$\frac{1}{n} \sum_{i=1}^n \lambda_{\ln}(p_i, y_i) \quad (12)$$

and the *root mean square error* (RMSE)

$$\sqrt{\frac{1}{n} \sum_{i=1}^n \lambda_{\text{sq}}(p_i, y_i)}, \quad (13)$$

where p_i is the probabilistic prediction for the label y_i of the i th observation in the test sequence. MLE (12) can be infinite, namely when predicting $p_i \in \{0, 1\}$ while being incorrect. It therefore penalises the overly confident probabilistic predictions much more significantly than RMSE. We compare the performance of the standard classifiers with their versions calibrated using the three methods (VA, SVA, and DIR) under both loss functions for each dataset. In each experiment we randomly permute the dataset and use the first 2/3 observations for training and the remaining 1/3 for testing.

One of the potential drawbacks of the Venn–Abers method is its computational inefficiency: for each test object the

scores have to be recalculated for the training sequence extended by including the test object first labelled as 0 and then labelled as 1. This implies that the total calculation time is at least $2n$ times that of the underlying classifier, where n is the number of test observations. Therefore, we define a simplified version of Venn–Abers predictors, for which the scores are calculated only once without recalculating them for each test object with postulated labels 0 and 1.

In detail, the *simplified Venn–Abers predictor* for a given scoring classifier is defined as follows. Let (z_1, \dots, z_l) be a training sequence and x be a test object. Define s to be the scoring function for (z_1, \dots, z_l) , g_0 to be the isotonic calibrator for

$$((s(x_1), y_1), \dots, (s(x_l), y_l), (s(x), 0)),$$

and g_1 to be the isotonic calibrator for

$$((s(x_1), y_1), \dots, (s(x_l), y_l), (s(x), 1)))$$

(cf. (6) and (7)). The multiprobabilistic prediction output for the label of x by the simplified Venn–Abers (SVA) predictor is (p_0, p_1) , where $p_0 := g_0(s(x))$ and $p_1 := g_1(s(x))$. This method, summarized as Algorithm 2, is intermediate between DIR and the Venn–Abers method.

Notice that Lemma 2 continues to hold for SVA predictors; therefore, they never suffer infinite loss even under the log loss function. On the other hand, the following proposition shows that SVA predictors can violate the property (2) of

Table 2: The analogue of Table 1 for square loss (RMSE).

Algorithm 2 Simplified Venn–Abers predictor

Input: training sequence (z_1, \dots, z_l)

Input: test object x

Output: multiprobabilistic prediction (p_0, p_1)

for $y \in \{0, 1\}$ **do**

 set s to the scoring function for (z_1, \dots, z_l)

 set g_y to the isotonic calibrator for

$(s(x_1), y_1), \dots, (s(x_l), y_l), (s(x), y))$

 set $p_y := g_y(s(x))$

end for

unbiasedness in the large; in particular, they are not Venn predictors (cf. Corollary 1).

Proposition 2. *There exists a simplified Venn–Abers predictor violating (2) for some l .*

Proof. Let the object space be the real line, $\mathbf{X} := \mathbb{R}$, and the probability distribution generating independent observations (X, Y) be such that: the marginal distribution of X is continuous; the probability that $X > 0$ (and, therefore, the probability that $X < 0$) is $1/2$; the probability that $Y = 1$ given $X < 0$ is $1/3$; the probability that $Y = 1$ given $X > 0$ is $2/3$. Therefore, $\mathbb{P}(Y = 1) = 1/2$. Let l be a large number (we are using a somewhat informal language, but formalization will be obvious). Given a training set (z_1, \dots, z_l) , where $z_i = (x_i, y_i)$ for all i , the scoring function s is:

$$s(x) := \begin{cases} 0 & \text{if } x \in \{x_1, \dots, x_l\} \text{ and } x < 0 \\ 1 & \text{if } x \in \{x_1, \dots, x_l\} \text{ and } x > 0 \\ 2 & \text{if } x \notin \{x_1, \dots, x_l\}. \end{cases}$$

It is easy to see that, with high probability,

$$\underline{V} \approx 2/3, \quad \bar{V} = 1.$$

Therefore, (2) is violated. \square

Proposition 2 shows that SVA predictors are not always valid; however, the construction in its proof is artificial, and our hope is that they will be “nearly valid” in practice, since they are a modification of provably valid predictors.

For each dataset/classifier combination, we repeat the same experiment a total of 100 times for standard classifiers (denoted W in the tables), SVA, and DIR and 16 times for VA (because of the computational inefficiency of the latter) and average the results. The same 100 random splits into training and test sets are used for W, SVA, and DIR, but for VA the 16 splits are different.

Tables 1–2 compare the overall losses computed according to (12) (MLE, used in Table 1) and (13) (RMSE, used in Table 2) for probabilities generated by the standard classifiers as implemented in Weka (W) and the corresponding Venn–Abers (VA), simplified Venn–Abers (SVA), and direct isotonic-regression (DIR) predictors. The values in bold indicate the lowest of the four losses for each dataset/classifier combination. The column titles mention both fuller and shorter names for the six standard classifiers; the short name “SVM” is especially appropriate when using VA, SVA, and DIR, in which case the application of the sigmoid function in Platt’s method is redundant. The three entries of ∞ in the column W for logistic regression of Table 1 come out as infinities in our experiments only because of the limited machine accuracy: logistic regres-

sion sometimes outputs probabilistic predictions that are so close to 0 or 1 that they are rounded to 0 or 1, respectively, by hardware.

In the case of MLE, the VA and SVA methods improve the predictive performance of the majority of the standard classifiers on most datasets. A major exception is J48 Bagging. The application of bagging to J48 decision trees improves the calibration significantly as bagging involves averaging over different training sets in order to reduce the underlying classifier's instability. The application of VA and SVA to J48 Bagging is not found to improve the log or square loss significantly. What makes VA and SVA useful is that for many data sets other classifiers, less well calibrated than J48 Bagging, provide more useful scores.

In the case of RMSE, the application of VA and SVA also often improves probabilistic predictions.

Whereas in the case of square loss the DIR method often produces values comparable to VA and SVA, under log loss this method fares less well (which is not obvious from [17], which only uses square loss). In all our experiments DIR suffers infinite log loss for at least one test observation, which makes the overall MLE infinite. There are modifications of the DIR method preventing probabilistic predictions in $\{0, 1\}$ (such as those mentioned in [12], Section 3.3), but they are somewhat arbitrary.

Table 3 ranks, for each loss function and dataset, the four calibration methods: W (none), VA (Venn–Abers), SVA (simplified Venn–Abers), and DIR (direct isotonic regression). Only the first three methods are given (the best, the second best, and the second worst), where the quality of a method is measured by the performance of the best underlying classifier (indicated in parentheses using the abbreviations given in the column titles of Tables 1–2) for the given method, data set, and loss function. Notice that we are ranking the four calibration methods rather than the 24 combinations of Weka classifiers with calibration methods (e.g., were we ranking the 24 combinations, the entry for log loss and Australian would remain the same but the next entry, for log loss and Breast, would become “SVA (NB), VA (NB), VA (LR)”).

For MLE, the best algorithm is VA or SVA for 8 data sets out of 9; for RMSE this is true for 6 data sets out of 9. In all other cases the best algorithm is W rather than DIR. (And as discussed earlier, in the case of log loss the performance of DIR is especially poor.) Therefore, it appears that the most interesting comparisons are between W and VA and between W and SVA.

What is interesting is that VA and SVA perform best on equal numbers of datasets, 4 each in the case of MLE and 3 each in the case of RMSE, despite the theoretical guarantees of validity for the former method (such as Theorem 1). The similar performance of the two methods needs

to be confirmed in more extensive empirical studies, but if it is, SVA will be a preferable method because of its greater computational efficiency.

Comparing W and SVA, we can see that SVA performs better than W on 7 data sets out of 9 for MLE, and on 5 data sets out of 9 for RMSE. And comparing W and VA, we can see that VA performs better than W on 6 data sets out of 9 for MLE, and on 5 data sets out of 9 for RMSE. This suggests that SVA might be an improvement of VA not only in computational but also in predictive efficiency (but the evidence for this is very slim).

6 CONCLUSION

This paper has introduced a new class of Venn predictors thereby extending the domain of applicability of the method. Our experimental results suggest that the Venn–Abers method can potentially lead to better calibrated probabilistic predictions for a variety of datasets and standard classifiers. The method seems particularly suitable in cases where alternative probabilistic predictors produce overconfident but erroneous predictions under an unbounded loss function such as log loss. In addition, the results suggest that an alternative simplified Venn–Abers method can yield similar results while retaining computational efficiency.

Unlike the previous methods for improving the calibration of probabilistic predictors, Venn–Abers predictors enjoy theoretical guarantees of validity (shared with other Venn predictors).

Acknowledgments

Thanks to the reviewers for helpful comments, which prompted us to state explicitly Proposition 2 and add several clarifications. In our experiments in Section 5 we used the R language [14]; in particular, we used the implementation of the PAVA in the standard R package `stats` (namely, the function `isoreg`). The first author has been partially supported by EPSRC (grant EP/K033344/1).

Tightness Results for Local Consistency Relaxations in Continuous MRFs

Yoav Wald

Abstract

Finding the MAP assignment in graphical models is a challenging task that generally requires approximations. One popular approximation approach is to use linear programming relaxations that enforce local consistency. While these are commonly used for discrete variable models, they are much less understood for models with continuous variables.

Here we define local consistency relaxations of MAP for continuous pairwise Markov Random Fields (MRFs), and analyze their properties. We begin by providing a characterization of models for which this relaxation is tight. These turn out to be models that can be reparameterized as a sum of local convex functions. We also provide a simple formulation of this relaxation for Gaussian MRFs.

Next, we show how the above insights can be used to obtain optimality certificates for loopy belief propagation (LBP) in such models. Specifically, we show that the messages of LBP can be used to calculate upper and lower bounds on the MAP value, and that these bounds coincide at convergence, yielding a natural stopping criterion which was not previously available.

Finally, our results illustrate a close connection between local consistency relaxations of MAP and LBP. They demonstrate that in the continuous case, whenever LBP is provably optimal so is the local consistency relaxation.

1 INTRODUCTION

Graphical models [13] have become a key tool for describing multivariate distributions. For many models of interest, the basic inference task of finding the most likely assignment (also known as the MAP assignment) is computationally hard [26], and one must resort to approximations.

When the model variables are discrete, a popular approximation scheme is linear programming relaxations (LPR). These approximate the MAP problem via minimization of a linear function over locally consistent *pseudo-marginals*. LPRs have several advantages: they provide optimality certificates, they can be optimized via message passing algorithms, they work well in practice, and they are provably exact in some cases (e.g., binary attractive models and trees) [8, 27, 28, 36, 11].

For models with continuous variables, it is less clear how to apply the local consistency perspective of LPRs. For example, the *pseudo-marginals* now become functions rather than a discrete set of variables. Moreover, the standard consistency constraints translate into a continuum of constraints. The goal of the current paper is to study such relaxations and understand when they are tight.

Another commonly used approximate inference algorithm is loopy belief propagation (LBP)[37]. It works by passing messages along the graph, in a manner motivated by variable elimination on tree structured models. Although LBP and LPR are generally distinct algorithms, there are cases where both are exact. For example, both yield the exact MAP for tree models, maximum weight matching [3, 24] and a few other problems (see Section 8). However, there is still no general result linking LPR and LBP. Since LBP in the continuous case is fairly well understood [16, 17], we will want to link our results to known results on LBP.

We begin by defining local consistency MAP relaxations for continuous models. Technically, these will be constructed in an analogous way to the LP relaxations for discrete variables. However, they will typically not correspond to standard linear programs and thus we refer to them as local consistency relaxations (LCRs).

We obtain several surprising results on LCRs. For simplicity of presentation we focus on pairwise MRFs, but extensions to larger cliques are possible (see Section 7). Our first key result is to show that the LCR of a model is tight if the model is “convex decomposable” (CD). A model is CD if it can be expressed as a sum of pairwise convex functions

(see [17] for a similar definition).

For continuous MRFs there are several cases where LBP is known to converge to the exact MAP. It is thus of interest to relate these to our LCR results in order to further our understanding of the relation between these two approximation schemes. The relation turns out to be simple and interesting. For Gaussian MRFs LBP is provably optimal when the model is walk-summable [16, 18], a property which turns out to be equivalent to convex decomposability of the model. In other words LCR and LBP are both exact on these models. For general MRFs, LBP is provably optimal for models that are scaled diagonally dominant [17]. These turn out to be a strict subset of CD models, suggesting that either LCR is a stronger approximation or that stronger properties of LBP can be shown.

The above results on LCR and the relation to LBP lead to an important practical implication. It turns out we can use these insights to obtain runtime optimality certificates for loopy belief propagation (LBP) in a wide range of models. Specifically, we show that the messages of LBP can be used to calculate upper and lower bounds on the MAP value, and that these bounds coincide at convergence, yielding a natural stopping criterion for LBP, which was not previously available.

2 MAP IN CONTINUOUS MRFs

We begin by recalling MAP inference in graphical models and how LP relaxations are used to obtain approximate solutions of the problem.

Consider n variables X_1, \dots, X_n , and a set of singleton and pairwise functions $f_i(x_i), f_{ij}(x_i, x_j)$ where the pairs ij are a set of edges of a graph $G = (V, E)$. Use these to define a function over $\mathbf{x} = x_1, \dots, x_n$:

$$F(\mathbf{x}) = \sum_i f_i(x_i) + \sum_{ij} f_{ij}(x_i, x_j). \quad (1)$$

For now we do not assume anything about the state spaces of the variables. We refer to $F(\mathbf{x})$ as an MRF over X_1, \dots, X_n and consider the MAP problem of minimizing $F(\mathbf{x})$.¹

It will be convenient in what follows to express $F(\mathbf{x})$ as a linear function of certain functions of \mathbf{x} (our notation follows that of [33]). Assume there exists a vector of functions $\phi_i(x_i)$ of x_i , and a vector θ_i such that:

$$f_i(x_i) = \langle \theta_i, \phi_i(x_i) \rangle.$$

For example if $\phi_i(x_i) = [x_i, x_i^2]$ then $f_i(x_i)$ is the quadratic function $f_i(x_i) = \theta_{i,1}x_i + \theta_{i,2}x_i^2$. Similarly

¹We refer to this as the MAP problem since it corresponds to finding the maximum a posteriori assignment to \mathbf{x} in the model $p(\mathbf{x}) \propto \exp(-F(\mathbf{x}))$.

assume there exist functions $\phi_{i,j}(x_i, x_j)$ and vectors θ_{ij} such that:

$$f_{ij}(x_i, x_j) = \langle \theta_{ij}, \phi_{ij}(x_i, x_j) \rangle. \quad (2)$$

Denote the concatenation of all θ_i, θ_{ij} by θ and the concatenation of all ϕ_i, ϕ_{ij} functions by ϕ . Furthermore, denote the dimension of θ and ϕ by m . We can thus write:

$$F(\mathbf{x}) = \langle \theta, \phi(\mathbf{x}) \rangle, \quad (3)$$

The MAP problem has an equivalent formulation in terms of mean parameters, as shown in [33] and as reviewed next. We define the set of realizable mean parameters:

$$\mathcal{M} = \{ \mu \in \mathbb{R}^m : \exists \hat{p} \in \Delta \text{ s.t. } \mathbb{E}_{\hat{p}}[\phi(\mathbf{x})] = \mu \},$$

where Δ is the set of densities over \mathbf{x} . It can be then shown that the MAP problem corresponds to optimization of a linear function over the set \mathcal{M} .

Theorem 2.1. [33] *For the MRF as defined above and the corresponding \mathcal{M} it holds that*²:

$$\min_{\mathbf{x}} F(\mathbf{x}) = \min_{\mu \in \mathcal{M}} \langle \theta, \mu \rangle. \quad (4)$$

The problem in Eq. (4) has a linear objective over m variables. m is usually not much larger than n , yet the definition of \mathcal{M} involves variables corresponding to densities and thus is generally hard to characterize explicitly. However, there are continuous variable cases where \mathcal{M} does have a compact form. For example, in Gaussian MRFs \mathcal{M} can be expressed via positive semi definiteness constraints (see [33, sec. 3.4.1]).

Finally, we recall the definition of a reparameterization of an MRF.

Definition 1. *We call any set of functions $\bar{f}_i(x_i), \bar{f}_{ij}(x_i, x_j)$ a reparameterization of $F(\mathbf{x})$ if it holds that for every \mathbf{x} :*

$$F(\mathbf{x}) = \sum_i \bar{f}_i(x_i) + \sum_{ij} \bar{f}_{ij}(x_i, x_j). \quad (5)$$

3 LOCAL CONSISTENCY RELAXATIONS

Optimizing over the set \mathcal{M} is generally hard. When X are discrete variables \mathcal{M} will involve an exponential number of inequalities. When X are continuous, even in cases where \mathcal{M} is tractable to optimize over, this optimization may be costly (e.g., a semidefinite program). This has prompted considerable research on relaxations of \mathcal{M} and the resulting optimization problem. Most of the work in this context has focused on discrete variables as reviewed next. Our goal is then to extend this framework to the continuous case.

²We note that the right hand side of Eq. (4) should have $\bar{\mathcal{M}}$ instead of \mathcal{M} . The closure is omitted for simplicity of presentation.

3.1 LCR FOR DISCRETE VARIABLES

Consider the case where X_i are discrete variables, each with D values, and the functions ϕ are defined as follows. $\phi_i(x_i)$ is D dimensional with $\phi_{i,k}(x_i) = \mathcal{I}(x_i = k)$, and $\phi_{ij}(x_i, x_j)$ is $D \times D$ dimensional with $\phi_{ij,kl}(x_i, x_j) = \mathcal{I}(x_i = k, x_j = l)$. The expected values $\mathbb{E}_{\hat{p}}[\phi_i(x_i)]$ and $\mathbb{E}_{\hat{p}}[\phi_{ij}(x_i, x_j)]$ are simply the singleton marginals $\hat{p}(x_i)$ and $\hat{p}(x_i, x_j)$ respectively. Thus, \mathcal{M} corresponds to the set of all singleton and pairwise marginals that are achieved by some distribution $\hat{p}(\mathbf{x})$. This is also known as the marginal polytope [33].

As mentioned earlier, the marginal polytope generally requires an exponential number of inequalities to describe. One natural alternative is to consider a *local consistency relaxation* (LCR) where instead of requiring the marginals to come from a “global” distribution $\hat{p}(\mathbf{x})$ we just require the singleton and pairwise marginals to be consistent. In other words, we define the set \mathcal{M}_L as the set of locally consistent pairwise marginals:

$$\mathcal{M}_L = \left\{ \boldsymbol{\mu} \geq 0 : \begin{array}{l} \sum_{x_i} \mu_i(x_i) = 1 \\ \sum_{x_j} \mu_{ij}(x_i, x_j) = \mu_i(x_i) \quad \forall ij, x_i. \end{array} \right\}$$

The local relaxation of the MAP problem is then to minimize $\boldsymbol{\mu} \cdot \boldsymbol{\theta}$ over $\boldsymbol{\mu} \in \mathcal{M}_L$ instead of $\boldsymbol{\mu} \in \mathcal{M}$. We next consider the extension of this relaxation to the continuous variable case.

3.2 LCR FOR CONTINUOUS VARIABLES

For continuous variables, a natural extension of the above is to replace the sum in the local consistency constraints with an integral:

$$\mathcal{M}_L = \left\{ \boldsymbol{\mu} : \begin{array}{l} \exists \text{ densities } \hat{p}_i, \hat{p}_{ij} \text{ s.t.} \\ \int \hat{p}_{ij}(x_i, x_j) dx_j = \hat{p}_i(x_i) \quad \forall ij, x_i \\ \mathbb{E}_{\hat{p}_i}[\phi_i(x_i)] = \boldsymbol{\mu}_i \quad \forall i \\ \mathbb{E}_{\hat{p}_{ij}}[\phi_{ij}(x_i, x_j)] = \boldsymbol{\mu}_{ij} \quad \forall ij. \end{array} \right\} \quad (6)$$

In other words we consider all pairwise consistent densities, and \mathcal{M}_L are all the expected values obtained from such densities. As in the discrete case the local relaxation of MAP is then the problem:

$$\min_{\boldsymbol{\mu} \in \mathcal{M}_L} \langle \boldsymbol{\theta}, \boldsymbol{\mu} \rangle. \quad (7)$$

Note that because $\mathcal{M} \subseteq \mathcal{M}_L$, the above minimum is a lower bound on the true MAP value (as in the case of discrete models [29]).

The key question we ask here is: for which cases is the relaxation in Eq. (7) tight? Before presenting our main result (Thm. 4.1), we will define an even looser relaxation in the next section which will be important for our analysis.

3.3 WEAK LCR AND ITS DUAL

In the constraints of Eq. (6) we require the singleton and pairwise marginals to be completely consistent. Namely, that $\hat{p}_{ij}(x_i)$, the marginal density calculated from $\hat{p}_{ij}(x_i, x_j)$ will equal $\hat{p}_i(x_i)$ for all x_i values. A weaker consistency constraint is to enforce that $\hat{p}_{ij}(x_j)$ and $\hat{p}_i(x_i)$ agree only on certain expected values. We next define the set corresponding to this constraint.

Given a vector of functions $\boldsymbol{\psi}_i(x_i)$ for each $i \in V$,³ we define the set:

$$\mathcal{M}_L^\boldsymbol{\psi} = \left\{ \boldsymbol{\mu} : \begin{array}{l} \exists \text{ densities } \hat{p}_i, \hat{p}_{ij} \text{ s.t.} \\ \mathbb{E}_{\hat{p}_{ij}}[\boldsymbol{\psi}_i(x_i)] = \mathbb{E}_{\hat{p}_i}[\boldsymbol{\psi}_i(x_i)] \quad \forall ij \\ \mathbb{E}_{\hat{p}_i}[\phi_i(x_i)] = \boldsymbol{\mu}_i \quad \forall i \\ \mathbb{E}_{\hat{p}_{ij}}[\phi_{ij}(x_i, x_j)] = \boldsymbol{\mu}_{ij} \quad \forall ij. \end{array} \right\}$$

Thus $\mathcal{M}_L^\boldsymbol{\psi}$ enforces consistency only in the sense that $\hat{p}_{ij}(x_j)$ and $\hat{p}_i(x_i)$ agree on the expected values of $\boldsymbol{\psi}_i$. Thus, for any choice of $\boldsymbol{\psi}$ we have $\mathcal{M}_L \subseteq \mathcal{M}_L^\boldsymbol{\psi}$.

The corresponding relaxation is then defined as:

$$\min_{\boldsymbol{\mu} \in \mathcal{M}_L^\boldsymbol{\psi}} \langle \boldsymbol{\theta}, \boldsymbol{\mu} \rangle. \quad (8)$$

Basic relations between the relaxations we consider are thus summarized by the inequalities:

$$\min_{\boldsymbol{\mu} \in \mathcal{M}_L^\boldsymbol{\psi}} \langle \boldsymbol{\theta}, \boldsymbol{\mu} \rangle \leq \min_{\boldsymbol{\mu} \in \mathcal{M}_L} \langle \boldsymbol{\theta}, \boldsymbol{\mu} \rangle \leq \min_{\boldsymbol{\mu} \in \mathcal{M}} \langle \boldsymbol{\theta}, \boldsymbol{\mu} \rangle = \min_{\mathbf{x}} F(\mathbf{x}).$$

The dual of Eq. (8) will play an important role in subsequent sections:

Lemma 3.1. *Given a pairwise MRF with functions $f_i(x_i), f_{ij}(x_i, x_j)$, the following is a dual problem of Eq. (8):*

$$\max_{\boldsymbol{\delta}} \sum_i \min_{x_i} \left\{ f_i(x_i) + \sum_{j \in N(i)} \langle \boldsymbol{\delta}_{ji}, \boldsymbol{\psi}_i(x_i) \rangle \right\} + \sum_{ij} \min_{x_i, x_j} \left\{ f_{ij}(x_i, x_j) - \langle \boldsymbol{\delta}_{ji}, \boldsymbol{\psi}_i(x_i) \rangle - \langle \boldsymbol{\delta}_{ij}, \boldsymbol{\psi}_j(x_j) \rangle \right\}. \quad (9)$$

We note that the bound achieved by this dual, and hence by weak LCR, is dependent on the reparameterization $f_i(x_i), f_{ij}(x_i, x_j)$ being used. The full LCR Eq. (7) may also yield different optimization problems for different reparameterizations, yet it turns out that the bound it achieves is invariant to the reparameterization. The proof of the following lemma can be found in the supplementary material.

Lemma 3.2. *LCR has the same value under any reparameterization $\{f_i(x_i), f_{ij}(x_i, x_j)\}$ of $F(x)$.*

³For example, $\boldsymbol{\psi}_i(x_i)$ could be $[x_i, x_i^3]$.

4 TIGHTNESS OF LCR ON CONVEX DECOMPOSABLE MODELS

We are now ready to provide our main result on the tightness of LCRs. We first recall the definition of Convex Decomposable (CD) models, as introduced by [17]⁴ in the context of LBP analysis. Next, we show that in these models the local consistency relaxation in Eq. (7) is exact.

Definition 2. *A pairwise MRF is convex decomposable if there exists a reparameterization $f_i(x_i), f_{ij}(x_i, x_j)$ of $F(\mathbf{x})$ such that all the functions in the reparameterization are convex.*

Our result regarding tightness of LCR on CD MRFs is stated in the following theorem:

Theorem 4.1. *For any CD pairwise MRF it holds that*

$$\min_{\mu \in \mathcal{M}_L} \langle \theta, \phi(\mathbf{x}) \rangle = \min_{\mathbf{x}} F(\mathbf{x}).$$

The proof is provided in the appendix. It relies on the following insights:

- From Lem. 3.2, the dual of weak LCR Eq. (9) taken with respect to any reparameterization of $F(\mathbf{x})$ is a lower bound on LCR's value.
- Specifically, we can consider Eq. (9) with $\psi_i = [x_i]$ when the reparameterization $f_i(x_i), f_{ij}(x_i, x_j)$ contains convex functions.
- Assuming \mathbf{x}^* is a MAP assignment, the dual assignment δ^* obtained by setting multipliers according to a subgradient of the pairwise functions $f_{ij}(x_i, x_j)$ taken at \mathbf{x}^* , achieves a dual objective of $F(\mathbf{x}^*)$ in Eq. (9).
- LCR's value cannot be lower than weak LCR's value, which in turn cannot be lower than $F(\mathbf{x}^*)$ because we constructed a dual assignment that achieves this objective. LCR is a lower bound on MAP, so that equality must hold.

4.1 RELATION TO LOOPY BP

In [17] it is shown that loopy BP is exact (i.e., guaranteed to converge to the true MAP assignment) on a class of models that satisfy scaled diagonal dominance. These are a strict subset of CD models. In particular, they require that a model is CD as well as its Hessian being scaled diagonally dominant. That is, there must exist a strictly positive vector $\mathbf{w} \in \mathbb{R}^n$ and a $0 < \lambda < 1$ such that for any \mathbf{x} it holds:

$$\sum_{j \in N(i)} w_j \left| \frac{\partial^2}{\partial x_i \partial x_j} F(\mathbf{x}) \right| \leq \lambda w_i \frac{\partial^2}{\partial x_i^2} F(\mathbf{x}).$$

⁴We note that the definition in [17] poses the additional demands of differentiability and that $f_i(x_i)$ are strictly convex, so the class we define here is a larger one.

Thus, we conclude that given currently known exactness results on LBP, the LCR approximation is stronger in the sense that it is exact whenever LBP is known to be exact. It remains an open question whether it can be shown that LBP is exact on CD models.

5 GAUSSIAN MRFs AND THEIR RELAXATION

Gaussian MRFs (GMRFs) have been studied widely, and are also of practical interest [5, 6, 16, 18, 34]. Here we give a simple characterization of \mathcal{M}_L for GMRFs, and then discuss when the corresponding relaxations are tight. We give a stronger result than Theorem 4.1 by showing that LCR is tight *if and only if* the Gaussian model is CD. Specifically, we show that for non CD models the LCR optimization problem has a value of $-\infty$, and is thus a meaningless relaxation.

Recall that a GMRF $F(\mathbf{x})$ is a quadratic form:

$$F(\mathbf{x}) = \frac{1}{2} \mathbf{x}^\top \Gamma \mathbf{x} - \mathbf{h}^\top \mathbf{x},$$

where $\Gamma \geq 0$. The function vectors $\phi_i(x_i), \phi_{ij}(x_i, x_j)$ for this type of MRF are given by

$$\phi_i(x_i) = \{x_i, x_i^2\}, \phi_{ij}(x_i, x_j) = \{x_i x_j\}. \quad (10)$$

As stated in [33], the set of realizable mean parameters \mathcal{M} in this case is the set of all first and second moments that can be realized by a density \hat{p} . Namely:

$$\mathcal{M} = \{(\Sigma, \boldsymbol{\eta}) : \Sigma - \boldsymbol{\eta} \boldsymbol{\eta}^\top \geq 0\}. \quad (11)$$

Here the elements Σ_{ij} correspond to the expected values of $x_i x_j$, the diagonal elements Σ_{ii} are the expected values of x_i^2 and $\boldsymbol{\eta}$ are the expected values of x_i .

5.1 A CHARACTERIZATION OF \mathcal{M}_L FOR GMRFs

Given this simple form of \mathcal{M} , it is interesting to see what \mathcal{M}_L translates into for this case. To characterize \mathcal{M}_L we define:

Definition 3. *Given an $n \times n$ matrix A , and an edge $(i, j) \in E$, define the following sub matrix of A*

$$A_{[ij]} = \begin{bmatrix} A_{ii} & A_{ij} \\ A_{ji} & A_{jj} \end{bmatrix}.$$

Similarly, for an n dimensional vector v , define

$$v_{[ij]} = \begin{bmatrix} v_i \\ v_j \end{bmatrix}.$$

Claim 5.1. *For GMRFs it holds that*

$$\mathcal{M}_L = \{(\Sigma, \boldsymbol{\eta}) : \Sigma_{[ij]} - \boldsymbol{\eta}_{[ij]} \boldsymbol{\eta}_{[ij]}^\top \geq 0 \forall ij \in E\}. \quad (12)$$

The proof can be found in the appendix. The characterization is very intuitive: it says that Σ should be such that its pairwise submatrices are valid covariance matrices of two variables with mean given by η .

5.1.1 LCR is Unbounded for non-CD GMRFs

We now turn to give a full characterization of the GMRFs on which LCR is tight. From Thm. 4.1 we know that whenever a GMRF is convex decomposable then LCR is tight, yet we do not know if tightness holds for any other GMRFs. It turns out that it does not, and in fact the objective of LCR is unbounded for non CD models. The proof relies on the following two claims. First we claim that for GMRFs, under a certain choice of $\psi_i(x_i)$, \mathcal{M}_L^ψ as given for the weak LCR in Eq. (8) is equal to \mathcal{M}_L :

Claim 5.2. *Let \mathcal{M}_L be the set defined in Eq. (6) with the functions in Eq. (10). For $\psi_i(x_i) = [x_i, x_i^2]$ it holds that:*

$$\mathcal{M}_L = \mathcal{M}_L^\psi. \quad (13)$$

From Claim 5.2 we gather that weak LCR achieves the same bound as LCR, and that Eq. (9) is also a dual of LCR. The second claim then states that Eq. (9) is unbounded when the GMRF is not CD.

Claim 5.3. *For any non-CD GMRF, the value of Eq. (9) taken with $\psi_i(x_i) = [x_i, x_i^2]$ is $-\infty$ for any choice of δ .*

The proof of both claims is provided in the appendix. It is easy to check that Slater's conditions hold for LCR as defined by Eq. (12) (see e.g. [4, p. 523] for the conditions). Thus when the optimum of LCR is bounded (i.e. larger than $-\infty$), strong duality holds and Eq. (9) obtains the same optimal value. Claim 5.3 states that this does not happen for non-CD GMRFs. We have thus shown the following corollary:

Corollary 5.4. *LCR is unbounded on any non-CD GMRF.*

5.2 RELATION TO LOOPY BP

Several works have analyzed the properties of LBP when applied to GMRFs [16, 34, 18]. These show that when a model is CD then LBP is exact.⁵ Note that the definition of convex decomposability used in [18] is somewhat more restrictive than what we consider here. It requires the pairwise functions $f_{ij}(x_i, x_j)$ in the convex decomposition to be strictly convex.

Given our results above, we conclude that LCR is exact precisely on the models where LBP is known to be exact. That is with the subtle exception of cases where the pairwise functions in the convex decomposition are not strictly convex, and then LBP is not known to be exact.

⁵As stated in Section 1, there are other characterizations of these models, e.g. walk summability, which turn out to be equivalent to convex decomposability.

6 A STOPPING CRITERION FOR LBP

In this section we highlight a practical application resulting from the close LCR and LBP connection. Since LBP does not optimize a clearly defined objective, it is hard to monitor its convergence. Below we show how in many cases, simple upper and lower bounds can be calculated for LBP.

Consider an MRF where f_{ij}, f_i are convex and LBP is known to be exact. We will provide upper and lower bounds on the MAP objective in this case and show that they are tight at convergence. These bounds can thus be used as a reliable, easy to apply stopping criterion for LBP in these cases.⁶

Given our assumption on the MRF, it follows that it is CD. Thus, the LCR is tight, and the maximum of the dual objective Eq. (9) will equal the MAP value. This leads us to the following bounding scheme. At each iteration of BP, calculate an estimate of the MAP and denote it by \mathbf{x}^t . Clearly $F(\mathbf{x}^t)$ is an upper bound on the MAP value.

The procedure for obtaining the lower bound is more involved, although technically simple. It is described (along with the upper bound) in Algorithm 1. First, it is easy to see that d in Algorithm 1 is a lower bound since it is a value of the dual in Eq. (9). Second, this bound is tight when \mathbf{x}^t is the MAP assignment, as the following result states:

Lemma 6.1. *Assume $\mathbf{x}^t \in \arg \min_{\mathbf{x}} F(\mathbf{x})$, then the bound returned by the procedure satisfies $p = d$.*

Algorithm 1 Bounding Scheme for Sum of Convex Functions

Input: MAP estimate \mathbf{x}^t at time t , accuracy parameter ε , convex reparameterization $\{f_i(x_i), f_{ij}(x_i, x_j)\}$.
For each $ij \in E$, find $g \in \partial f_{ij}(x_i^t, x_j^t)$ and set

$$\hat{\delta}_{ji} = g_i, \hat{\delta}_{ij} = g_j.$$

Set for each $i \in V$ and $ij \in E$

$$\bar{f}_i(x_i) = f_i(x_i) + \sum_{j \in N(i)} \hat{\delta}_{ji} x_i$$

$$\bar{f}_{ij}(x_i, x_j) = f_{ij}(x_i, x_j) - \hat{\delta}_{ji} x_i - \hat{\delta}_{ij} x_j$$

Calculate primal and dual objectives ⁷

$$p = \sum_i f_i(x_i^t) + \sum_{ij} f_{ij}(x_i^t, x_j^t)$$

$$d = \sum_i \min_{x_i} \bar{f}_i(x_i) + \sum_{ij} \min_{x_i, x_j} \bar{f}_{ij}(x_i, x_j)$$

If $p - d < \varepsilon$ then determine convergence.

⁶It is possible to apply these bounds to any iterative algorithm that provides a sequence of approximate MAP assignments. We focus on LBP since the bounds are tight in the case we address.

The proof of this lemma follows exactly the same argument given in the third step for the proof of Thm. 4.1. When the singleton functions f_i are strongly convex and the objective is smooth, then it is also possible to give a guarantee on the size of the bound for x^t that is not a MAP assignment (see Lem. B.1 in the supplementary material).

Thus, we have obtained a scheme that provides tight lower and upper bounds on the iterates of BP in a subclass of the cases when it converges. Figure 1 illustrates these bounds for a Gaussian MRF.

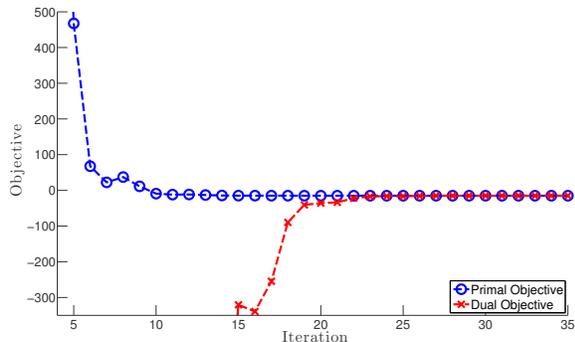

Figure 1: Illustration of the bounds for a 10×10 grid Gaussian MRF. We generate random convex quadratic functions for each node and edge in the model, and use the described bounding scheme to determine LBP’s convergence.

7 HIGHER ORDER MODELS

Thus far we only considered pairwise models. In this section we briefly mention the generalization of our results to higher order models. We propose two possible LCR approaches in this context and provide the related tightness results.

A non pairwise MRF may be written as follows:

$$F(\mathbf{x}) = \sum_{\alpha \in C} f_{\alpha}(\mathbf{x}_{\alpha}),$$

where $C \subseteq 2^V$. One option to define \mathcal{M}_L for this case is:

$$\mathcal{M}_L = \left\{ \mu : \begin{array}{l} \exists \text{ densities } \hat{p}_i, \hat{p}_{\alpha} \text{ s.t.} \\ \int \hat{p}_{\alpha}(\mathbf{x}_{\alpha}) dx_{\alpha \setminus i} = \hat{p}_i(x_i) \quad \forall \alpha, i \in \alpha, x_i \\ \mathbb{E}_{\hat{p}_{\alpha}}[\phi_{\alpha}(\mathbf{x}_{\alpha})] = \mu_{\alpha} \quad \forall \alpha \in C. \end{array} \right\} \quad (14)$$

In other words, \mathcal{M}_L constrains marginals over the α sets to agree on singleton marginals. Another reasonable choice is to define a set \mathcal{M}_C that enforces stronger consistency

⁷Notice that in order to calculate d it is not required to perform optimization over $\bar{f}_{ij}(x_i, x_j)$. The manner in which we set $\hat{\delta}$ guarantees that the minimum is attained at (x_i^t, x_j^t) . The calculation of d will only demand optimizing $\bar{f}_i(x_i)$ for each i .

constraints than \mathcal{M}_L :

$$\int \hat{p}_{\alpha}(\mathbf{x}_{\alpha}) dx_{\alpha \setminus \beta} = \int \hat{p}_{\beta}(\mathbf{x}_{\beta}) dx_{\beta \setminus \alpha} \quad \forall \alpha, \beta \in C. \quad (15)$$

Instead of consistency over single variables, \mathcal{M}_C enforces consistency on the overlap of pairs $\alpha, \beta \in C$.

Similar derivations to those of the pairwise case lead to tightness characterization for the constraints above. For our tightness results to carry, $F(\mathbf{x})$ should be given as a sum of convex functions. The first result states that if the functions $f_{\alpha}(\mathbf{x}_{\alpha})$ are all convex, then the \mathcal{M}_L relaxation is tight.

Claim 7.1. *If $F(\mathbf{x})$ is given as a sum of convex functions then $\min_{\mu \in \mathcal{M}_L} \langle \theta, \mu \rangle = \min_{\mathbf{x}} F(\mathbf{x})$.*

In this case we can also use the bounds described in Section 6. An interesting example of such a model is the one underlying the AMP algorithm of Donoho et al. [19].

The relaxation defined by Eq. (15) may be more complicated to solve due to the additional constraints. At the cost of this complication, the obtained relaxation is invariant to reparameterizations and an analogue of Thm. 4.1 holds.⁸

Definition 4. *An MRF is CD w.r.t $C \subseteq 2^V$ if there exists a reparameterization $\{\bar{f}_{\alpha}(\mathbf{x}_{\alpha})\}$ for $F(\mathbf{x})$ such that all the functions in the reparameterization are convex.*

Claim 7.2. *For any MRF that is CD w.r.t C it holds that $\min_{\mu \in \mathcal{M}_C} \langle \theta, \mu \rangle = \min_{\mathbf{x}} F(\mathbf{x})$.*

See supplementary material for proofs of the above results.

8 RELATED WORK

The current paper studies local consistency relaxations as applied to continuous MRFs, and their relation to loopy belief propagation. Below we briefly survey related results on this relation, focusing on discrete variable models where local consistency relaxations are typically considered.

For discrete tree structured MRFs, it can be shown that LBP and LCR are equivalent in the sense that they are both tight, and in fact there is a mapping between dual LCR variables and BP optima (see [33, p. 200]).

In [35] Weiss *et al.* consider the relation between LCR and convex belief propagation (and *not* standard LBP). They show that if a convex variant of max-product LBP converges, and the sharpened version of its beliefs (where sharpening means to distribute all probability mass evenly between maximizing arguments of the beliefs) are locally consistent, then they are a solution to the LCR.

For maximum weight bipartite matching it is known that LBP is exact [3] and so is the standard LP relaxation of the problem [31] (see also [1, sec. 6] on the relation between

⁸This result holds under a non-restrictive assumption that $\alpha \cap \beta \in C$ for all $\alpha, \beta \in C$ and also $\{i\} \in C$ for all $i \in V$.

this relaxation and local consistency relaxations). For non bipartite matching a more subtle result is available [24] showing that if the LCR does not have fractional optima then LBP is exact. Otherwise LBP will not be exact. Related results are available for maximum weight independent set [25] and packing and covering problems [7].

For the problem of decoding LDPC codes, both LCR approaches [9] and LBP [21] have been successful. Although some relations between these have been shown [32, 2], a clear link establishing cases where they are both exact has not been provided.

Tarlow *et al.* [30] show that for the min-cut problem, where LCR is known to be tight (e.g., see [31]), a modified version of LBP is exact as well.

Another connection between the LPR and message passing algorithms relies on the notion of graph covers [23, 12]. It is shown that for discrete models, LPR solves the MAP problem on a model that has the lowest objective amongst a family of graphical models who are in some sense isomorphic to the model it tries to approximate. Message passing algorithms are unable to distinguish between these isomorphic models, and thus an intuitive link between LPR and message passing is made.

On GMRFs, both LBP [16, 34, 18] and graph covers [22] were studied. One of the conclusions reached by studying graph covers [22] is that for non-CD GMRFs, dual coordinate ascent algorithms [10, 14, 15] are bound to fail at producing the MAP estimate. Our result for GMRFs provides an arguably simpler explanation of this failure: These algorithms perform dual coordinate ascent on the LCR, and whenever the LCR is inapplicable (as in the case of non-CD GMRFs) they yield a useless bound. See Section 5.2 for further discussion of GMRFs and LBP.

Relaxations for continuous MRFs have been less studied. The most relevant work is [20], who arrived at the dual of Eq. (7) (notice we did not use this dual, rather we used Eq. (9) which is a dual of Eq. (8)) but did not analyze when these are exact. Another recent work [38] suggested a different relaxation for continuous variables, but one that is more involved than standard LPRs and also has no clear connection to BP.

Another work on MAP estimation in continuous MRFs suggested an algorithm called Linear Coordinate Descent [40]. This algorithm was later generalized by the authors [39]. For both versions, the authors do not give an objective over which the updates yield an improvement at each step. In fact, our analysis provides a very simple interpretation of the algorithm in [40]. It essentially performs dual coordinate ascent on the dual of weak LCR (see Eq. (9)). This also leads to a much simpler convergence proof than that given in [40], since coordinate ascent in this case has a unique maximum and therefore converges globally [4].

9 DISCUSSION

We considered the MAP problem for MRFs on continuous variables, and derived a local relaxation for these. For convex decomposable MRFs we showed that these relaxations are in fact exact. For Gaussian MRFs we provided a stronger result showing that convex decomposability is necessary and sufficient for exactness of local relaxations.

Comparing our results to those on exactness of loopy belief propagation we find that local relaxations are exact in a strictly larger class of models. This further strengthens the known relation between LBP and LCR, adding to numerous other models where exactness of local relaxations coincides with exactness of LBP. It also leaves interesting open questions. For example, does BP in fact converge on general CD models or is the scaled diagonal dominance condition of [17] necessary.

We note that it is possible to use the LCR and its dual to derive coordinate ascent algorithms for the dual LCR. We have indeed derived MPLP-like algorithms [27] for this case. However, our experiments (not shown here) indicate that they are typically slower than LBP. Thus, LBP remains an attractive option for optimizing such models, and the tight bounds we develop in Section 6 are very useful when using it in practice. An interesting open problem is to devise such bounds for LBP in other models, and to provide general transformations between LCR and LBP solutions.

A Proofs

A.1 Proof of Lem. 3.1

Proof. Let us write \mathcal{M}_L^ψ with auxiliary variables η :

$$\mathcal{M}_L^\psi = \left\{ \mu, \eta : \begin{array}{ll} \exists \hat{p}_i, \hat{p}_{ij} \text{ s.t.} & \\ \mathbb{E}_{\hat{p}_i} [\phi_i(x_i)] = \mu_i & \forall i \\ \mathbb{E}_{\hat{p}_{ij}} [\phi_{ij}(x_i, x_j)] = \mu_{ij} & \forall ij \\ \mathbb{E}_{\hat{p}_i} [\psi_i(x_i)] = \eta_i & \forall i \\ \mathbb{E}_{\hat{p}_{ij}} [\psi_i(x_i)] = \eta_{ji} & \forall i, j \in N(i) \\ \eta_{ji} = \eta_i & \forall i, j \in N(i). \end{array} \right\}$$

Define for each $i \in V, ij \in E$ the sets of realizable mean parameters:

$$\mathcal{M}_i = \left\{ \mu_i, \eta_i : \begin{array}{l} \exists \hat{p}_i \text{ s.t.} \\ \mathbb{E}_{\hat{p}_i} [\phi_i(x_i)] = \mu_i \\ \mathbb{E}_{\hat{p}_i} [\psi_i(x_i)] = \eta_i \end{array} \right\},$$

$$\mathcal{M}_{ij} = \left\{ \mu_{ij}, \eta_{ij}, \eta_{ji} : \begin{array}{l} \exists \hat{p}_{ij} \text{ s.t.} \\ \mathbb{E}_{\hat{p}_{ij}} [\phi_{ij}(x_i, x_j)] = \mu_{ij} \\ \mathbb{E}_{\hat{p}_{ij}} [\psi_i(x_i)] = \eta_{ji} \\ \mathbb{E}_{\hat{p}_{ij}} [\psi_j(x_j)] = \eta_{ij} \end{array} \right\}$$

Then \mathcal{M}_L^ψ can now be written compactly as:

$$\mathcal{M}_L^\psi = \left\{ \begin{array}{ll} (\boldsymbol{\mu}_i, \boldsymbol{\eta}_i) \in \mathcal{M}_i & \forall i \\ (\boldsymbol{\mu}_{ij}, \boldsymbol{\eta}_{ij}, \boldsymbol{\eta}_{ji}) \in \mathcal{M}_{ij} & \forall ij \\ \boldsymbol{\eta}_{ji} = \boldsymbol{\eta}_i & \forall i, j \in N(i). \end{array} \right\}$$

Using the expressions for $f_i(x_i), f_{ij}(x_i, x_j)$ from Eq. (2), our problem is:

$$\min_{(\boldsymbol{\mu}, \boldsymbol{\eta}) \in \mathcal{M}_L^\psi} \sum_i \langle \boldsymbol{\theta}_i, \boldsymbol{\mu}_i \rangle + \sum_{ij} \langle \boldsymbol{\theta}_{ij}, \boldsymbol{\mu}_{ij} \rangle$$

We now assign a Lagrange multiplier to each consistency constraint

$$\begin{aligned} \delta_{ji} &\leftrightarrow \boldsymbol{\eta}_{ji} = \boldsymbol{\eta}_i \\ \delta_{ij} &\leftrightarrow \boldsymbol{\eta}_{ij} = \boldsymbol{\eta}_j, \end{aligned}$$

and write the resulting Lagrangian:

$$\begin{aligned} \mathcal{L}(\boldsymbol{\delta}, \boldsymbol{\eta}, \boldsymbol{\mu}) &= \sum_i \left\{ \langle \boldsymbol{\theta}_i, \boldsymbol{\mu}_i \rangle + \sum_{j \in N(i)} \langle \boldsymbol{\delta}_{ji}, \boldsymbol{\eta}_i \rangle \right\} \\ &+ \sum_{ij} \left\{ \langle \boldsymbol{\theta}_{ij}, \boldsymbol{\mu}_{ij} \rangle - \langle \boldsymbol{\delta}_{ij}, \boldsymbol{\eta}_{ij} \rangle - \langle \boldsymbol{\delta}_{ji}, \boldsymbol{\eta}_{ji} \rangle \right\}. \end{aligned}$$

To obtain a dual, we first minimize $\mathcal{L}(\boldsymbol{\delta}, \boldsymbol{\mu}, \boldsymbol{\eta})$ w.r.t $\boldsymbol{\mu}, \boldsymbol{\eta}$ under the remaining constraints: $(\boldsymbol{\mu}_i, \boldsymbol{\eta}_i) \in \mathcal{M}_i, (\boldsymbol{\mu}_{ij}, \boldsymbol{\eta}_{ij}, \boldsymbol{\eta}_{ji}) \in \mathcal{M}_{ij}$. Since the relevant variables for each constraint all lie in a single summand, we can push the minimization inside the sums:

$$\begin{aligned} \mathcal{L}(\boldsymbol{\delta}) &= \sum_i \min_{\boldsymbol{\mu}_i, \boldsymbol{\eta}_i \in \mathcal{M}_i} \left\{ \langle \boldsymbol{\theta}_i, \boldsymbol{\mu}_i \rangle + \sum_{j \in N(i)} \langle \boldsymbol{\delta}_{ji}, \boldsymbol{\eta}_i \rangle \right\} + \\ &\sum_{ij} \min_{\boldsymbol{\mu}_{ij}, \boldsymbol{\eta}_{ij}, \boldsymbol{\eta}_{ji} \in \mathcal{M}_{ij}} \left\{ \langle \boldsymbol{\theta}_{ij}, \boldsymbol{\mu}_{ij} \rangle - \langle \boldsymbol{\delta}_{ij}, \boldsymbol{\eta}_{ij} \rangle - \langle \boldsymbol{\delta}_{ji}, \boldsymbol{\eta}_{ji} \rangle \right\}. \end{aligned}$$

Each summand includes optimization over the set of realizable mean parameters, thus according to Thm. 2.1 our Lagrangian is given by:

$$\begin{aligned} \mathcal{L}(\boldsymbol{\delta}) &= \sum_i \min_{x_i} \left\{ \langle \boldsymbol{\theta}_i, \boldsymbol{\phi}_i(x_i) \rangle + \sum_{j \in N(i)} \langle \boldsymbol{\delta}_{ji}, \boldsymbol{\psi}_i(x_i) \rangle \right\} + \\ &\sum_{ij} \min_{x_i, x_j} \left\{ \langle \boldsymbol{\theta}_{ij}, \boldsymbol{\phi}_{ij}(x_i, x_j) \rangle \right. \\ &\quad \left. - \langle \boldsymbol{\delta}_{ij}, \boldsymbol{\phi}_{ij}(x_j) \rangle - \langle \boldsymbol{\delta}_{ji}, \boldsymbol{\phi}_{ji}(x_i) \rangle \right\}. \end{aligned}$$

The desired dual is obtained by maximizing over $\boldsymbol{\delta}$. \square

A.2 Proof of Thm. 4.1

Proof. Assume $\{f_i(x_i), f_{ij}(x_i, x_j)\}$ is a reparameterization of $F(\boldsymbol{x})$ for which all the functions are convex. According to Lem. 3.2 the minimum of LCR does not depend

on the reparameterization, thus it is enough to prove weak LCR's tightness with respect to this decomposition in order to establish LCR's tightness.

Consider weak LCR taken with $\psi_i(x_i) = [x_i]$. In this case the dual problem Eq. (9) is:

$$\begin{aligned} \max_{\boldsymbol{\delta}} \sum_i \min_{x_i} \left\{ f_i(x_i) + \sum_{j \in N(i)} \delta_{ji} x_i \right\} + \\ \sum_{ij} \min_{x_i, x_j} \left\{ f_{ij}(x_i, x_j) - \delta_{ji} x_i - \delta_{ij} x_j \right\}. \end{aligned}$$

Let $\boldsymbol{x}^* \in \arg \min_{\boldsymbol{x}} F(\boldsymbol{x})$, and for each $ij \in E$ take some $g \in \partial f_{ij}(x_i^*, x_j^*)$. Set the multipliers δ_{ji}, δ_{ij} as the components of g :

$$\delta_{ji}^* = g_i, \delta_{ij}^* = g_j,$$

and define the reparameterization obtained under $\boldsymbol{\delta}^*$:

$$\begin{aligned} \bar{f}_i(x_i) &= f_i(x_i) + \sum_{j \in N(i)} \delta_{ji}^* x_i \\ \bar{f}_{ij}(x_i, x_j) &= f_{ij}(x_i, x_j) - \delta_{ji}^* x_i - \delta_{ij}^* x_j. \end{aligned}$$

Each of the functions \bar{f}_i, \bar{f}_{ij} is a sum convex functions, hence is convex. From how we set g , each \bar{f}_{ij} is minimized at (x_i^*, x_j^*) . We also have:

$$\sum_i \bar{f}_i(x_i^*) = F(\boldsymbol{x}^*) - \sum_{ij} \bar{f}_{ij}(x_i^*, x_j^*).$$

It holds that $0 \in \partial \bar{f}_{ij}(x_i^*, x_j^*)$ and that $0 \in \partial F(\boldsymbol{x}^*)$ (because \boldsymbol{x}^* is a minimizer). From additivity of the subgradient, we now get $0 \in \partial \sum_i \bar{f}_i(x_i^*)$, and since each function in the sum depends on a different variable it also holds that $0 \in \partial \bar{f}_i(x_i^*)$ for each i . We conclude that \boldsymbol{x}^* minimizes each function in the reparameterization \bar{f}_i, \bar{f}_{ij} , and the dual objective our assignment $\boldsymbol{\delta}^*$ achieves is:

$$\sum_i \bar{f}_i(x_i^*) + \sum_{ij} \bar{f}_{ij}(x_i^*, x_j^*) = F(\boldsymbol{x}^*).$$

Any objective reached by a feasible dual assignment yields a lower bound on LCR's optimal objective, thus LCR's optimum is bounded below the MAP objective and we may conclude that the relaxation is tight. \square

A.3 Proof of Claims on LCR for GMRFs

A.3.1 Proof of Claims 5.1 and 5.2

Recall that for a GMRF we have:

$$\boldsymbol{\phi}_i = \{x_i, x_i^2\}, \boldsymbol{\phi}_{ij} = \{x_i x_j\}.$$

For any feasible element in \mathcal{M}_L , let \hat{p}_i, \hat{p}_{ij} be the densities that generated these feasible mean parameters. For any $ij \in$

$E, i \in V$ denote:

$$\begin{aligned}\Sigma_{ij} &= \mathbb{E}_{\hat{p}_{ij}} [x_i x_j], \\ \Sigma_{ii} &= \mathbb{E}_{\hat{p}_{ij}} [x_i^2] = \mathbb{E}_{\hat{p}_i} [x_i^2], \\ \eta_i &= \mathbb{E}_{\hat{p}_{ij}} [x_i] = \mathbb{E}_{\hat{p}_i} [x_i].\end{aligned}\quad (16)$$

The equalities of expectations with respect to \hat{p}_i and \hat{p}_{ij} hold due to local consistency constraints. Since for any $ij \in E$, the parameters $(\Sigma_{[ij]}, \eta_{[ij]})$ are first and second moments of the density \hat{p}_{ij} then it must hold that:

$$\Sigma_{[ij]} - \eta_{[ij]} \eta_{[ij]}^\top \geq 0. \quad (17)$$

On the other hand, assume we are given (Σ, η) such that Eq. (17) holds for all $ij \in E$. Take \hat{p}_{ij} as the bivariate Gaussian density with moments $(\Sigma_{[ij]}, \eta_{[ij]})$ for all $ij \in E$, and \hat{p}_i as the univariate Gaussian density with moments (Σ_{ii}, η_i) for all $i \in V$. These densities satisfy the local consistency constraints:

$$\int \tilde{p}_{ij}(x_i, x_j) dx_j = \tilde{p}_i(x_i),$$

which means $(\Sigma, \eta) \in \mathcal{M}_L$ and that Claim 5.1 holds.

To see Claim 5.2 holds, we use the same type of argument and prove $\mathcal{M}_L^\psi \subseteq \mathcal{M}_L$. Given any feasible element in \mathcal{M}_L^ψ , consider the densities \hat{p}_i, \hat{p}_{ij} who generated it. The weak local consistency constraints imposed by \mathcal{M}_L^ψ assure that the equalities in Eq. (16) hold. Thus Eq. (17) also holds and this element must also be feasible in \mathcal{M}_L .

A.3.2 Proof of Claim 5.3

Proof. Let δ be any assignment to the dual Eq. (9), we will prove it achieves an objective of $-\infty$. It will then follow that this is the maximal value achieved by the dual, and in turn the minimal value achieved by LCR. Let us define the functions:

$$\begin{aligned}\bar{f}_i(x_i) &= f_i(x_i) + \sum_{j \in N(i)} \langle \delta_{ji}, \psi_i(x_i) \rangle \\ \bar{f}_{ij}(x_i, x_j) &= f_{ij}(x_i, x_j) - \langle \delta_{ji}, \psi_i(x_i) \rangle - \langle \delta_{ij}, \psi_j(x_j) \rangle.\end{aligned}$$

The dual objective may then be written as:

$$\sum_i \min_{x_i} \bar{f}_i(x_i) + \sum_{ij} \min_{x_i, x_j} \bar{f}_{ij}(x_i, x_j).$$

Under the choice of $\psi_i(x_i)$ made in Claim 5.2, each function in $\{\bar{f}_i(x_i), \bar{f}_{ij}(x_i, x_j)\}$ is quadratic. $\{\bar{f}_i(x_i), \bar{f}_{ij}(x_i, x_j)\}$ is also a reparameterization of $F(x)$, so for non-CD GMRFs, at least one of these functions must be non-convex. The minimum of a non-convex quadratic function is unbounded, so one of the minimizations in the sum of the dual objective must be unbounded, and the objective achieved by δ is $-\infty$. \square

Abstract

In this paper we present a novel non-parametric approach to Bayesian filtering, where the prediction and observation models are learned in an online fashion. Our approach is able to handle multimodal distributions over both models by employing a mixture model representation with Gaussian Processes (GP) based components. To cope with the increasing complexity of the estimation process, we explore two computationally efficient GP variants, sparse online GP and local GP, which help to manage computation requirements for each mixture component. Our experiments demonstrate that our approach can track human motion much more accurately than existing approaches that learn the prediction and observation models offline and do not update these models with the incoming data stream.

1 INTRODUCTION

Many real world problems involve high dimensional data. In this paper we are interested in *modeling* and *tracking* human motion. In this setting, dimensionality reduction techniques are widely employed to avoid the curse of dimensionality.

Linear approaches such as principle component analysis (PCA) are very popular as they are simple to use. However, they often fail to capture complex dependencies due to their assumption of linearity. Non-linear dimensionality reduction techniques that attempt to preserve the local structure of the manifold (*e.g.*, Isomap [21, 8], LLE [19, 14]) can capture more complex dependencies, but often suffer when the manifold assumptions are violated, *e.g.*, in the presence of noise.

Probabilistic latent variable models have the advantage of being able to take the uncertainties into account when learning the latent representations. Perhaps the most suc-

cessful model in the context of modelling human motion is the Gaussian process latent variable model (GPLVM) [12], where the non-linear mapping between the latent space and the high dimensional space is modeled with a Gaussian process. This provides powerful prior models, which have been employed for character animation [28, 26, 15] and human body tracking [24, 16, 25].

In the context of tracking, one is interested in estimating the state of a dynamic system. The most commonly used technique for state estimation is Bayesian filtering, which recursively estimates the posterior probability of the state of the system. The two key components in the filter are the prediction model, which describes the temporal evolution of the process, as well as the observation model which links the state and the observations. A parametric form is typically employed for both models.

Ko and Fox [10] introduced the GP-BayesFilter, which defines the prediction and observation models in a non-parametric way via Gaussian processes. This approach is well suited when accurate parametric models are difficult to obtain. Its main limitation, however, resides in the fact that it requires ground truth states (as GPs are supervised), which are typically not available. GPLVMs were employed in [11] to learn the latent space in an unsupervised manner, bypassing the need for labeled data. This, however, can not exploit the incoming stream of data available in the online setting as the latent space is learned offline. Furthermore, only unimodal prediction and observation models can be captured due to the fact that the models learned by GP are nonlinear but Gaussian.

In this paper we extend the previous non-parametric filters to learn the latent space in an online fashion as well as to handle multimodal distributions for both the prediction and observation models. Towards this goal, we employ a mixture model representation in the particle filtering framework. For the mixture components, we investigate two computationally efficient GP variants which can update the prediction and observation models in an online fashion, and cope with the growth in complexity as the number of data points increases over time. More specifically, the sparse

online GP [3] selects the active set in an online fashion to efficiently maintain sparse approximations to the models. Alternatively, the local GP [26] reduces the computation by imposing local sparsity.

We demonstrate the effectiveness of our approach on a wide variety of motions, and show that both approaches perform better than existing algorithms. In the remainder of the paper we first present a review on Bayesian filtering and the GPLVM. We then introduce our algorithm and show our experimental evaluation followed by the conclusions.

2 BACKGROUND

In this section we review Bayesian filtering and Gaussian process latent variable models.

2.1 BAYESIAN FILTERING

Bayesian filtering is a sequential inference technique typically employed to perform state estimation in dynamic systems. Specifically, the goal is to recursively compute the posterior distribution of the current hidden state \mathbf{x}_t given the history of observations $\mathbf{y}_{1:t} = (\mathbf{y}_1, \dots, \mathbf{y}_t)$ up to the current time step

$$p(\mathbf{x}_t | \mathbf{y}_{1:t}) \propto p(\mathbf{y}_t | \mathbf{x}_t) \int p(\mathbf{x}_t | \mathbf{x}_{t-1}) p(\mathbf{x}_{t-1} | \mathbf{y}_{1:t-1}) d\mathbf{x}_{t-1}$$

where $p(\mathbf{x}_t | \mathbf{x}_{t-1})$ is the *prediction model* that represents the system dynamics, and $p(\mathbf{y}_t | \mathbf{x}_t)$ is the *observation model* that represents the likelihood of an observation \mathbf{y}_t given the state \mathbf{x}_t .

One of the most fundamental Bayesian filters is the Kalman filter, which is a maximum-a-posteriori estimator for linear and Gaussian models. Unfortunately, it is often not applicable in practice since most real dynamical systems are non-linear and/or non-Gaussian. Two popular extensions for non-linear systems are the extended Kalman filter (EKF) and the unscented Kalman filter (UKF) [9]. However, similar to the Kalman filter, the performance of EKF and UKF is poor when the models are multimodal [5].

In contrast, particle filters that are not restricted to linear and Gaussian models have been developed by using sequential Monte Carlo sampling to represent the underlying posterior $p(\mathbf{x}_t | \mathbf{y}_{1:t})$ [5]. More specifically, at each time step, N_p particles of \mathbf{x}_t are drawn from the prediction model $p(\mathbf{x}_t | \mathbf{x}_{t-1})$, and then all the particles are weighted according to the observation model $p(\mathbf{y}_t | \mathbf{x}_t)$. The posterior $p(\mathbf{x}_t | \mathbf{y}_{1:t})$ is approximated using these N_p weighted particles. Finally, the N_p particles are resampled for the next step. Unfortunately, the parametric description of the dynamic models limits the estimation accuracy of Bayesian filters.

Recently, a number of GP-based Bayesian filters were proposed by learning the prediction and observation models using GP regression [10, 4]. This is a promising alternative as GPs are non-parametric and can capture complex mappings. However, training these methods requires access to ground truth data before filtering. Unfortunately, the inputs of the training set are the hidden states which are not always known in real-world applications. Two extensions were introduced to learn the hidden states of the training set via a non-linear latent variable model [11] or a sparse pseudo-input GP regression [22]. However, these methods require offline learning procedures, which are not able to exploit the incoming data streams. In contrast, we propose two non-parametric particle filters that are able to exploit the incoming data to learn better models in an online fashion.

2.2 GAUSSIAN PROCESS DYNAMICAL MODEL

The Gaussian Process Latent Variable Model (GPLVM) is a probabilistic dimensionality reduction technique, which places a GP prior on the observation model [12]. Wang et al. [28] proposed the Gaussian Process Dynamical Model (GPDM), which enriches the GPLVM to capture temporal structure by incorporating a GP prior over the dynamics in the latent space. Formally, the model is:

$$\begin{aligned} \mathbf{x}_t &= f_{\mathbf{x}}(\mathbf{x}_{t-1}) + \eta_{\mathbf{x}} \\ \mathbf{y}_t &= f_{\mathbf{y}}(\mathbf{x}_t) + \eta_{\mathbf{y}} \end{aligned}$$

where $\mathbf{y} \in \mathbb{R}^{D_y}$ represents the observation and $\mathbf{x} \in \mathbb{R}^{D_x}$ the latent state, with $D_y \gg D_x$. The noise processes are assumed to be Gaussian $\eta_{\mathbf{x}} \sim \mathcal{N}(0, \sigma_{\mathbf{x}}^2 I)$ and $\eta_{\mathbf{y}} \sim \mathcal{N}(0, \sigma_{\mathbf{y}}^2 I)$. The nonlinear functions $f_{\mathbf{x}}^i$ and $f_{\mathbf{y}}^i$ have GP priors, i.e., $f_{\mathbf{x}}^i \sim \mathcal{GP}(0, k_x(\mathbf{x}, \mathbf{x}'))$ and $f_{\mathbf{y}}^i \sim \mathcal{GP}(0, k_y(\mathbf{x}, \mathbf{x}'))$ where $k_x(\cdot, \cdot)$ and $k_y(\cdot, \cdot)$ are the kernel functions. For simplicity, we denote the hyperparameters of the kernel functions by θ .

Let $\mathbf{x}_{1:T_0} = (\mathbf{x}_1, \dots, \mathbf{x}_{T_0})$ be the latent space coordinates from time $t = 1$ to time $t = T_0$. GPDM is typically learned by minimizing the negative log posterior $-\log(p(\mathbf{x}_{1:T_0}, \theta | \mathbf{y}_{1:T_0}))$ with respect to $\mathbf{x}_{1:T_0}$, and θ [28]. After $\mathbf{x}_{1:T_0}$ and θ are obtained, a standard GP prediction is used to construct the model $p(\mathbf{x}_t | \mathbf{x}_{t-1}, \theta, \mathcal{X}_{T_0})$ and $p(\mathbf{y}_t | \mathbf{x}_t, \theta, \mathcal{Y}_{T_0})$ with data $\mathcal{X}_{T_0} = \{(\mathbf{x}_{k-1}, \mathbf{x}_k)\}_{k=2}^{T_0}$ and $\mathcal{Y}_{T_0} = \{(\mathbf{x}_k, \mathbf{y}_k)\}_{k=1}^{T_0}$. Tracking ($t > T_0$) is then performed assuming the model is fixed and can be done using, e.g., a particle filter as described above. The major drawback of this approach is that it is not able to adapt to new observations during tracking. As shown in our experimental evaluation, this results in poor performance when the training set is small.

3 ONLINE GP PARTICLE FILTER

In order to solve the above-mentioned difficulties in learning and filtering with dynamic systems, we propose an *Online GP Particle Filter* framework to learn and refine the model during tracking, *i.e.*, the prediction $p(\mathbf{x}_t|\mathbf{x}_{t-1})$ and observation $p(\mathbf{y}_t|\mathbf{x}_t)$ models are updated online in the particle filtering framework. To account for multi-modality and the significant amount of uncertainty that can be present, we propose to represent the prediction and observation models by a mixture model. For each mixture component, we will investigate two different GP variants.

Let the prediction and observation models at $t - 1$ be

$$p(\mathbf{x}_t|\mathbf{x}_{t-1}, \Theta_{t-1,M}) = \frac{1}{R_M} \sum_{i=1}^{R_M} p(\mathbf{x}_t|\mathbf{x}_{t-1}, \Theta_{t-1,M}^i) \quad (1)$$

$$p(\mathbf{y}_t|\mathbf{x}_t, \Theta_{t-1,O}) = \frac{1}{R_O} \sum_{i=1}^{R_O} p(\mathbf{y}_t|\mathbf{x}_t, \Theta_{t-1,O}^i) \quad (2)$$

where $\Theta_{t-1,M}^i$ and $\Theta_{t-1,O}^i$ represents the parameters of the i -th component, $\Theta_{t-1,M} = \{\Theta_{t-1,M}^i\}_{i=1}^{R_M}$ and $\Theta_{t-1,O} = \{\Theta_{t-1,O}^i\}_{i=1}^{R_O}$ are the parameters of all components. At the t -th time step, we run a standard particle filter to obtain a number of weighted particles. The latent space representations at time t can be obtained by resampling the weighted particles. Then, we assign each particle to the most likely mixture component of $p(\mathbf{x}_t|\mathbf{x}_{t-1}, \Theta_{t-1,M})$ and $p(\mathbf{y}_t|\mathbf{x}_t, \Theta_{t-1,O})$ to capture the multi-modality of the prediction and observation models. Finally, we compute the mean latent states of the assigned particles and use this mean state to update the corresponding components parameters, $\Theta_{t,M}^i$ for the prediction (or motion) model and $\Theta_{t,O}^i$ for the observation model. The whole framework is summarized in Algorithm 1.

What remains is to specify how the parameters of individual components are represented and updated (lines 18 and 23 in Algorithm 1). As noted above, we aim to use a GP model for each mixture component. However, a standard implementation would require $O(t^3)$ operations and $O(t^2)$ memory. As t grows linearly over time, the particle filter will quickly become too computationally and memory intensive. Thus a primary challenge is how to efficiently update the GP mixture components in the prediction and observation models.

In order to efficiently update $\Theta_{t,M}^i$ and $\Theta_{t,O}^i$ in an online manner, we consider two fast GP-based strategies: Sparse Online GP (SOGP) and Local GPs (LGP) in which the reduction in memory and/or computation is achieved by an online sparsification and a local experts mechanism respectively. A detailed review of fast GP approaches can be found in [1, 18].

The specific contents of $\Theta_{t,M}^i$ or $\Theta_{t,O}^i$ will vary depending on the method used. In the case of SOGP it will contain some computed quantities and the active set while for LGP it will simply be the set of all training points. While we will

focus on these two strategies, we note that in principle any similar update strategy could be used instead, such as informative vector machines [13] or local regression approaches [7, 6, 20]. In what follows, to avoid confusion with the notations of the latent state and observation, we will use \mathbf{a} and \mathbf{b} to indicate the input and output when we describe SOGP and LGP regression in which we consider modeling a generic function $\mathbf{b} = f(\mathbf{a}) + \xi$, with $\xi \sim \mathcal{N}(0, \sigma^2 I)$.

3.1 SPARSE ONLINE GAUSSIAN PROCESS

The Sparse Online Gaussian Process (SOGP) of [3, 27] is a well-known algorithm for online learning of GP models. To cope with the fact that data arrives in an online manner, SOGP trains a GP model sequentially by updating the posterior mean and covariance of the latent function values of the training set. This online procedure is coupled with a sparsification strategy which iteratively selects a fixed-size subset of points to form the active set, preventing the otherwise unbounded growth of the computation and memory load.

The key of SOGP is to maintain the joint posterior over the latent function values of the fixed-size active set \mathcal{D}_{t-1} , *i.e.*,

$\mathcal{N}(\mu_{t-1}, \Sigma_{t-1})$, by recursively updating μ_{t-1} and Σ_{t-1} . When a new observation $(\mathbf{a}_t, \mathbf{b}_t)$ ¹ is available, we perform the following update to take the new data point into account [27]

$$\mathbf{q}_t = Q_{t-1} \mathbf{k}_{t-1}(\mathbf{a}_t) \quad (3)$$

$$\rho_t^2 = k(\mathbf{a}_t, \mathbf{a}_t) - \mathbf{k}_{t-1}(\mathbf{a}_t)^T Q_{t-1} \mathbf{k}_{t-1}(\mathbf{a}_t) \quad (4)$$

$$\hat{\sigma}_t^2 = \sigma^2 + \rho_t^2 + \mathbf{q}_t^T \Sigma_{t-1} \mathbf{q}_t \quad (5)$$

$$\delta_t = \begin{bmatrix} \Sigma_{t-1} \mathbf{q}_t \\ \rho_t^2 + \mathbf{q}_t^T \Sigma_{t-1} \mathbf{q}_t \end{bmatrix} \quad (6)$$

$$\mu_t = \begin{bmatrix} \mu_{t-1} \\ \mathbf{q}_t^T \mu_{t-1} \end{bmatrix} + \hat{\sigma}_t^{-2} (\mathbf{b}_t - \mathbf{q}_t^T \mu_{t-1}) \delta_t \quad (7)$$

$$\Sigma_t = \begin{bmatrix} \Sigma_{t-1} & \Sigma_{t-1} \mathbf{q}_t \\ \mathbf{q}_t^T \Sigma_{t-1} & \rho_t^2 + \mathbf{q}_t^T \Sigma_{t-1} \mathbf{q}_t \end{bmatrix} - \hat{\sigma}_t^{-2} \delta_t \delta_t^T \quad (8)$$

where $\mathbf{k}_{t-1}(\mathbf{a}_t)$ is the kernel vector which is constructed from \mathbf{a}_t and the active set \mathcal{D}_{t-1} , and Q_{t-1} is the inverse kernel matrix of the active set \mathcal{D}_{t-1} .

One of the key steps in this algorithm is how to decide when to add the new point to the active set. We employed the strategy suggested by [3, 27], and ignore the new point with $\rho_t^2 < \epsilon$ for some small value of ϵ (we use $\epsilon = 10^{-6}$). In this case, the μ_t, Σ_t are updated as $\mu_t \leftarrow [\mu_t]_{-i}, \Sigma_t \leftarrow [\Sigma_t]_{-i, -i}$ where $i = t$ is the index of the new point, $[\cdot]_{-i}$ removes the i -th entry of a vector, and $[\cdot]_{-i, -i}$ removes the i -th row and column of a matrix. Additionally, the inverse kernel matrix is simply $Q_t = Q_{t-1}$ because the new point is not included in the active set. When $\rho_t^2 \geq \epsilon$, we add the new point to the active set $\mathcal{D}_t = \mathcal{D}_{t-1} \cup \{(\mathbf{a}_t, \mathbf{b}_t)\}$. The μ_t, Σ_t are then the same as Eq.(7) and (8), and the inverse kernel matrix is updated to be [27]

$$Q_t = \begin{bmatrix} Q_{t-1} & \mathbf{0} \\ \mathbf{0} & 0 \end{bmatrix} + \rho_t^{-2} \begin{bmatrix} \mathbf{q}_t \mathbf{q}_t^T & -\mathbf{q}_t \\ -\mathbf{q}_t^T & 1 \end{bmatrix} \quad (9)$$

When the size of the active set is larger than the fixed size N_A because a new point was added, we must remove a point. This is done by selecting the one which minimally affects the predictions according to the squared predicted error. Following [3, 27], we remove the j -th data point with

$$j = \arg \min_j \left(\frac{[Q_t \mu_t]_j}{[Q_t]_{j,j}} \right)^2 \quad (10)$$

where $[\cdot]_j$ selects the j -th entry of a vector and $[\cdot]_{j,j}$ select the j th diagonal entry of a matrix. Once a point has been selected for removal, μ_t, Σ_t and Q_t are updated as

$$\mu_t \leftarrow [\mu_t]_{-j} \quad (11)$$

$$\Sigma_t \leftarrow [\Sigma_t]_{-j, -j} \quad (12)$$

$$Q_t \leftarrow [Q_t]_{-j, -j} - \frac{[Q_t]_{-j,j} [Q_t]_{j,j}^T}{[Q_t]_{j,j}} \quad (13)$$

¹For simplicity of presentation, we assume that \mathbf{b} is a scalar. The extension to vector valued \mathbf{b} is straightforward.

Algorithm 2 SOGP Update

input Previous posterior quantities $\mu_{t-1}, \Sigma_{t-1}, Q_{t-1}$

input Previous active set \mathcal{D}_{t-1}

input New input-output observation $(\mathbf{a}_t, \mathbf{b}_t)$ pair

1: Compute ρ_t, μ_t and Σ_t as in Equations (4), (7) and (8).

2: **if** $\rho_t^2 < \epsilon$ **then**

3: Perform update $\mu_t \leftarrow [\mu_t]_{-i}, \Sigma_t \leftarrow [\Sigma_t]_{-i, -i}$ where i is the index of the newly added row to μ_t .

4: Set $Q_t = Q_{t-1}, \mathcal{D}_t = \mathcal{D}_{t-1}$.

5: **else**

6: Compute Q_t as in Equation (9).

7: Add to active set $\mathcal{D}_t = \mathcal{D}_{t-1} \cup \{(\mathbf{a}_t, \mathbf{b}_t)\}$.

8: **end if**

9: **if** $|\mathcal{D}_t| > N_A$ **then**

10: Select point j to remove using Equation (10).

11: Perform update $\mu_t \leftarrow [\mu_t]_{-j}, \Sigma_t \leftarrow [\Sigma_t]_{-j, -j}$ and

$$Q_t \leftarrow [Q_t]_{-j, -j} - \frac{[Q_t]_{-j,j} [Q_t]_{j,j}^T}{[Q_t]_{j,j}}$$

12: Remove j from active set $\mathcal{D}_t \leftarrow \mathcal{D}_t \setminus \{(\mathbf{a}_j, \mathbf{b}_j)\}$.

13: **end if**

output μ_t, Σ_t, Q_t and \mathcal{D}_t

where $[\cdot]_{-j,j}$ selects the j -th column of the matrix with the j -th row removed and the point is removed from the active set $\mathcal{D}_t \leftarrow \mathcal{D}_t \setminus \{(\mathbf{a}_j, \mathbf{b}_j)\}$.

The joint posterior at time t can be used to construct the predictive distribution for a new input \mathbf{a}^*

$$p^{SOGP}(\mathbf{b}|\mathbf{a}^*, \mathcal{D}_t, \Theta) = \mathcal{N}(\mathbf{b}|\tilde{\mathbf{b}}, \tilde{\sigma}^2) \quad (14)$$

where $\tilde{\mathbf{b}} = \mathbf{k}_t(\mathbf{a}^*)^T Q_t \mu_t$ and $\tilde{\sigma}^2 = \sigma^2 + k(\mathbf{a}^*, \mathbf{a}^*) + \mathbf{k}_t(\mathbf{a}^*)^T (Q_t \Sigma_t Q_t - Q_t) \mathbf{k}_t(\mathbf{a}^*)$. We summarize the SOGP updates in Algorithm 2.

3.2 LOCAL GAUSSIAN PROCESSES

An alternative to the SOGP approach is to use Local Gaussian Processes (LGP), which was developed specifically to deal with large, multi-modal regression problems [17, 23]. In LGP, given a test input \mathbf{a}^* and a set of input-output pairs $\mathcal{D} = \{(\mathbf{a}_i, \mathbf{b}_i)\}_{i=1}^N$, the $M_{\mathbf{a}}$ -nearest neighbors $\mathcal{D}_{\mathbf{a}^*} = \{(\mathbf{a}_\ell, \mathbf{b}_\ell)\}_{\ell=1}^{M_{\mathbf{a}}}$ are selected based on the distance in the input space $d_\ell = \|\mathbf{a}_\ell - \mathbf{a}^*\|$. Then, for each of the $M_{\mathbf{a}}$ neighbors, $M_{\mathbf{b}}$ -nearest neighbors $\mathcal{D}_{\mathbf{b}_\ell} = \{(\mathbf{a}_j, \mathbf{b}_j)\}_{j=1}^{M_{\mathbf{b}}}$ are selected based on the distance in the output space to \mathbf{b}_ℓ . These neighbors are then combined to form a local GP expert which makes a Gaussian prediction with mean and covariance

$$\mu_\ell = B_{\mathcal{D}_{\mathbf{b}_\ell}} K_{\mathcal{D}_{\mathbf{b}_\ell}, \mathcal{D}_{\mathbf{b}_\ell}}^{-1} \mathbf{k}_{\mathcal{D}_{\mathbf{b}_\ell}}(\mathbf{a}^*)$$

$$\sigma_\ell^2 = k(\mathbf{a}^*, \mathbf{a}^*) - \mathbf{k}_{\mathcal{D}_{\mathbf{b}_\ell}}(\mathbf{a}^*)^T K_{\mathcal{D}_{\mathbf{b}_\ell}, \mathcal{D}_{\mathbf{b}_\ell}}^{-1} \mathbf{k}_{\mathcal{D}_{\mathbf{b}_\ell}}(\mathbf{a}^*) + \sigma^2$$

where $B_{\mathcal{D}_{\mathbf{b}_\ell}}$ is the matrix whose columns are the $M_{\mathbf{b}}$ nearest neighbors of \mathbf{b}_ℓ , $\mathbf{k}_{\mathcal{D}_{\mathbf{b}_\ell}}(\mathbf{a}^*)$ is the vector of kernel function values for the input \mathbf{a}^* and the points in $\mathcal{D}_{\mathbf{b}_\ell}$, and

$K_{\mathcal{D}_{\mathbf{b}_\ell}, \mathcal{D}_{\mathbf{b}_\ell}}$ is the kernel matrix for the points in $\mathcal{D}_{\mathbf{b}_\ell}$. The final predictive distribution is then formed by combining all local experts in a mixture model

$$p^{LGP}(\mathbf{b}|\mathbf{a}^*, \mathcal{D}, \Theta) = \sum_{\ell=1}^{M_a} w_\ell \mathcal{N}(\mathbf{b}|\mu_\ell, \sigma_\ell^2 I) \quad (15)$$

with weights $w_\ell \propto 1/d_\ell$.

4 EXPERIMENTAL EVALUATION

To illustrate our approach we choose 4 very different motions, *i.e.*, walking, golf swing, swimming as well as exercises (composed of side twist and squat). The data consists of motion capture from the CMU dataset [2], where each observation is a 62 dimensional vector containing the 3D rotations of all joints. We normalize the data to be mean zero and subsample the observations to reduce the correlation between consecutive frames. We use a frequency of 12 frames/s for walking and swimming, 24 frames/s for golf swing and 30 frames/s for the exercise motion. We compute all results averaged over 3 trials and report the average root mean squared error as our measure of performance.

In all the experiments, the latent space dimensionality is set to be 3 as is common for human motion models [28]. We use PCA to initialize the latent space and K-means to obtain the data points used for the mixture components. We choose the compound kernel function $k(\mathbf{x}, \mathbf{x}') = \sigma_f^2 \exp(-0.5 \|\mathbf{x} - \mathbf{x}'\|^2 / \gamma^2) + l^2 \mathbf{x}^T \mathbf{x}'$ for both prediction and observation mappings. Unless otherwise stated, we use 50 particles, a training set of size of 20/30/50/450 and 2/2/5/5 mixture components for walking/golf/swimming/exercise motions respectively. For LGP, the number of local GP experts is 2/2/2/5, and the size of each local expert is 5/8/5/20. For SOGP, the size of the active set is 20/5/50/20. The parameter values were chosen to balance computational cost with the prediction accuracy and in our experiments we demonstrate the robustness of our approach to these parameters.

4.1 COMPARISON TO STATE-OF-THE-ART

We compare our approaches to two baselines: The first one is the approach of Ko and Fox [11] where a GPDM is learned offline with gradient descent [28] before performing particle filtering for state estimation. The second baseline is similar, but learns the GPDM offline using stochastic gradient descent [29]. We tested the baselines in two different settings. First, only the initial training set is available to learn the prediction and observation models. Second, all the data (including future streamed examples) are used to learn the prediction and observation models. Note that the latter represents the oracle for Ko and Fox [11].

Number of Particles: We evaluate how the accuracy changes as a function of the number of particles, N_p . As

expected, the prediction error is reduced in all the methods when the number of particles increases. As shown in the first row of Fig. 1, our approaches are superior to the baselines. Importantly, we outperformed the oracle baseline as we are able to represent multi-modal distributions effectively. This is particularly important in the exercise sequence as the dynamics are clearly multimodal due to the different motions that are performed in the sequence. Furthermore, our LGP variant outperforms SOGP. We believe this is due to the fact that SOGP has a fixed capacity while LGP is able to leverage more training data when making predictions.

Influence of noise: In this experiment we evaluate the robustness of all approaches to additive noise in the observations. The second row of Fig. 1 shows that our LGP particle filter significantly outperforms the baselines, particularly in the exercise sequence. Our SOGP outperforms all baselines that have access to the same training set, and is only beaten by the oracle for walking.

Size of Training Set: We next evaluate how the accuracy depends on the size of the initial training set, T_0 . The first row of Fig. 2 clearly indicates that our methods perform well even when the training set is very small. In contrast, the two baselines require bigger training sets to achieve comparable performance. This is expected as the baselines do not update the latent space to take the incoming observations into account.

4.2 QUALITATIVE EXPERIMENTS

Fig. 3 shows the latent space of both SOGP and LGP filters when employing 50 particles for each time step (depicted in blue). From the 3D latent space and predicted skeletons, we find that the manifolds of both LGP and SOGP particle filters have a good representation of the high-dimensional human motion data.

4.3 PROPERTIES OF OUR METHODS

We next discuss various aspects of our method and evaluate the influence of the parameters of SOGP and LGP filters. For LGP, due to the fact that the data sizes of walking, golf and swimming motions are small, we reduced the number (size) of local experts to be able to increase the size (number) of the local experts.

Computational Complexity: Overall the computational complexity of our method (Alg 1) is mainly determined by the complexity of constructing a prediction distribution for each components (lines 5-6 and 11-12) and model updates (line 18 and line 23). Specifically, for an individual component which is either SOGP or LGP, computing the prediction distribution is $O(N_A^2)$ or $O(M_a M_b^3 + T M_a M_b)$ respectively where N_A is the size of active set, M_a is the number of local experts, M_b are the number of neigh-

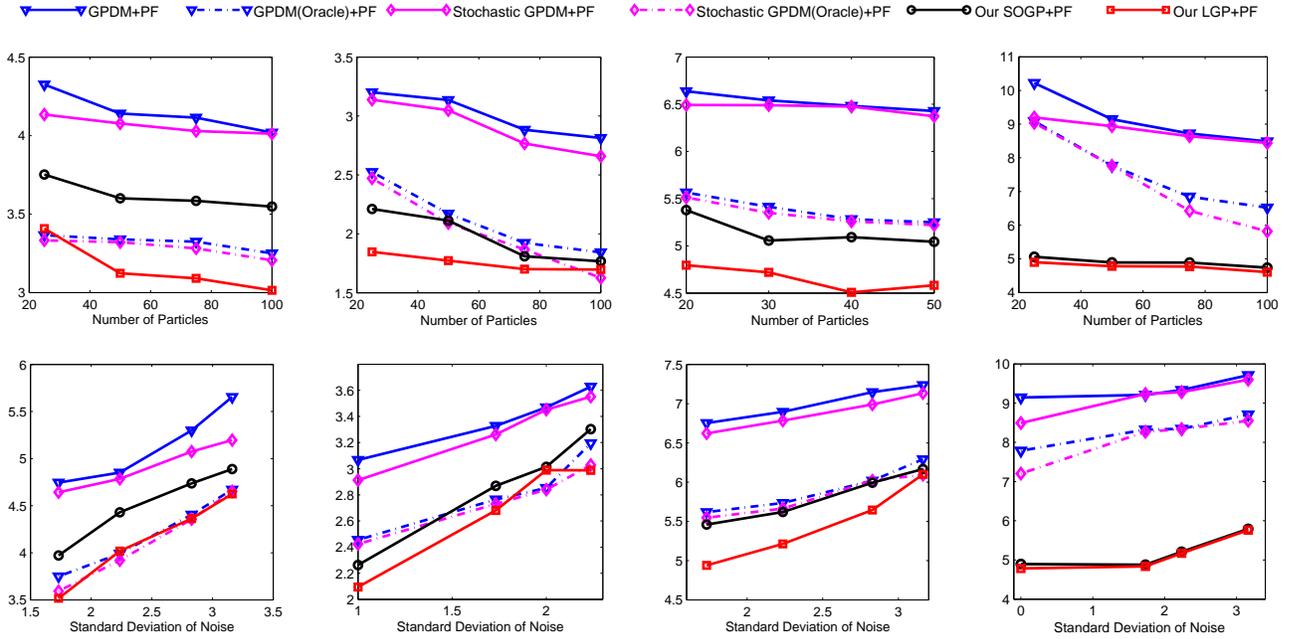

Figure 1: Root mean squared error as a function of (1st row) the number of particles in the particle filter, (2nd row) the standard deviation of noise added to the observations. The columns (from left to right) represent walking, golf, swimming and exercise motions. Note that our approach outperforms the baselines in all settings. Handling multimodal distributions is particularly important in the exercise example as it is composed of a variety of different motions.

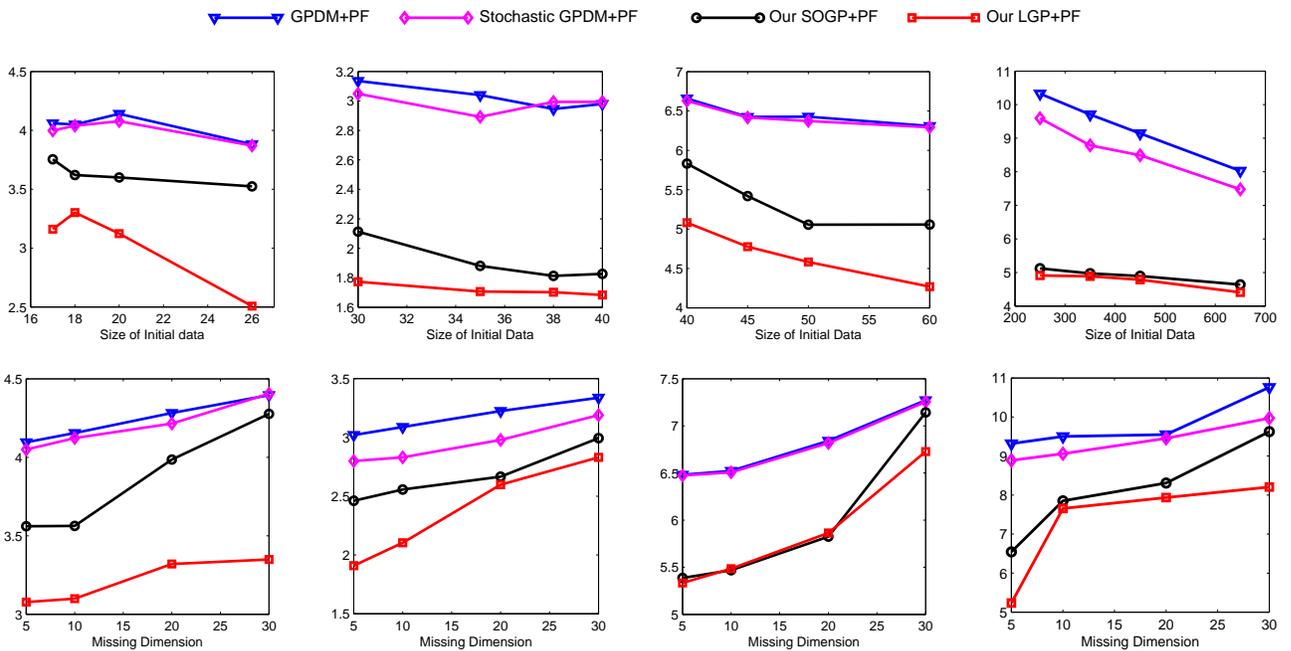

Figure 2: Root Mean Squared Error as a function of (1st row) the number of initial training points, (2nd row) the number of the missing dimensions. The columns (from left to right) are respectively for walking, golf, swimming and exercise motions.

bers in the output space and TM_aM_b comes from the KNN search. The model updates for the mixture compo-

ments (lines 18 and 23) have a computational complexity of $O(N_A^2)$ and $O(1)$ for SOGP and LGP respectively.

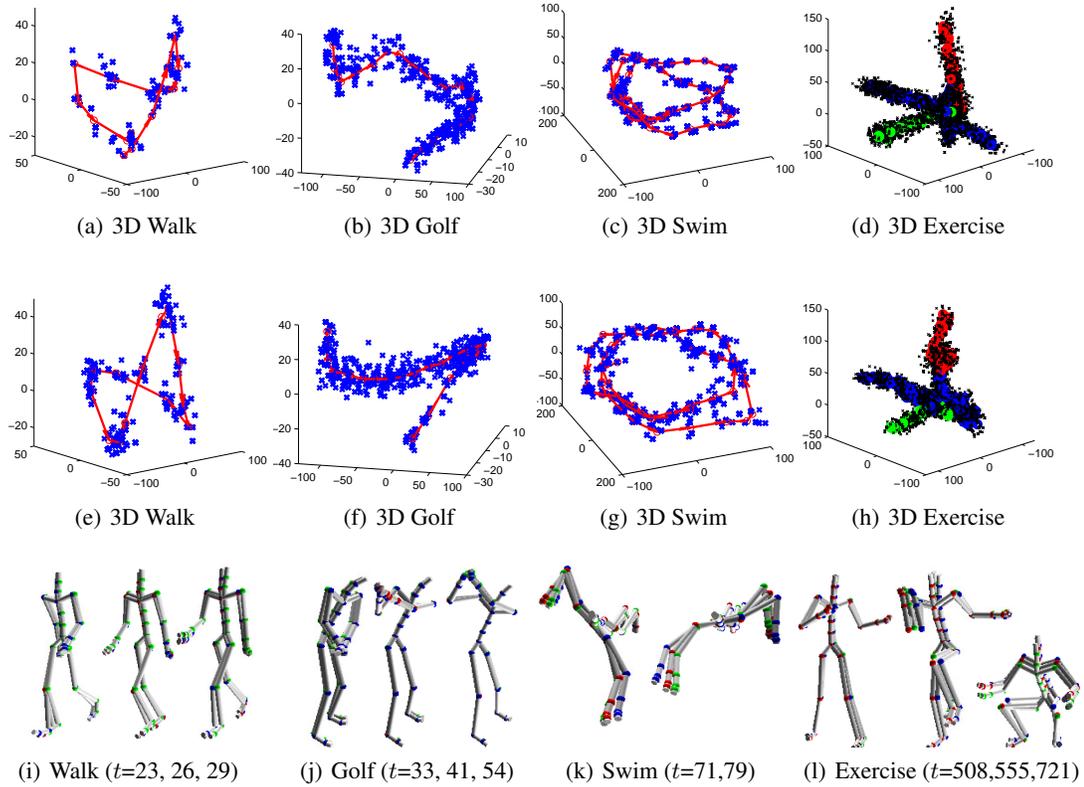

Figure 3: 3D latent spaces learned while tracking: The first row depicts the results of our SOGP variant, while the second row shows our LGP variant. In the walk/golf/swimming plots the red curve represents the predicted mean of the latent state sequence and the blue crosses are the particles at each step. In the plots for exercise (last column), the red, blue and green curves are the predicted mean of the latent state for three motions in the exercise sequence, and the black crosses are the particles at each step. The third row depicts the predicted skeletons, where ground truth is shown in green, our SOGP variant in blue and our LGP variant in red.

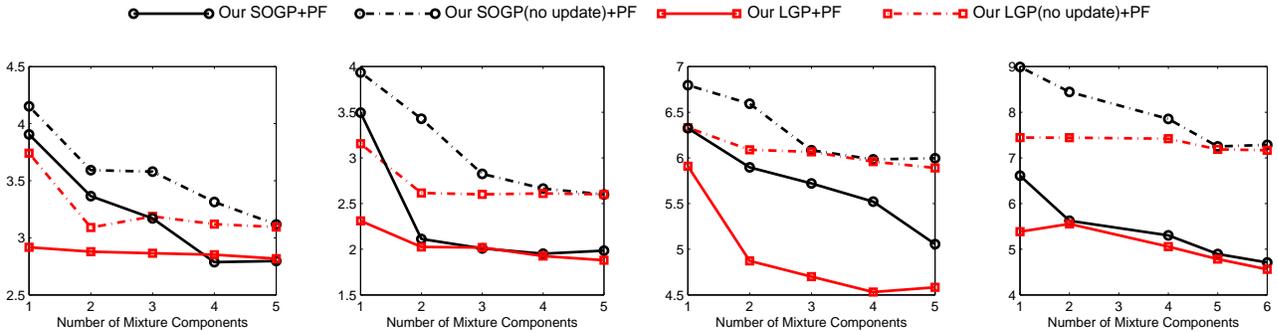

Figure 4: Root Mean Squared Error as a function of the number of mixture components. The columns (from left to right) are respectively for walking, golf, swimming and exercise motions.

Number of Mixture Components: Fig. 4 shows performance as a function of the number of mixture components, R_M and R_O , for both SOGP and LGP. For LGP+PF in walk/golf/swim/exercise, the number of local GPs are 1/1/2/5 and the size of each local GP are 3/3/5/20. In all cases, we set $R_M = R_O$. Note that performance typi-

cally increases with the number of mixture components, for SOGP, but less so for LGP. Furthermore, our approaches outperform the baselines in which the model is not updated during filtering indicating that the online model updating is very important in practice. Also note that while LGP generally outperforms SOGP, the difference quickly declines

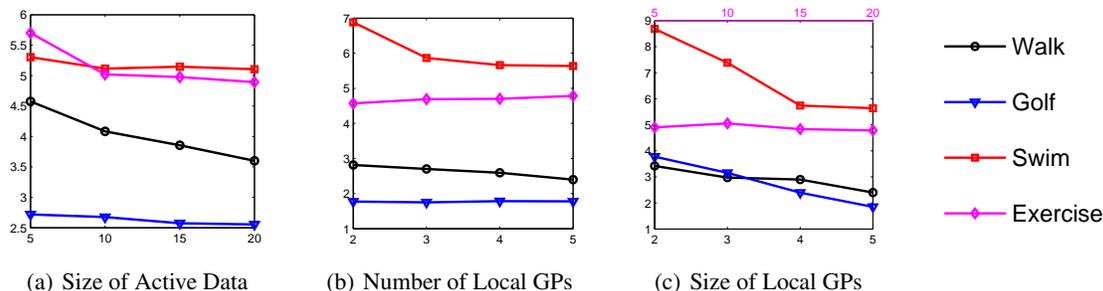

Figure 5: Root mean squared error as a function of the size of the active set in SOGP, the number of the local GP experts and the size of each local GP expert in LGP. In the subplot 5(c), the top x -axis is for exercise and the bottom one for the other motions.

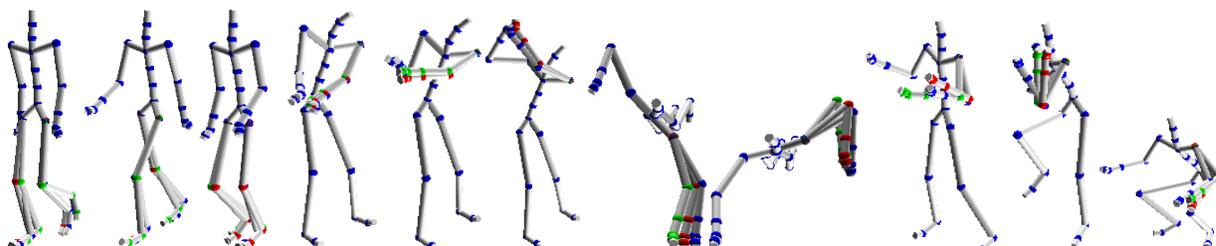

Figure 6: Predicted skeleton for missing parts (Walk: two legs; Golf, Swim and Exercise: left arm). The ground truth is shown in green, our SOGP particle filter in blue and LGP particle filter in red. We show the predicted performance at $t=24, 27, 32$ for walk, $t=34, 38, 50$ for golf, $t=71, 79$ for swim, $t=470, 592, 711$ for exercise.

as the number of mixture components increases. This suggests that, when the fixed memory requirements of SOGP is desirable, a larger number of mixture components will achieve performance comparable to LGP.

Active Set size in SOGP: To explore the effect of the size of the active set, N_A , on performance we set the number of mixture components, R_M and R_O , to be 2/1/5/5 for walk/golf/swim/exercise, and use the same settings as before for the other parameters. Results are shown in Fig. 5(a). As expected performance improves when the size of the active set increases.

Number and Size of Local Experts in LGP: Figs. 5(b) and 5(c) show the performance of our approach as a function of the number of local GP experts, M_a , as well as their size, M_b . For this experiment we set the number of mixture components, R_M and R_O , to be 1/2/1/5 and used the same settings as before for the other parameters except when evaluating the size of each local GP expert where we set the number of local GP experts to 5/2/5/5. As shown in the figure, even with the small number (size) of local GP experts, we still achieve good performance.

4.4 HANDLING MISSING DATA

In this setting, we evaluate the capabilities of our approaches to handle missing data. We assume that the initial set has no missing values, but a fixed set of joint angles are

missing for all incoming frames. Our approach is able to cope with missing data with only two small modifications. First, particles are weighted only based on the observed dimensions. Furthermore, when updating the prediction and observation models, we employ mean imputation for the missing observation dimensions. Fig. 6 shows reconstructions of the missing dimensions for all our motions, which consists of the two legs for walking, the left arm for golf swing, swimming and exercise motions. We can see that our approach is able to reconstruct the missing parts well.

Finally, to evaluate the tracking performance as a function of the number of missing dimensions, we randomly generate the indices for the missing dimensions and use the same missing dimensions for all incoming frames. The second row of Fig. 2 shows that, compared to the baselines, our methods perform well even when the number of missing dimensions is 20 (1/3 of the skeleton) for all the motions. In addition, our LGP particle filter outperforms our SOGP variant.

5 CONCLUSION

In this paper we have presented a novel non-parametric approach to Bayesian filtering, where the observation and prediction models are constructed using a mixture model with GP components learned in an online fashion. We have demonstrated that our approach can capture the mul-

timodality accurately and efficiently by online updates. We have explored two fast GP variants for updating which keep memory and computation bounded for individual mixture components. We have demonstrated the effectiveness of our approach when tracking different human motions and explored the impact of various parameters on performance. The Local GP particle filter proved superior to our SOGP variant, however these differences can be mitigated by using more mixture components when using SOGP. In the future, we plan to investigate the usefulness of our approach in other settings such as shape deformation estimation and financial time series.

Abstract

When belief propagation (BP) converges, it does so to a stationary point of the Bethe free energy \mathcal{F} , and is often strikingly accurate. However, it may converge only to a local optimum or may not converge at all. An algorithm was recently introduced by Weller and Jebara for attractive binary pairwise MRFs which is guaranteed to return an ϵ -approximation to the global minimum of \mathcal{F} in polynomial time provided the maximum degree $\Delta = O(\log n)$, where n is the number of variables. Here we extend their approach and derive a new method based on analyzing first derivatives of \mathcal{F} , which leads to much better performance and, for attractive models, yields a fully polynomial-time approximation scheme (FPTAS) without any degree restriction. Further, our methods apply to general (non-attractive) models, though with no polynomial time guarantee in this case, demonstrating that approximating \log of the Bethe partition function, $\log Z_B = -\min \mathcal{F}$, for a general model to additive ϵ -accuracy may be reduced to a discrete MAP inference problem. This allows the merits of the global Bethe optimum to be tested.

1 INTRODUCTION

Undirected graphical models, also termed Markov random fields (MRFs), are central tools in machine learning. A set of variables and a score function is specified such that the probability of a configuration of variables is proportional to the value of the score function, which factorizes into sub-functions over subsets of variables in a way that defines a topology on the variables.

Three central problems are: (1) To evaluate the partition function Z , which is the sum of the score function over all possible settings, and hence is the normalization con-

stant for the probability distribution; (2) Marginal inference, which is computing the probability distribution of a given subset of variables; and (3) Maximum a posteriori (MAP) inference, which is the task of identifying a setting of all the variables which has maximum probability.

All these are NP-hard, and (1) and (2) are closely related (marginals are a ratio of two partition functions). Variational methods show that the partition function may be obtained by minimizing the free energy over the marginal polytope, and that if instead the Bethe free energy (Bethe, 1935) is minimized over the local polytope, this should yield a good approximation¹. Although this is not a formal result, and there are cases where it performs poorly - typically when there are many short cycles with strong edge interactions (Wainwright and Jordan, 2008, § 4.1), still, the approach has proved very popular and often strikingly accurate. Belief propagation is often used to perform this minimization (Pearl, 1988; Yedidia et al., 2001). Performance is often excellent (McEliece et al., 1998; Murphy et al., 1999), but when applied to models with cycles, termed loopy belief propagation (LBP), convergence is not guaranteed in general, even to a local minimum. Some conjectured that when LBP behaves poorly, it is likely that the Bethe approximation, as given by the global minimum, also performs poorly, but it has not previously been possible to test this.

Approaches such as gradient descent (Welling and Teh, 2001), double-loop methods (Yuille, 2002) or Frank-Wolfe (Belanger et al., 2013) will converge but only to a local minimum, and with no runtime guarantee. Recently, two methods with polynomial runtime were given for the important subclass of binary pairwise models: one returns an approximately stationary point (Shin, 2012), though its value may be far even from a local minimum; the other returns an ϵ -approximate global optimum value (Weller and Jebara, 2013a) but only for the restricted case of attractive models (where pairwise relationships tend to pull connected variables to the same value)¹. Both these methods restrict the topology to have maximum degree $O(\log n)$,

¹All terms are defined in §2.

where n is the number of variables.

1.1 CONTRIBUTION AND SUMMARY

We obtain results for binary pairwise MRFs by expanding on ideas from Weller and Jebara (2013a). The approach is to construct a *sufficient mesh* of discretized points in such a way that the optimum mesh point q^* is guaranteed to have $\mathcal{F}(q^*)$ within ϵ of the true optimum. Our first derivative method typically results in a mesh that is much coarser (by many orders of magnitude, see §6.1), yet still sufficient, and admits adaptive methods to focus points in regions where \mathcal{F} may vary rapidly. This leads to a FPTAS for attractive models with no restriction on topology. In addition, we refine and extend the second derivative approach of Weller and Jebara (2013a) to derive a method that performs well for very small ϵ . With our new methods, both approaches apply to general binary pairwise models (not necessarily attractive) to reduce the problem of finding an ϵ -approximate global optimum to solving a derived discrete optimization problem, which may be framed as multi-label MAP inference, where a rich family of methods already exists.

There are several motivations for this work:

- To our knowledge, we present the first way to solve for the global Bethe optimum (within ϵ accuracy) of a general binary pairwise MRF. Runtime is practical for small real-world problems.
- This now allows the accuracy of the global Bethe optimum to be tested.
- For attractive models, we obtain a fully polynomial time approximation scheme for any topology, thus answering an open theoretical question.

In §2, we establish notation and present preliminary results, then apply these in §3 to derive our new approach for mesh construction based on analyzing first derivatives of \mathcal{F} . In §4 we revisit the second derivative approach of Weller and Jebara (2013a). We show how this method can be refined and extended to yield better performance and also to admit non-attractive models, though for most cases of interest, unless ϵ is very small, the method of §3 is much superior.

In §5, we discuss the resulting discrete optimization problem. In certain settings this is tractable, and in general we mention several features that can make it easier to find a satisfactory solution, or at least to bound its value. Experiments are described in §6 demonstrating practical application of the algorithm. Conclusions are presented in §7.

For a sketch of the overall approach, see Algorithm, 1.

1.2 RELATED WORK

Jerrum and Sinclair (1993) derived a fully polynomial-time randomized approximation scheme (FPRAS) for the true

Algorithm 1 Mesh method to return ϵ -approximate global optimum $\log Z_B$ for a general binary pairwise model

Input: ϵ , model parameters (convert using §2.1 if required)

Output: estimate of global optimum $\log Z_B$ guaranteed to be in range $[\log Z_B - \epsilon, \log Z_B]$, together with corresponding pseudo-marginal as arg for the discrete optimum

- 1: Preprocess by computing bounds on the locations of minima, see §2.4.
- 2: Construct a sufficient mesh using one of the methods in this paper, see §3 & 4. All approaches are fast, so several may be used and the most efficient mesh selected.
- 3: Attempt to solve the resulting multi-label MAP inference problem, see §5.
- 4: If unsuccessful, but a strongly persistent partial solution was obtained, then improved location bounds may be generated (see §5.2.1), repeat from 2.

At anytime, one may stop and compute bounds on $\log Z_B$, see §5.2.

partition function, but only when singleton potentials are uniform (i.e. a uniform external field), and the runtime is high at $O(\epsilon^{-2}m^3n^{11} \log n)$. Heinemann and Globerson (2011) have shown that models exist such that the true marginal probability cannot possibly be the location of a minimum of the Bethe free energy. Approaches have been developed to solve related convex problems but results are typically less good (Meshi et al., 2009). Our work demonstrates an interesting connection between MAP inference techniques (NP-hard) and estimating the partition function Z (#P-hard). A different connection was shown by using MAP inference on randomly perturbed models to approximate and bound Z (Hazan and Jaakkola, 2012).

2 NOTATION & PRELIMINARIES

Our notation is similar to Weller and Jebara (2013a) and Welling and Teh (2001). We focus on a binary pairwise model with n variables $X_1, \dots, X_n \in \mathbb{B} = \{0, 1\}$ and graph topology $(\mathcal{V}, \mathcal{E})$ with $m = |\mathcal{E}|$; that is \mathcal{V} contains nodes $\{1, \dots, n\}$ where i corresponds to X_i , and $\mathcal{E} \subseteq V \times V$ contains an edge for each pairwise score relationship. Let $\mathcal{N}(i)$ be the neighbors of i . Let $x = (x_1, \dots, x_n)$ be one particular configuration, and introduce the notion of energy $E(x)$ through²

$$p(x) = \frac{e^{-E(x)}}{Z}, \quad E = - \sum_{i \in \mathcal{V}} \theta_i x_i - \sum_{(i,j) \in \mathcal{E}} W_{ij} x_i x_j, \quad (1)$$

²The probability or score function can always be reparameterized in this way, with finite θ_i and W_{ij} terms provided $p(x) > 0 \forall x$, which is a requirement for our approach. There are reasonable distributions where this does not hold, i.e. distributions where $\exists x : p(x) = 0$, but this can often be handled by assigning such configurations a sufficiently small positive probability ϵ .

where the partition function $Z = \sum_x e^{-E(x)}$ is the normalizing constant, and $\{\theta_i, W_{ij}\}$ are parameters of the model.

Given any joint probability distribution $p(X_1, \dots, X_n)$ over all variables, the (Gibbs) free energy is defined as $\mathcal{F}_G(p) = \mathbb{E}_p(E) - S(p)$, where $S(p)$ is the (Shannon) entropy of the distribution. Using variational methods, a remarkable result is easily shown (Wainwright and Jordan, 2008): minimizing \mathcal{F}_G over the set of all globally valid distributions (termed the *marginal polytope*) yields a value of $-\log Z$ at the true marginal distribution, given in (1).

This minimization is, however, computationally intractable, hence the approach of minimizing the Bethe free energy \mathcal{F} makes two approximations: (i) the marginal polytope is relaxed to the *local polytope*, where we require only *local* consistency, that is we deal with a *pseudo-marginal* vector q , which in our context may be considered $\{q_i = q(X_i = 1) \forall i \in \mathcal{V}, \mu_{ij} = q(x_i, x_j) \forall (i, j) \in \mathcal{E}\}$ subject to $q_i = \sum_{j \in \mathcal{N}(i)} \mu_{ij}, q_j = \sum_{i \in \mathcal{N}(j)} \mu_{ij} \forall i, j \in \mathcal{V}$; and (ii) the entropy S is approximated by the Bethe entropy $S_B = \sum_{(i,j) \in \mathcal{E}} S_{ij} + \sum_{i \in \mathcal{V}} (1 - d_i) S_i$, where S_{ij} is the entropy of μ_{ij} , S_i is the entropy of the singleton distribution and $d_i = |\mathcal{N}(i)|$ is the degree of i . The local polytope constraints imply that, given q_i and q_j ,

$$\mu_{ij} = \begin{pmatrix} 1 + \xi_{ij} - q_i - q_j & q_j - \xi_{ij} \\ q_i - \xi_{ij} & \xi_{ij} \end{pmatrix} \quad (2)$$

for some $\xi_{ij} \in [0, \min(q_i, q_j)]$, where $\mu_{ij}(a, b) = q(X_i = a, X_j = b)$. Hence, the global optimum of the Bethe free energy,

$$\begin{aligned} \mathcal{F}(q) &= \mathbb{E}_q(E) - S_B(q) \\ &= \sum_{(i,j) \in \mathcal{E}} -(W_{ij} \xi_{ij} + S_{ij}(q_i, q_j)) \\ &\quad + \sum_{i \in \mathcal{V}} (-\theta_i q_i + (d_i - 1) S_i(q_i)), \end{aligned} \quad (3)$$

is achieved by minimizing \mathcal{F} over the local polytope, with Z_B defined s.t. the result obtained equals $-\log Z_B$. See (Wainwright and Jordan, 2008) for details. Let $\alpha_{ij} = e^{W_{ij}} - 1$. $\alpha_{ij} = 0 \Leftrightarrow W_{ij} = 0$ may be assumed not to occur else the edge (i, j) may be deleted. α_{ij} has the same sign as W_{ij} , if positive then the edge (i, j) is *attractive*; if negative then the edge is *repulsive*. The MRF is attractive if all edges are attractive. As shown by Welling and Teh (2001), one can solve for ξ_{ij} explicitly in terms of q_i and q_j by minimizing \mathcal{F} , leading to a quadratic with real roots,

$$\alpha_{ij} \xi_{ij}^2 - [1 + \alpha_{ij}(q_i + q_j)] \xi_{ij} + (1 + \alpha_{ij}) q_i q_j = 0. \quad (4)$$

For $\alpha_{ij} > 0$, $\xi_{ij}(q_i, q_j)$ is the lower root, for $\alpha_{ij} < 0$ it is the higher. Thus we may consider the minimization of \mathcal{F} over $q = (q_1, \dots, q_n) \in [0, 1]^n$. Collecting the pairwise terms of \mathcal{F} from (3) for one edge, define

$$f_{ij}(q_i, q_j) = -W_{ij} \xi_{ij}(q_i, q_j) - S_{ij}(q_i, q_j). \quad (5)$$

We are interested in *discretized pseudo-marginals* where for each q_i , we restrict its possible values to a discrete mesh \mathcal{M}_i of points in $[0, 1]$. The points may be spaced unevenly and we may have $\mathcal{M}_i \neq \mathcal{M}_j$. Let $N_i = |\mathcal{M}_i|$, and define $N = \sum_{i \in \mathcal{V}} N_i$ and $\Pi = \prod_{i \in \mathcal{V}} N_i$, the sum and product respectively of the number of mesh points in each dimension. Write \mathcal{M} for the entire mesh. Let \hat{q} be the location of a global optimum of \mathcal{F} . We say that a mesh construction $\mathcal{M}(\epsilon)$ is *sufficient* if, given $\epsilon > 0$, it can be guaranteed that \exists a mesh point $q^* \in \prod_{i \in \mathcal{V}} \mathcal{M}_i$ s.t. $\mathcal{F}(q^*) - \mathcal{F}(\hat{q}) \leq \epsilon$. The resulting discrete optimization problem may be framed as MAP inference in a multi-label MRF, where variable i takes values in \mathcal{M}_i , with the same topology (see §5).

2.1 INPUT MODEL SPECIFICATION

To be consistent with Welling and Teh (2001) and Weller and Jebara (2013a), for all theoretical analysis in this paper, we assume the reparameterization in (1). However, when an input model is specified, in order to avoid bias, we use singleton terms θ_i as in (1), but instead use pairwise energy terms given by $-\frac{W_{ij}}{2} x_i x_j - \frac{W_{ij}}{2} (1 - x_i)(1 - x_j)$. With this form, varying W_{ij} simply alters the degree of association between i and j . We assume maximum possible values W and T are known with $|\theta_i| \leq T \forall i \in \mathcal{V}$, and $|W_{ij}| \leq W \forall (i, j) \in \mathcal{E}$. The required transformation to convert from input model to the format of (1), simply takes $\theta_i \leftarrow \theta_i - \sum_{j \in \mathcal{N}(i)} W_{ij}/2$, leaving W_{ij} unaffected.

2.2 SUBMODULARITY

If all pairwise cost functions f_{ij} over $\mathcal{M}_i \times \mathcal{M}_j$ from (5) are submodular³, then the global discretized optimum may be found efficiently using graph cuts (Schlesinger and Flach, 2006). We require the following earlier result.

Theorem 1 (Submodularity for any discretization of an attractive model, see Weller and Jebara (2013a) Theorem 8, Korč et al. (2012)). *In a binary pairwise MRF, if an edge (i, j) is attractive, i.e. $W_{ij} > 0$, then the discretized multi-label MRF for any mesh \mathcal{M} is submodular for that edge. Hence if the MRF is fully attractive, then the discretized multi-label MRF is fully submodular for any discretization.*

2.3 FLIPPING VARIABLES

A useful technique for our analysis is to consider a model where some variables are flipped, i.e. given a model on $\{X_i\}$, consider a new model on $\{X'_i\}$ where $X'_i = 1 - X_i$ for some $i \in \mathcal{V}$. New model parameters $\{\theta'_i, W'_{ij}\}$ may be identified as in (Weller and Jebara, 2013a, §3) to preserve

³Here a pairwise multi-label function on a set of ordered labels $X_{ij} = \{1, \dots, K_i\} \times \{1, \dots, K_j\}$ is *submodular* iff $\forall x, y \in X_{ij}, f(x \wedge y) + f(x \vee y) \leq f(x) + f(y)$, where for $x = (x_1, x_2)$ and $y = (y_1, y_2)$, $(x \wedge y) = (\min(x_1, y_1), \min(x_2, y_2))$ and $(x \vee y) = (\max(x_1, y_1), \max(x_2, y_2))$. For binary variables this is equivalent to the edge potential being attractive.

energies of all states up to a constant. If all variables are flipped, new parameters are given by

$$W'_{ij} = W_{ij}, \theta'_i = -\theta_i - \sum_{j \in \mathcal{N}(i)} W_{ij}. \quad (6)$$

If the original model was attractive, so too is the new. If only a subset $\mathcal{R} \subseteq \mathcal{V}$ is flipped, let $X'_i = 1 - X_i$ if $i \in \mathcal{R}$, else $X'_i = X_i$ for $i \in \mathcal{S}$, where $\mathcal{S} = \mathcal{V} \setminus \mathcal{R}$. Let $\mathcal{E}_t = \{\text{edges with exactly } t \text{ ends in } \mathcal{R}\}$ for $t = 0, 1, 2$. Then we obtain

$$W'_{ij} = \begin{cases} W_{ij} & (i, j) \in \mathcal{E}_0 \cup \mathcal{E}_2, \\ -W_{ij} & (i, j) \in \mathcal{E}_1, \end{cases} \quad (7)$$

$$\theta'_i = \begin{cases} \theta_i + \sum_{(i,j) \in \mathcal{E}_1} W_{ij} & i \in \mathcal{S}, \\ -\theta_i - \sum_{(i,j) \in \mathcal{E}_2} W_{ij} & i \in \mathcal{R}. \end{cases}$$

Lemma 2. *Flipping variables changes affected pseudo-marginal matrix entries' locations but not values. \mathcal{F} is unchanged up to a constant, hence the locations of stationary points are unaffected. Proof in Weller and Jebara (2013a)*

2.4 PRELIMINARY BOUNDS

We use the following earlier results.

Lemma 3 (Weller and Jebara (2013a) Lemma 2). $\alpha_{ij} \geq 0 \Rightarrow \xi_{ij} \geq q_i q_j, \alpha_{ij} \leq 0 \Rightarrow \xi_{ij} \leq q_i q_j$.

Lemma 4 (Upper bound for ξ_{ij} for an attractive edge, Weller and Jebara (2013a) Lemma 6). *If $\alpha_{ij} > 0$, then $\xi_{ij} - q_i q_j \leq \frac{\alpha_{ij} m(1-M)}{1+\alpha_{ij}}$, where $m = \min(q_i, q_j)$ and $M = \max(q_i, q_j)$.*

Theorem 5 (Weller and Jebara (2013a) Theorem 4). *For general edge types (associative or repulsive), let $W_i = \sum_{j \in \mathcal{N}(i): W_{ij} > 0} W_{ij}, V_i = -\sum_{j \in \mathcal{N}(i): W_{ij} < 0} W_{ij}$. At any stationary point of the Bethe free energy, $\sigma(\theta_i - V_i) \leq q_i \leq \sigma(\theta_i + W_i)$, where $\sigma(x) = 1/(1 + \exp(-x))$ (sigmoid).*

For the efficiency of our overall approach, it is very desirable to tighten these bounds on locations of minima of \mathcal{F} since this both reduces the search space and allows a lower density of discretizing points in the mesh. For our theoretical results, we do not assume this can be done but in practice, it can be attempted efficiently by running either of the following two algorithms: Bethe bound propagation (BBP) from (Weller and Jebara, 2013a, §6), or using the approach from Mooij and Kappen (2007) which we term MK. Either method can achieve striking results quickly, though MK is our preferred method⁴ - this considers cavity fields around each variable and determines the range of possible beliefs after iterating LBP, starting from any initial values; since any minimum of \mathcal{F} corresponds to a fixed point of LBP (Yedidia et al., 2001), this bounds all minima.

⁴Both BBP and MK are anytime methods that converge quickly, and can be implemented such that each iteration runs in $O(m)$ time. MK takes a little longer but can yield tighter bounds.

Let the lower bounds obtained for q_i and $1 - q_i$ respectively be A_i and B_i so that $A_i \leq q_i \leq 1 - B_i$, and let the *Bethe box* be the orthotope given by $\prod_{i \in \mathcal{V}} [A_i, 1 - B_i]$. Define $\eta_i = \min(A_i, B_i)$, i.e. the closest that q_i can come to the extreme values of 0 or 1.

2.5 DERIVATIVES OF \mathcal{F}

Welling and Teh (2001) derived first partial derivatives of the Bethe free energy as

$$\frac{\partial \mathcal{F}}{\partial q_i} = -\theta_i + \log Q_i, \quad (8)$$

$$\text{where } Q_i = \frac{(1 - q_i)^{d_i - 1} \prod_{j \in \mathcal{N}(i)} (q_i - \xi_{ij})}{q_i^{d_i - 1} \prod_{j \in \mathcal{N}(i)} (1 + \xi_{ij} - q_i - q_j)}.$$

Weller and Jebara (2013a) derived all second partial derivatives.

Theorem 6 (All terms of the Hessian, see Weller and Jebara (2013a) §4.3 and Lemma 9). *Let H be the Hessian of \mathcal{F} for a binary pairwise model, i.e. $H_{ij} = \frac{\partial^2 \mathcal{F}}{\partial q_i \partial q_j}$, and d_i be the degree of variable X_i , then*

$$H_{ii} = -\frac{d_i - 1}{q_i(1 - q_i)} + \sum_{j \in \mathcal{N}(i)} \frac{q_j(1 - q_j)}{T_{ij}} \geq \frac{1}{q_i(1 - q_i)},$$

$$H_{ij} = \begin{cases} \frac{q_i q_j - \xi_{ij}}{T_{ij}} & (i, j) \in \mathcal{E} \\ 0 & (i, j) \notin \mathcal{E}, i \neq j, \end{cases}$$

$$\text{where } T_{ij} = q_i q_j (1 - q_i)(1 - q_j) - (\xi_{ij} - q_i q_j)^2 \geq 0 \text{ with equality iff } q_i \text{ or } q_j \in \{0, 1\}. \quad (9)$$

3 NEW APPROACH: GRADMESH

We develop a new approach to constructing a sufficient mesh \mathcal{M} by analyzing bounds on the first derivatives of \mathcal{F} . To help distinguish between methods, we call the new first derivative approach *gradMesh*, and the earlier, second derivative approach *curvMesh*. The new gradMesh approach yields several attractive features:

- For attractive models, we obtain a FPTAS with worst case runtime $O(\epsilon^{-3} n^3 m^3 W^3)$ and no restriction on topology, unlike earlier work (Weller and Jebara, 2013a) which required max degree $\Delta = O(\log n)$.
- Our sufficient mesh is typically dramatically coarser than the earlier method of Weller and Jebara (2013a) unless ϵ is very small, leading to a much smaller subsequent MAP problem. Here, the sum of the number of discretizing points in each dimension, $N = O\left(\frac{nmW}{\epsilon}\right)$. For comparison, the earlier method, even after our improvements in §4, forms a mesh with $N = O\left(\epsilon^{-1/2} n^{7/4} \Delta^{3/4} \exp\left[\frac{1}{2}(W(1 + \Delta/2) + T)\right]\right)$. See §6.1 for examples.

- The approach immediately handles a general model with both attractive and repulsive edges. Hence approximating $\log Z_B$ may be reduced to a discrete multi-label MAP inference problem. This is valuable due to the availability of many MAP techniques, see §5.

First consider a model which is fully attractive around variable X_i , i.e. $W_{ij} > 0 \forall j \in \mathcal{N}(i)$. From (8) and Lemma 3, we obtain

$$\frac{\partial \mathcal{F}}{\partial q_i} = -\theta_i + \log Q_i \leq -\theta_i + \log \frac{q_i}{1 - q_i}. \quad (10)$$

Flip all variables (see §2.3). Write $'$ for the parameters of the new flipped model, which is also fully attractive, then using (6) and (10),

$$\begin{aligned} \frac{\partial \mathcal{F}'}{\partial q'_i} &\leq -\theta'_i + \log \frac{q'_i}{1 - q'_i} \\ \Leftrightarrow -\theta_i - W_i + \log \frac{q_i}{1 - q_i} &\leq \frac{\partial \mathcal{F}}{\partial q_i}. \end{aligned}$$

Combining this with (10) yields the sandwich result

$$-\theta_i - W_i + \log \frac{q_i}{1 - q_i} \leq \frac{\partial \mathcal{F}}{\partial q_i} \leq -\theta_i + \log \frac{q_i}{1 - q_i}.$$

Now generalize to consider the case that i has some neighbors \mathcal{R} to which it is adjacent by repulsive edges. In this case, flip those nodes \mathcal{R} (see §2.3) to yield a model, which we denote by $''$, which is fully attractive around i , hence we may apply the above result. By (7) we have $\theta''_i = \theta_i - V_i$, and using $W''_i = W_i + V_i$, we obtain that for a general model,

$$-\theta_i - W_i + \log \frac{q_i}{1 - q_i} \leq \frac{\partial \mathcal{F}}{\partial q_i} \leq -\theta_i + V_i + \log \frac{q_i}{1 - q_i}. \quad (11)$$

This bounds each first derivative $\frac{\partial \mathcal{F}}{\partial q_i}$ within a range of width $V_i + W_i = \sum_{j \in \mathcal{N}(i)} |W_{ij}|$, which is sufficient for the main theoretical result, see (15). We take the opportunity, however, to describe a method which sometimes significantly narrows this range, thereby improving the result in practice.

Using one $O(m)$ iteration of the belief propagation algorithm (BBP) derived in (Weller and Jebara, 2013a, Supplement), allows us to refine the bounds for variable X_i of (11) based on the $[A_j, 1 - B_j]$ location bounds on its neighbors $j \in \mathcal{N}(i)$, to show

$$\begin{aligned} f_i^L(q_i) &\leq \frac{\partial \mathcal{F}}{\partial q_i} \leq f_i^U(q_i), \text{ where} \\ f_i^L(q_i) &= -\theta_i - W_i + \log \frac{q_i}{1 - q_i} + \log U_i \\ f_i^U(q_i) &= -\theta_i + V_i + \log \frac{q_i}{1 - q_i} - \log L_i. \end{aligned} \quad (12)$$

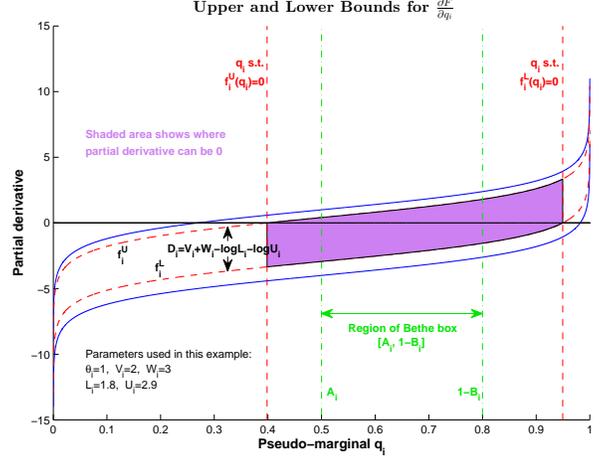

Figure 1: Upper and Lower Bounds for $\frac{\partial \mathcal{F}}{\partial q_i}$. Solid blue curves show worst case bounds (11) as functions of q_i , and are different by a constant $V_i + W_i = \sum_{j \in \mathcal{N}(i)} |W_{ij}|$. Dashed red curves show the upper $f_i^U(q_i)$ and lower $f_i^L(q_i)$ bounds (12) after being lowered by $\log L_i$ and raised by $\log U_i$ respectively, which incorporate the information from the bounds of neighboring variables. All bounding curves are strictly monotonic. The Bethe box region for q_i must lie within the shaded region demarcated by vertical red dashed lines, but we may have better bounds available, e.g. from MK, as shown by A_i and $1 - B_i$.

L_i, U_i are each > 1 with $\log L_i + \log U_i \leq V_i + W_i$. They are computed as $L_i = \prod_{j \in \mathcal{N}(i)} L_{ij}$, $U_i = \prod_{j \in \mathcal{N}(i)} U_{ij}$,

$$\text{with } L_{ij} = \begin{cases} 1 + \frac{\alpha_{ij} A_j}{1 + \alpha_{ij} (1 - B_i)(1 - A_j)} & \text{if } W_{ij} > 0 \\ 1 + \frac{\alpha_{ij} B_j}{1 + \alpha_{ij} (1 - B_i)(1 - B_j)} & \text{if } W_{ij} < 0 \end{cases},$$

$$U_{ij} = \begin{cases} 1 + \frac{\alpha_{ij} B_j}{1 + \alpha_{ij} (1 - A_i)(1 - B_j)} & \text{if } W_{ij} > 0 \\ 1 + \frac{\alpha_{ij} A_j}{1 + \alpha_{ij} (1 - A_i)(1 - A_j)} & \text{if } W_{ij} < 0 \end{cases}.$$

See Figure 1 for an example. We make the following observations:

- The upper bound is equal to the lower bound plus the constant $D_i = V_i + W_i - \log L_i - \log U_i \geq 0$.
- The bound curves are monotonically increasing with q_i , ranging from $-\infty$ to $+\infty$ as q_i ranges from 0 to 1.
- A necessary condition to be within the Bethe box is that the upper bound is ≥ 0 and the lower bound is ≤ 0 . Hence, anywhere within the Bethe box, we must have bounded derivative, $|\frac{\partial \mathcal{F}}{\partial q_i}| \leq D_i$. BBP generates $\{[A_i, 1 - B_i]\}$ bounds by iteratively updating with L_i, U_i terms. In general, however, we may have better bounds from any other method, such as MK, which lead to higher L_i and U_i parameters and lower D_i .

\mathcal{F} is continuous on $[0, 1]^n$ and differentiable everywhere in $(0, 1)^n$ with partial derivatives satisfying (12). $f_i^L(q_i)$ and $f_i^U(q_i)$ are continuous and integrable. Indeed, using the

notation $[\phi(x)]_{x=a}^{x=b} = \phi(b) - \phi(a)$,

$$\int_a^b \log \frac{q_i}{1-q_i} dq_i = \left[q_i \log q_i + (1-q_i) \log(1-q_i) \right]_{q_i=a}^{q_i=b} \quad (13)$$

for $0 \leq a \leq b \leq 1$, which relates to the binary entropy function $H(p) = -p \log p - (1-p) \log(1-p)$, recall the definition of \mathcal{F} . We remark that although $\frac{\partial \mathcal{F}}{\partial q_i}$ tends to $-\infty$ or $+\infty$ as q_i tends to 0 or 1, the integral converges (taking $0 \log 0 = 0$).

Hence if $\hat{q} = (\hat{q}_1, \dots, \hat{q}_n)$ is the location of a global minimum, then for any $q = (q_1, \dots, q_n)$ in the Bethe box,

$$\mathcal{F}(q) - \mathcal{F}(\hat{q}) \leq \sum_{i: \hat{q}_i \leq q_i} \int_{\hat{q}_i}^{q_i} f_i^U(q_i) dq_i + \sum_{i: \hat{q}_i > q_i} \int_{q_i}^{\hat{q}_i} -f_i^L(q_i) dq_i. \quad (14)$$

To construct a sufficient mesh, a simple initial bound relies on $|\frac{\partial \mathcal{F}}{\partial q_i}| \leq D_i$. If mesh points \mathcal{M}_i are chosen s.t. in dimension i there must be a point q^* within γ_i of a global minimum (which can be achieved using a mesh width in each dimension of $2\gamma_i$), then by setting $\gamma_i = \frac{\epsilon}{nD_i}$, we obtain $\mathcal{F}(q^*) - \mathcal{F}(\hat{q}) \leq \sum_i D_i \frac{\epsilon}{nD_i} = \epsilon$. It is easily seen that $N_i \leq 1 + \lceil \frac{1}{2\gamma_i} \rceil$, hence the total number of mesh points, $N = \sum_{i \in \mathcal{V}} N_i$, satisfies

$$\begin{aligned} N &\leq 2n + \frac{n}{2\epsilon} \sum_i D_i \leq 2n + \frac{n}{\epsilon} \sum_{(i,j) \in \mathcal{E}} |W_{ij}| \\ &= O\left(\frac{n}{\epsilon} \sum_{(i,j) \in \mathcal{E}} |W_{ij}|\right) = O\left(\frac{nmW}{\epsilon}\right), \end{aligned} \quad (15)$$

since $D_i \leq V_i + W_i = \sum_{j \in \mathcal{N}(i)} |W_{ij}|$. Here $W = \max_{(i,j) \in \mathcal{E}} |W_{ij}|$ and $m = |\mathcal{E}|$ is the number of edges.

If the initial model is fully attractive, then by Theorem 1 we obtain a submodular multi-label MAP problem which is solvable using graph cuts with worst case runtime $O(N^3) = O(\epsilon^{-3} n^3 m^3 W^3)$ (Schlesinger and Flach, 2006; Greig et al., 1989; Goldberg and Tarjan, 1988).

Note from the first expression in (15) that if we have information on individual edge weights then we have a better bound using $\sum_{(i,j) \in \mathcal{E}} |W_{ij}|$ rather than just mW .

For comparison, the earlier second derivative approach of Weller and Jebara (2013a) has runtime $O(\epsilon^{-\frac{3}{2}} n^6 \Sigma^{\frac{3}{2}} \Omega^{\frac{3}{2}})$, where, even using the improved method in §4 here, $\Omega = O(\Delta e^{W(1+\Delta/2)+T})$. Unless ϵ is very small, the new first derivative approach is typically dramatically more efficient and more useful in practice. Further, it naturally handles both attractive and repulsive edge weights in the same way.

3.1 REFINEMENTS, ADAPTIVE METHODS

Since the resulting multi-label MAP inference problem (which is not submodular in general) is NP-hard (Shimony,

1994), it is helpful to minimize its size. As noted above, setting $\gamma_i = \frac{\epsilon}{nD_i}$, which we term the *simple method*, yields a sufficient mesh, where $|\frac{\partial \mathcal{F}}{\partial q_i}| \leq D_i = V_i + W_i - \log L_i - \log U_i$. However, since the bounding curves are monotonic with $f_i^U \geq 0$ and $f_i^L \leq 0$, a better bound for the magnitude of the derivative is available by setting $D_i = \max\{f_i^U(1 - B_i), -f_i^L(A_i)\}$.

3.1.1 The minsum Method

We define $N_i =$ the number of mesh points in dimension i , with sum $N = \sum_{i \in \mathcal{V}} N_i$ and product $\Pi = \prod_{i \in \mathcal{V}} N_i$. For a fully attractive model, the resulting MAP problem may be solved in time $O(N^3)$ by graph cuts (Theorem 1, (Schlesinger and Flach, 2006; Greig et al., 1989; Goldberg and Tarjan, 1988)), so it is sensible to minimize N . In other cases, however, it is less clear what to minimize. For example, a brute force search over all points would take time $\Theta(\Pi)$.

Define the spread of possible values in dimension i as $S_i = 1 - B_i - A_i$ and note $N_i = 1 + \lceil \frac{S_i}{2\gamma_i} \rceil$ is required to cover the whole range. To minimize N while ensuring the mesh is sufficient, consider the Lagrangian $\mathcal{L} = \sum_{i \in \mathcal{V}} \frac{S_i}{2\gamma_i} - \lambda(\epsilon - \sum_{i \in \mathcal{V}} \gamma_i D_i)$, where D_i is set as in the simple method (§3.1). Optimizing gives

$$\gamma_i = \frac{\epsilon}{\sum_{j \in \mathcal{V}} \sqrt{S_j D_j}} \sqrt{\frac{S_i}{D_i}}, \text{ and } N \leq 2n + \frac{1}{2\epsilon} \left(\sum_{i \in \mathcal{V}} \sqrt{S_i D_i} \right)^2 \quad (16)$$

which we term the *minsum method*. Note $D_i \leq d_i W$ where d_i is the degree of X_i , hence $(\sum_{i \in \mathcal{V}} \sqrt{S_i D_i})^2 \leq W (\sum_{i \in \mathcal{V}} \sqrt{d_i})^2$. By Cauchy-Schwartz and the handshake lemma, $(\sum_{i \in \mathcal{V}} \sqrt{d_i})^2 \leq n \sum_{i \in \mathcal{V}} d_i = 2mn$, with equality iff the d_i are constant, i.e. the graph is regular.

If instead Π is minimized, rather than N , a similar argument shows that the simple method (§3.1) is optimal.

3.1.2 Adaptive Methods

The previous methods rely on one bound D_i for $|\frac{\partial \mathcal{F}}{\partial q_i}|$ over the whole range $[A_i, 1 - B_i]$. However, we may increase efficiency by using local bounds to vary the mesh width across the range. A bound on the maximum magnitude of the derivative over any sub-range may be found by checking just $-f_i^L$ at the lower end and f_i^U at the upper end.

This may be improved by using the exact integral as in (14). First, constant proportions $k_i > 0$ should be chosen with $\sum_i k_i = 1$. Next, the first or smallest mesh point $\gamma_1^i \in \mathcal{M}_i$ should be set s.t. $\int_{A_i}^{\gamma_1^i} f_i^U(q_i) dq_i = k_i \epsilon$. This will ensure that γ_1^i covers all points to its left in the sense that $\mathcal{F}[q_i = \gamma_1^i] - \mathcal{F}[q_i \in [A_i, \gamma_1^i]] \leq k_i \epsilon$ where all other variables $q_j, j \neq i$, are held constant at any values within the Bethe box. γ_1^i also covers all points to its right up to what we term

its *reach*, i.e. the point r_1^i s.t. $\int_{\gamma_1^i}^{r_1^i} -f_i^L(q_i)dq_i = k_i\epsilon$. Next, γ_2^i is chosen as before, using r_1^i as the left extreme rather than A_i , and so on, until the final mesh point is computed with reach $\geq 1 - B_i$. This yields an optimal mesh for the choice of $\{k_i\}$.

If $k_i = \frac{1}{n}$, we achieve an optimized *adaptive simple* method. If $k_i = \frac{\sqrt{S_i D_i}}{\sum_{j \in \mathcal{V}} \sqrt{S_j D_j}}$, we achieve an *adaptive minsum* method. For many problems, this adaptive minsum method will be the most efficient.

Integrals are easily computed using (13). To our knowledge, computing optimal points $\{\gamma_s^i\}$ is not possible analytically, but each may be found with high accuracy in just a few iterations using a search method, hence total time to compute the mesh is $O(N)$, which is negligible compared to solving the subsequent MAP problem.

4 REVISITING THE SECOND DERIVATIVE APPROACH: CURVMESH

We shall review and then refine the second derivative approach used in (Weller and Jebara, 2013a, §5), which we call *curvMesh*. Its mesh size (measured by N , the total number of points summed over the dimensions) grows as $O(\epsilon^{-1/2})$ rather than as $O(\epsilon^{-1})$ in the new first derivative gradMesh approach. In practice, however, unless ϵ is very small, gradMesh is much more efficient (see Figure 2).

As in this paper, the possible location of a global minimum \hat{q} was first bounded in the Bethe box given by $\prod_{i \in \mathcal{V}} [A_i, 1 - B_i]$. Next an upper bound Λ was derived on the maximum possible eigenvalue of the Hessian H of \mathcal{F} anywhere within the Bethe box, where it was required that all edges be attractive. Then a mesh of constant width in every dimension was introduced s.t. the nearest mesh point q^* to \hat{q} was at most γ away in each dimension. Hence the ℓ_2 distance δ satisfies $\delta^2 \leq n\gamma^2$ and by Taylor’s theorem, $F(q^*) \leq F(\hat{q}) + \frac{1}{2}\Lambda\delta^2$. Λ was computed by bounding the maximum magnitude of any element of H . Considering Theorem 6, this involves separate analysis of diagonal H_{ii} terms, which are positive and were bounded above by the term b ; and edge H_{ij} terms, which are negative for attractive edges, whose magnitude was bounded above by a . Then Ω was set as $\max(a, b)$, and Σ as the proportion of non-zero entries in H . Finally, $\Lambda \leq \sqrt{\text{tr}(H^T H)} \leq \sqrt{\Sigma n^2 \Omega^2} = n\Omega\sqrt{\Sigma}$.

4.1 IMPROVED BOUND FOR AN ATTRACTIVE MODEL

We improve the upper bound for Λ by improving the a bound for attractive edges to derive \tilde{a} , a better upper bound on $-H_{ij}$. Essentially, a more careful analysis allows a po-

tentially small term in the numerator and denominator to be canceled before bounding. Writing $\bar{\eta} = \min_{i \in \mathcal{V}} \eta_i(1 - \eta_i)$, i.e. the closest that any dimension can come to 0 or 1, the result is that

$$\begin{aligned} -H_{ij} &\leq \left(\frac{\alpha_{ij}}{1 + \alpha_{ij}} \right) / \bar{\eta} \left(1 - \left(\frac{\alpha_{ij}}{1 + \alpha_{ij}} \right)^2 \right) \\ &= O(e^{W(1+\Delta/2)+T}). \end{aligned} \quad (17)$$

Thus, $\tilde{a} = O(e^{W(1+\Delta/2)+T})$ which compares favorably to the earlier bound in Weller and Jebara (2013a), where $a = O(e^{W(1+\Delta)+2T})$. Recall $b = O(\Delta e^{W(1+\Delta/2)+T})$ and $\Omega = \max(a, b)$, so using the new \tilde{a} bound, now $\Omega = O(\Delta e^{W(1+\Delta/2)+T})$. Details and derivations are in the supplement.

4.2 EXTENDING TO A GENERAL MODEL

Using flipping arguments from §2.3, we are able to extend the method of Weller and Jebara (2013a) to apply to general (non-attractive) models. Interestingly, the bounds derived for $\Omega = \max(a, b)$ take exactly the same form as for the purely attractive case, except that now $-W \leq W_{ij} \leq W$, whereas previously it was required that $0 \leq W_{ij} \leq W$. Details and derivations are in the supplement.

5 RESULTING MULTI-LABEL MAP

After computing a sufficient mesh, it remains to solve the multi-label MAP inference problem on a MRF with the same topology as the initial model, where each q_i takes values in \mathcal{M}_i . In general, this is NP-hard (Shimony, 1994).

5.1 TRACTABLE CASES

If it happens that all cost functions are submodular (as is always the case if the initial model is fully attractive by Theorem 1), then as already noted, it may be solved efficiently using graph cut methods, which rely on solving a max flow/min cut problem on a related graph, with worst case runtime $O(N^3)$ (Schlesinger and Flach, 2006; Greig et al., 1989; Goldberg and Tarjan, 1988). Using the algorithm of Boykov and Kolmogorov (2004), performance is typically much faster, sometimes approaching $O(N)$. This submodular setting is the only known class of problem which is solvable for any topology.

Alternatively, the topological restriction of bounded tree-width allows tractable inference (Pearl, 1988). Further, under mild assumptions, this was shown to be the only restriction which will allow efficient inference for any cost functions (Chandrasekaran et al., 2008). We note that if the problem has bounded tree-width, then so too does the original binary pairwise model, hence exact inference (to yield the true marginals or the true partition function Z) on

the original model is tractable using the junction tree algorithm, making our approximation result less interesting for this class. In contrast, although MAP inference is tractable for any attractive binary pairwise model, marginal inference and computing Z are not (Jerrum and Sinclair, 1993).

A recent approach reducing MAP inference to identifying a maximum weight stable set in a derived weighted graph (Jebara, 2014; Weller and Jebara, 2013b) shows promise, allowing efficient inference if the derived graph is perfect. Further, testing if this graph is perfect can be performed in polynomial time (Jebara, 2014; Chudnovsky et al., 2005).

5.2 INTRACTABLE MAP CASES

Many different methods are available, see Kappes et al. (2013) for a recent survey. Some, such as dual approaches, may provide a helpful bound even if the optimum is not found. Indeed, a LP relaxation will run in polynomial time and return an upper bound on $\log Z_B$ that may be useful. A lower bound may be found from any discrete point, and this may be improved using local search methods.

Note that the Bethe box bounds on each $q_i \in [A_i, 1 - B_i]$ are worst case, irrespective of other variables. However, given a particular value for one or more $q_j, j \in \mathcal{N}(i)$, either BBP (Weller and Jebara, 2013a, §6) or MK (Mooij and Kappen, 2007) can produce better bounds on q_i , which may be helpful for pruning the solution space.

5.2.1 Persistent partial optimization approaches

The multi-label implementation of quadratic pseudo-Boolean optimization (Kohli et al., 2008, MQPBO), and the method of Kovtun (2003), are examples of this class. Both consider LP-relaxations and run in polynomial time. In our context, the output consists of ranges (which in the best case could be one point) of settings for some subset of the variables. If any such ranges are returned, the strong persistence property ensures that *any* MAP solution satisfies the ranges. Hence, these may be used to update $\{A_i, B_i\}$ bounds (padding the discretized range to the full continuous range covered by the end points if needed), compute a new, smaller, sufficient mesh and repeat until no improvement is obtained.

6 EXPERIMENTS

6.1 COMPARISON TO EARLIER WORK

We compared the new mesh construction methods from this paper with the earlier approach by Weller and Jebara (2013a), see Figure 2. We considered two values of ϵ : 1 (medium resolution) and 0.1 (fine resolution). For each value, we generated random MRFs on n variables, all pairwise connected, where $\theta_i \sim U[-2, 2]$ and $W_{ij} \sim$

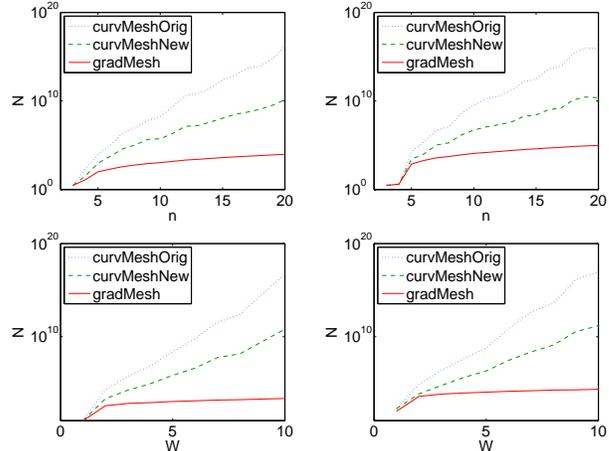

Figure 2: Variation in $N =$ sum of number of mesh points in each dimension, **log scale**, as: (top) $n =$ number of variables is changed, keeping $W = 5$ fixed; (bottom) $W =$ maximum coupling strength is changed, keeping $n = 10$ fixed. On the left, $\epsilon = 1$ (medium resolution); on the right, $\epsilon = 0.1$ (fine resolution). In each case the topology is a complete graph, edge weights are chosen $W_{ij} \sim U[-W, W]$ and $\theta_i \sim U[-2, 2]$. Average over 10 random models for each value. *curvMeshOrig* is the original method of Weller and Jebara (2013a); *curvMeshNew* is our refinement, see §4; *gradMesh* is our new first derivative minsum method, see §3. For more details, see text of §6.1.

$U[-W, W]$, using the input convention of §2.1.⁵ We show results first for fixed $W = 5$ as n is varied from 3 to 20, then for fixed $n = 10$ as W is varied from 1 to 10, generating 10 random models for each value. Of the various first derivative gradMesh methods, only minsum is shown since the others would not be sufficiently distinguishable on these plots.⁶

Note that N is shown on a log axis, thus we observe that the new methods dramatically outperform that of Weller and Jebara (2013a) by many orders of magnitude for most cases of interest, even for small ϵ . Further, recall that $N = \sum_i N_i$ is the sum of the number of mesh points in each dimension. The runtime of the overall algorithm is certainly $\Omega(N)$, even for attractive models⁷, and for general models is typically a significantly higher power, thus further demonstrating the benefit of the new methods.

⁵The original method of Weller and Jebara (2013a) could only handle attractive models but we augment it as in §4.2. Plots for attractive models, where $W_{ij} \sim U[0, W]$ are very similar to those shown.

⁶In practice, the adaptive methods typically produce a mesh with about half the number of points in each dimension.

⁷In our experiments on attractive models, the Boykov-Kolmogorov algorithm typically runs in time $O(N^{1.5})$ to $O(N^{2.5})$.

6.2 POWER NETWORK

As a first step toward applying our algorithm to explore the usefulness of the global optimum of the Bethe approximation, here we consider one setting where LBP fails to converge, yet still we achieve reasonable results.

We aim to predict transformer failures in a power network (Rudin et al., 2012). Since the real data is sensitive, our experiments use synthetic data. Let $X_i \in \{0, 1\}$ indicate if transformer i has failed or not. Each transformer has a probability of failure on its own which is represented by a singleton potential θ_i . However, when connected in a network, a transformer can propagate its failure to nearby nodes (as in viral contagion) since the edges in the network form associative dependencies. We assume that homogeneous attractive pairwise potentials couple all transformers that are connected by an edge, i.e. $W_{ij} = W \forall (i, j) \in \mathcal{E}$. The network topology creates a Markov random field specifying the distribution $p(X_1, \dots, X_n)$. Our goal is to compute the marginal probability of failure of each transformer within the network (not simply in isolation as in Rudin et al. (2012)). Since recovering $p(X_i)$ is hard, we estimate Bethe pseudo-marginals $q_i = q(X_i = 1)$ through our algorithm, which emerge as the arg min when optimizing the Bethe free energy.

A single simulated sub-network of 55 connected transformers was generated using a random preferential attachment model, resulting in average degree 2 (see Figure 3 in the Appendix). Typical settings of $\theta_i = -2$ and $W = 4$ were specified (using the input model specification of §2.1). We attempted to run BP using the libDAI package (Mooij, 2010) but were unable to achieve convergence, even with multiple initial values, using various sequential or parallel settings and with damping. However, running our gradMesh adaptive minsum algorithm with $\epsilon = 1$ achieved reasonable results as shown in Table 1, where true values were obtained with the junction tree algorithm.

$\epsilon = 1$ PTAS for $\log Z_B$	Error from true value
Mean ℓ_1 error of single marginals	0.003
Log-partition function	0.26

Table 1: Results on simulated power network

It has been suggested that the Bethe approximation is poor when BP fails to converge (Mooij and Kappen, 2005). Our new method will allow this to be explored rigorously in future work. The initial result above is a promising first step and justifies further investigation.

7 DISCUSSION & FUTURE WORK

To our knowledge, we have derived the first ϵ -approximation algorithm for $\log Z_B$ for a general binary pairwise model. Our approaches are useful in practice, and

much more efficient than the earlier method of Weller and Jebara (2013a). From experiments run, we note that the ϵ bounds for the adaptive minsum first derivative *gradMesh* approach appear to be close to tight since we have found models where the optimum returned when run with $\epsilon = 1$ is more than 0.5 different to that for $\epsilon = 0.1$. When applied to attractive models, we guarantee a FPTAS with no degree restriction.

As described in §6.2, Bethe pseudo-marginals may be recovered from our approach by taking the q^* that is returned as the arg min of \mathcal{F} over the discrete mesh. However, although $\mathcal{F}(q^*)$ is guaranteed within ϵ of the optimum, there is no guarantee that q^* will necessarily be close to a true Bethe optimum pseudo-marginal. For example, the surface could be very flat over a wide region, or the true optimum might be $\frac{\epsilon}{2}$ better at a location far from q^* . We sketch out how our approach may be used to bound the location of a global optimum pseudo-marginal, though note that there is no runtime guarantee. First pick an initial ϵ_1 and run the main algorithm to find q_1^* . Now use any method to solve for the second best discretized mesh point q_2^* . If it happens that $\mathcal{F}(q_2^*) \geq \mathcal{F}(q_1^*) + \epsilon_1$ then, by the nature of the mesh construction, there must be a global minimum within the orthotope given by the neighboring mesh points of q_1^* in each dimension⁸ and we terminate. On the other hand, if $\mathcal{F}(q_2^*) < \mathcal{F}(q_1^*)$ then we reduce ϵ , for example to $\frac{\epsilon_1}{2}$ and repeat until we're successful.

Future work includes further reducing the size of the mesh, considering how it should be selected to simplify the subsequent discrete optimization problem, and exploring applications. Importantly, we now have the opportunity to examine rigorously the performance of the global Bethe optimum. In addition, this will provide a benchmark against which to compare other (non-global) Bethe approaches that typically run more quickly, such as LBP or CCCP (Yuille, 2002). Another interesting avenue is to use our algorithm as a subroutine in a dual decomposition approach to optimize over a tighter relaxation of the marginal polytope.

Abstract

Belief propagation is a remarkably effective tool for inference, even when applied to networks with cycles. It may be viewed as a way to seek the minimum of the Bethe free energy, though with no convergence guarantee in general. A variational perspective shows that, compared to exact inference, this minimization employs two forms of approximation: (i) the true entropy is approximated by the Bethe entropy, and (ii) the minimization is performed over a relaxation of the marginal polytope termed the local polytope. Here we explore when and how the Bethe approximation can fail for binary pairwise models by examining each aspect of the approximation, deriving results both analytically and with new experimental methods.

1 INTRODUCTION

Graphical models are a central tool in machine learning. However, the task of inferring the marginal distribution of a subset of variables, termed *marginal inference*, is NP-hard (Cooper, 1990), even to approximate (Dagum and Luby, 1993), and the closely related problem of computing the normalizing partition function is #P-hard (Valiant, 1979). Hence, much work has focused on finding efficient approximate methods. The sum-product message-passing algorithm termed belief propagation is guaranteed to return exact solutions if the underlying topology is a tree. Further, when applied to models with cycles, known as loopy belief propagation (LBP), the method is popular and often strikingly accurate (McEliece et al., 1998; Murphy et al., 1999).

A variational perspective shows that the true partition function and marginal distributions may be obtained by minimizing the true free energy over the marginal polytope. The standard Bethe approximation instead minimizes the Bethe free energy, which incorporates the Bethe pairwise approximation to the true entropy, over a relaxed pseudo-marginal

set termed the local polytope. A fascinating link to LBP was shown (Yedidia et al., 2001), in that fixed points of LBP correspond to stationary points of the Bethe free energy \mathcal{F} . Further, stable fixed points of LBP correspond to minima of \mathcal{F} (Heskes, 2003). Werner (2010) demonstrated a further equivalence to stationary points of an alternate function on the space of homogeneous reparameterizations.

In general, LBP may converge only to a local optimum or not converge at all. Various sufficient conditions have been derived for the uniqueness of stationary points (Mooij and Kappen, 2007; Watanabe, 2011), though convergence is often still not guaranteed (Heskes, 2004). Convergent methods based on analyzing derivatives of the Bethe free energy (Welling and Teh, 2001) and double-loop techniques (Heskes et al., 2003) have been developed. Recently, algorithms have been devised that are guaranteed to return an approximately stationary point (Shin, 2012) or a point with value ϵ -close to the optimum (Weller and Jebara, 2013a).

However, there is still much to learn about when and why the Bethe approximation performs well or badly. We shall explore both aspects of the approximation in this paper. Interestingly, sometimes they have opposing effects such that together, the result is better than with just one (see §4 for an example). We shall examine minima of the Bethe free energy over three different polytopes: marginal, local and cycle (see §2 for definitions). For experiments, we explore two methods, dual decomposition and Frank-Wolfe, which may be of independent interest. To provide another benchmark and isolate the entropy component, we also examine the tree-reweighted (TRW) approximation (Wainwright et al., 2005). Sometimes we shall focus on models where all edges are *attractive*, that is neighboring variables are pulled toward the same value; in this case it is known that the Bethe approximation is a lower bound for the true partition function (Rozzi, 2012).

Questions we shall address include:

- In attractive models, why does the Bethe approximation perform well for the partition function but, when local potentials are low and coupling high, poorly for

marginals?

- In models with both attractive and repulsive edges, for low couplings, the Bethe approximation performs much better than TRW, yet as coupling increases, this advantage disappears. Can this be repaired by tightening the relaxation of the marginal polytope?
- Does tightening the relaxation of the marginal polytope always improve the Bethe approximation? In particular, is this true for attractive models?

This paper is organized as follows. Notation and preliminary results are presented in §2. In §3-4 we derive instructive analytic results, first focusing on the simplest topology that is not a tree, i.e. a single cycle. Already we observe interesting effects from both the entropy and polytope approximations. For example, even for attractive models, the Bethe optimum may lie outside the marginal polytope and tightening the relaxation leads to a worse approximation to the partition function. In §5 we examine more densely connected topologies, demonstrating a dramatic phase transition in attractive models as a consequence of the entropy approximation that leads to poor singleton marginals. Experiments are described in §6, where we examine test cases. Conclusions are discussed in §7. Related work is discussed throughout the text. An Appendix with technical details and proofs is attached in the Supplement.

2 NOTATION AND PRELIMINARIES

Throughout this paper, we restrict attention to binary pairwise Markov random fields (MRFs). We consider a model with n variables $X_1, \dots, X_n \in \mathbb{B} = \{0, 1\}$ and graph topology $(\mathcal{V}, \mathcal{E})$; that is \mathcal{V} contains nodes $\{1, \dots, n\}$ where i corresponds to X_i , and $\mathcal{E} \subseteq \mathcal{V} \times \mathcal{V}$ contains an edge for each pairwise relationship. Let $x = (x_1, \dots, x_n)$ be a configuration of all the variables, and $\mathbf{N}(i)$ be the neighbors of i . Primarily we focus on models with no ‘hard’ constraints, i.e. $p(x) > 0 \forall x$, though many of our results extend to this case. We may reparameterize the potential functions (Wainwright and Jordan, 2008) and define the energy E such that $p(x) = \frac{e^{-E(x)}}{Z}$ with

$$E = - \sum_{i \in \mathcal{V}} \theta_i x_i - \sum_{(i,j) \in \mathcal{E}} \frac{W_{ij}}{2} [x_i x_j + (1 - x_i)(1 - x_j)]. \quad (1)$$

This form allows edge coupling weights W_{ij} to be varied independently of the singleton potentials θ_i . If $W_{ij} > 0$ then an edge is *attractive*, if $W_{ij} < 0$ then it is *repulsive*. If all edges are attractive, then the model is attractive. We write μ_{ij} for pairwise marginals and, collecting together the θ_i and W_{ij} potential terms into a vector θ , with a slight abuse of notation, sometimes write (1) as $E = -\theta \cdot \mu$.

2.1 FREE ENERGY, VARIATIONAL APPROACH

Given any joint probability distribution $q(x)$ over all variables, the (Gibbs) free energy is defined as $\mathcal{F}_G(q) = \mathbb{E}_q(E) - S(q)$, where $S(q)$ is the (Shannon) entropy of the distribution.

It is easily shown (Wainwright and Jordan, 2008) that $-\log Z(\theta) = \min_q \mathcal{F}_G$, with the optimum when $q = p(\theta)$, the true distribution. This optimization is to be performed over all valid probability distributions, that is over the *marginal polytope*. However, this problem is intractable due to the difficulty of both computing the exact entropy S , and characterizing the polytope (Deza and Laurent, 2009).

2.2 BETHE APPROXIMATION

The standard approach of minimizing the *Bethe free energy* \mathcal{F} makes two approximations:

1. The entropy S is approximated by the *Bethe entropy*

$$S_B(\mu) = \sum_{(i,j) \in \mathcal{E}} S_{ij}(\mu_{ij}) + \sum_{i \in \mathcal{V}} (1 - d_i) S_i(\mu_i), \quad (2)$$

where S_{ij} is the entropy of μ_{ij} , S_i is the entropy of the singleton distribution of X_i and $d_i = |\mathbf{N}(i)|$ is the degree of i ; and

2. The marginal polytope is relaxed to the *local polytope*, where we require only local (pairwise) consistency, that is we deal with a *pseudo-marginal* vector q , that may not be globally consistent, which consists of $\{q_i = q(X_i = 1) \forall i \in \mathcal{V}, \mu_{ij} = q(x_i, x_j) \forall (i, j) \in \mathcal{E}\}$ subject to the constraints $q_i = \sum_{j \in \mathbf{N}(i)} \mu_{ij}$, $q_j = \sum_{i \in \mathbf{N}(j)} \mu_{ij} \forall i, j \in \mathcal{V}$.

In general, the Bethe entropy S_B is not concave and hence, the Bethe free energy $\mathcal{F} = E - S_B$ is not convex.

The global optimum of the Bethe free energy $\mathcal{F} = \mathbb{E}_q(E) - S_B(q)$ is achieved by minimizing \mathcal{F} over the local polytope, with the *Bethe partition function* Z_B defined such that the global minimum obtained equals $-\log Z_B$.

The local polytope constraints imply that, given q_i and q_j ,

$$\mu_{ij} = \begin{pmatrix} 1 + \xi_{ij} - q_i - q_j & q_j - \xi_{ij} \\ q_i - \xi_{ij} & \xi_{ij} \end{pmatrix} \quad (3)$$

for some $\xi_{ij} \in [0, \min(q_i, q_j)]$, where $\mu_{ij}(a, b) = q(X_i = a, X_j = b)$.

As in (Welling and Teh, 2001), one can solve for the Bethe optimal ξ_{ij} explicitly in terms of q_i and q_j by minimizing \mathcal{F} , leading to

$$\xi_{ij}^*(q_i, q_j) = \frac{1}{2\alpha_{ij}} \left(Q_{ij} - \sqrt{Q_{ij}^2 - 4\alpha_{ij}(1 + \alpha_{ij})q_i q_j} \right), \quad (4)$$

where $\alpha_{ij} = e^{W_{ij}} - 1$, $Q_{ij} = 1 + \alpha_{ij}(q_i + q_j)$.

Thus, we may consider the Bethe approximation as minimizing \mathcal{F} over $q = (q_1, \dots, q_n) \in [0, 1]^n$. Further, the derivatives are given by

$$\frac{\partial \mathcal{F}}{\partial q_i} = -\phi_i + \log \left[\frac{(1 - q_i)^{d_i - 1}}{q_i^{d_i - 1}} \prod_{j \in \mathcal{N}(i)} \frac{(q_i - \xi_{ij}^*)}{(1 + \xi_{ij}^* - q_i - q_j)} \right], \quad (5)$$

where $\phi_i = \theta_i - \frac{1}{2} \sum_{j \in \mathcal{N}(i)} W_{ij}$.

2.3 TREE-REWEIGHTED APPROXIMATION

Our primary focus in this paper is on the Bethe approximation but we shall find it helpful to compare results to another form of approximate inference. The *tree-reweighted* (TRW) approach may be regarded as a family of variational methods, where first one selects a point from the *spanning tree polytope*, that is the convex hull of all spanning trees of the model, represented as a weighting for each edge. Given this selection, the corresponding TRW entropy is the weighted combination of entropies on each of the possible trees. This is then combined with the energy and optimized over the local polytope, similarly to the Bethe approximation. Hence it provides an interesting contrast to the Bethe method, allowing us to focus on the difference in the entropy approximation. An important feature of TRW is that its entropy is concave and always upper bounds the true entropy (neither property is true in general for the Bethe entropy). Hence minimizing the TRW free energy is a convex problem and yields an upper bound on the true partition function. Sometimes we shall consider the optimal upper bound, i.e. the lowest upper bound achievable over all possible selections from the spanning tree polytope.

2.4 CYCLE POLYTOPE

We shall consider an additional relaxation of the marginal polytope termed the *cycle polytope*. This inherits all constraints of the local polytope, hence is at least as tight, and in addition enforces consistency around any cycle. A polyhedral approach characterizes this by requiring the following *cycle inequalities* to be satisfied (Barahona, 1993; Deza and Laurent, 2009; Sontag, 2010) for all cycles C and every subset of edges $F \subseteq C$ with $|F|$ odd:

$$\sum_{(i,j) \in F} (\mu_{ij}(0,0) + \mu_{ij}(1,1)) + \sum_{(i,j) \in C \setminus F} (\mu_{ij}(1,0) + \mu_{ij}(0,1)) \geq 1. \quad (6)$$

Each cycle inequality describes a facet of the marginal polytope (Barahona and Mahjoub, 1986). It is typically easier to optimize over the cycle polytope than the marginal polytope, and earlier work has shown that results are often similar (Sontag and Jaakkola, 2007).

2.5 SYMMETRIC AND HOMOGENEOUS MRFS

For analytic tractability, we shall often focus on particular forms of MRFS. We say a MRF is *homogeneous* if all singleton potentials are equal, all edge potentials are equal, and its graph has just one vertex and edge orbit.¹

A MRF is *symmetric* if it has no singleton potentials, hence flipping all variables $0 \leftrightarrow 1$ leaves the energy unchanged, and the true marginals for each variable are $(\frac{1}{2}, \frac{1}{2})$. For symmetric, planar binary pairwise MRFS, it is known that the cycle polytope is equal to the marginal polytope (Barahona and Mahjoub, 1986). Using (4) and (5), it is easy to show the following result.

Lemma 1. *The Bethe free energy of any symmetric MRF has a stationary point at $q_i = \frac{1}{2} \forall i$.*

We remark that this is *not* always a minimum (see §5).

2.6 DERIVATIVES AND MARGINALS

It is known that the derivatives of $\log Z$ with respect to the potentials are the marginals, and that this also holds for any convex free energy, where pseudo-marginals replace marginals if a polytope other than the marginal is used (Wainwright, 2006). Using Danskin's theorem (Bertsekas, 1995), this can be generalized as follows.

Lemma 2. *Let $\hat{F} = E - \hat{S}(\mu)$ be any free energy approximation, X be a compact space, and $\hat{A} = -\min_{\mu \in X} \hat{F}$ be the corresponding approximation to $\log Z$.*

If the arg min is unique at pseudo-marginals τ ,

then $\frac{\partial \hat{A}}{\partial \theta_i} = \tau_i(1)$, $\frac{\partial \hat{A}}{\partial W_{ij}} = \tau_{ij}(0,0) + \tau_{ij}(1,1)$.

If the arg min is not unique then let $Q(\theta)$ be the set of arg mins; the directional derivative of \hat{A} in direction $\theta \leftarrow \theta + y$ is given by $\nabla_y \hat{A} = \max_{\tau \in Q(\theta)} \tau \cdot y$.

In the next Section we begin to apply these results to analyze the locations and values of the minima of the Bethe free energy.

3 HOMOGENEOUS CYCLES

Since the Bethe approximation is exact for models with no cycles, it is instructive first to consider the case of one cycle on n variables, which we write as C_n . Earlier analysis considered the perspective of belief updates (Weiss, 2000; Aji, 2000). Here we examine the Bethe free energy, which in this context is convex (Pakzad and Anantharam, 2002) with a unique optimum.² We consider symmetric models, initially analyzing the homogeneous case.

¹This means there is a graph isomorphism mapping any edge to any other, and the same for any vertex.

²This follows by considering (2) and observing that $S_{ij} - S_i$ (conditional entropy) is concave over the local consistency constraints, hence by appropriate counting, the total Bethe entropy is concave provided an MRF has at most one cycle.

With Lemma 1, we see that singleton marginals are $\frac{1}{2}$ across all approximation methods. For pairwise marginals, the following result holds due to convexity.

Lemma 3. *For any symmetric MRF and a free energy that is convex, the optimum occurs at uniform pseudo-marginals across all pairs of variables, either where the derivative is zero or at an extreme point of the range.*

The uniformity of the optimal edge pseudo-marginals, together with Lemma 1, shows that all are $\mu_{ij} = \begin{pmatrix} x & \frac{1}{2} - x \\ \frac{1}{2} - x & x \end{pmatrix} \forall (i, j) \in \mathcal{E}$, where just x remains to be identified. The optimum x with zero derivative is always contained within the local polytope but we shall see that this is not always the case when we consider the cycle relaxation. Using (4), it is straightforward to derive the following result for the Bethe pairwise marginals.

Lemma 4. *For a symmetric homogeneous cycle, the Bethe optimum over the local polytope is at $x = x_B(W) = \frac{1}{2}\sigma(W/2)$, where we use standard sigmoid $\sigma(y) := \frac{1}{1+e^{-y}}$. Observe that $x_B(-W) = 1/2 - x_B(W)$.*

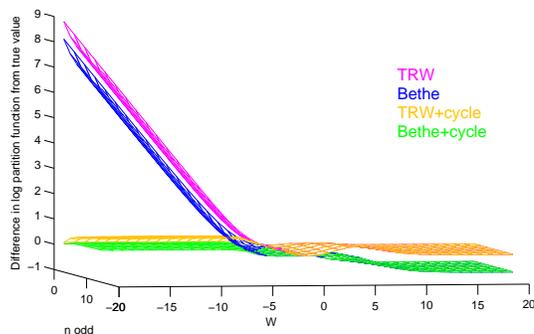

Further, we can derive the error of the Bethe pairwise marginals by using the loop series result given in Lemma 5 of §4, taking log, differentiating and using Lemma 2, to give the difference between true x and Bethe x_B as

$$x - x_B = \frac{1}{4} \frac{\operatorname{sech}^2 \frac{W}{4} \tanh^{n-1} \frac{W}{4}}{1 + \tanh^n \frac{W}{4}}. \quad (7)$$

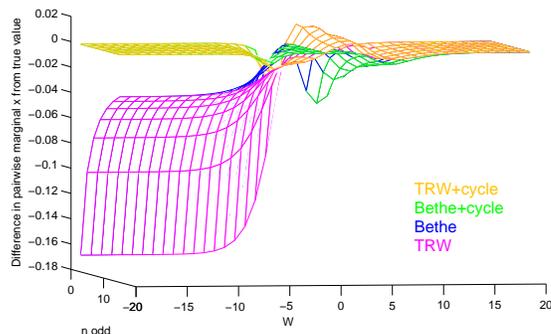

Remarks: Observe that at $W = 0$, $x - x_B = 0$; as $W \rightarrow \pm\infty$, $x - x_B \rightarrow 0$. For $W \neq 0$, $x - x_B$ is always > 0 unless n is even and $W < 0$, in which case it is negative. Differentiating (7) and solving for where x and x_B are most apart gives empirically $W \approx 2 \log n + 0.9$ with corresponding max value of $x - x_B \approx \frac{1}{5n}$ for large n .

See Figure 1 for plots, where, for TRW, values were computed using optimal edge weights, as derived in the Appendix. Observe that at $W = 0$, all methods are exact. As W increases, the Bethe approximations to both $\log Z$ and the marginal x rise more slowly than the true values, though once W is high enough that x is large and cannot rise much further, then the Bethe x_B begins to catch up until they are both close to $\frac{1}{2}$ for large W . We remark that since the Bethe approximation is always a lower bound on the partition function for an attractive model (Ruozzi, 2012), and both the partition functions and marginals are equal at $W = 0$, we know from Lemma 2 that x_B must rise more slowly than x , as seen.

For $W > 0$, tightening the polytope makes no difference. The picture is different for negative W if n is odd, in which case we have a *frustrated cycle*, that is a cycle with an odd number of repulsive edges, which often causes difficulties with inference methods (Weller and Jebara, 2013b).

(a) Errors of $\log Z$ approximations

(b) Errors of pairwise marginal x

Figure 1: Homogeneous cycle C_n , n odd, edge weights W . By Lemma 2, the slope of the error of $\log Z$ wrt W is twice the error of x . For $W > 0$, local and cycle polytopes have the same values.

In this case, (6) is binding for $W < -2 \log(n - 1)$ and prevents the Bethe+cycle marginal x_{BC} from falling below $\frac{1}{2n}$. As $W \rightarrow -\infty$, the true x also does not fall below $\frac{1}{2n}$.³ Thus, as $W \rightarrow -\infty$, the score (negative energy) and hence $\log Z \rightarrow -\infty$ for the true distribution. This also holds for Bethe or TRW on the cycle polytope, but on the local polytope, their energy and $\log Z \rightarrow 0$. Observe that for $W < 0$, Bethe generally outperforms TRW over both polytopes.

Tables 1 and 2 summarize results as $W \rightarrow \pm\infty$, again using optimal edge weights for TRW.

Model	$W \rightarrow -\infty$		$W \rightarrow \infty$	
	$\log Z'$	x	$\log \frac{Z'}{Z}$	x
Bethe	0	0	$-\log 2$	$1/2$
Bethe+cycle	0	0	$-\log 2$	$1/2$
TRW	$\log 2$	0	0	$1/2$
TRW+cycle	$\log 2$	0	0	$1/2$
True distribution	$\log 2$	0	0	$1/2$

Table 1: Analytic results for homogenous cycle C_n , n even. As $W \rightarrow \infty$, $\log Z'$ and $\log Z \rightarrow \infty$ so the difference is shown.

³To see this, note there are $2n$ configurations whose probabilities dominate as $W \rightarrow -\infty$: $01 \dots 0$, its inverse flipping $0 \leftrightarrow 1$, and all n rotations; of these, just one has 00 and one has 11 for a specific edge.

Model	$W \rightarrow -\infty$		$W \rightarrow \infty$	
	$\log Z'$	x	$\log \frac{Z'}{Z}$	x
Bethe	0	0	$-\log 2$	1/2
Bethe+cycle	$-\infty$	$1/(2n)$	$-\log 2$	1/2
TRW	$\log 2$	0	0	1/2
TRW+cycle	$-\infty$	$1/(2n)$	0	1/2
True distribution	$-\infty$	$1/(2n)$	0	1/2

Table 2: Analytic results for homogeneous cycle C_n , n odd. As $W \rightarrow \infty$, $\log Z'$ and $\log Z \rightarrow \infty$ so the difference is shown.

4 NONHOMOGENEOUS CYCLES

The loop series method (Chertkov and Chernyak, 2006; Sudderth et al., 2007) provides a powerful tool to analyze the ratio of the true partition function to its Bethe approximation. In symmetric models with at most one cycle, by Lemma 3, we know that the unique Bethe optimum is at uniform marginals $q_i = \frac{1}{2}$. Using this and (4), and substituting into the loop series result yields the following.

Lemma 5. *For a symmetric MRF which includes exactly one cycle C_n , with edge weights W_1, \dots, W_n , then $Z/Z_B = 1 + \prod_{i=1}^n \tanh \frac{W_i}{4}$.*

Remarks: In this setting, the ratio Z/Z_B is always ≤ 2 and ≈ 1 if even one cycle edge is weak, as might be expected since then the model is almost a tree. The ratio has no dependence on edges not in the cycle and those pairwise marginals will be exact. Further, since the Bethe entropy is concave, by Lemma 1, all singleton marginals are exact at $\frac{1}{2}$. Errors of pairwise pseudo-marginals on the cycle can be derived by using the expression for Z/Z_B from Lemma 5, taking log then differentiating and using Lemma 2.

Several principles are illustrated by considering 3 variables, A , B and C , connected in a triangle. Suppose AB and AC have strongly attractive edges with weight $W = 10$. We examine the effect of varying the weight of the third edge BC , see Figure 2.

It was recently proved (Ruozi, 2012) that $Z_B \leq Z$ for attractive models. A natural conjecture is that the Bethe optimum pseudo-marginal in the local polytope must lie inside the marginal polytope. However, our example, when BC is weakly attractive, proves this conjecture to be false. As a consequence, tightening the local polytope to the marginal polytope for the Bethe free energy in this case worsens the approximation of the log-partition function (though it improves the marginals), see Figure 2 near 0 BC edge weight. For this model, the two aspects of the Bethe approximation to $\log Z$ act in opposing directions - the result is more accurate with both than with either one alone. For intuition, note that via the path $B-A-C$, in the globally consistent probability distribution, B and C are overwhelmingly likely to take the same value. Given that singleton marginals are $\frac{1}{2}$, the Bethe approximation, however, decomposes into a sep-

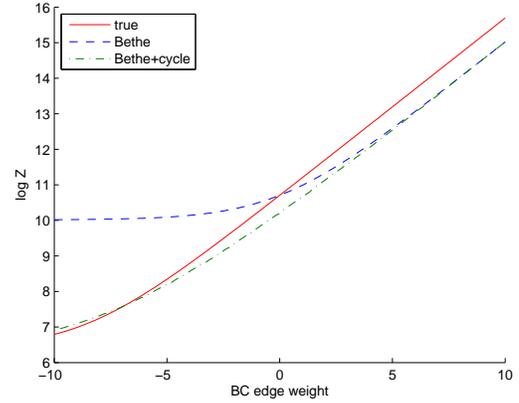

Figure 2: Log partition function and approximations for ABC triangle, see §4. Edge weights for AB and AC are 10 (strongly attractive) while BC is varied as shown. Near 0: Bethe is a better approximation to $\log Z$ but Bethe+cycle has better derivative, hence better marginals by Lemma 2; since Bethe+cycle is below Bethe in this region, its optimum does not lie in the local polytope.

arate optimization for each edge, which for the weak edge BC , yields that B and C are almost independent, leading to a conflict with the true marginal. This causes the Bethe optimum over the local polytope to lie outside the marginal polytope. The same conclusion may be drawn rigorously by considering the cycle inequality (6), taking the edge set $F = \{BC\}$ and observing that the terms are approximately $\frac{1}{4} + \frac{1}{4} + 2(0 + 0) \approx \frac{1}{2} < 1$. Recall that here the cycle and marginal polytopes are the same (see §2.5). The same phenomenon can also be shown to occur for the TRW approximation with uniform edge appearance probabilities.

Notice in Figure 2 that as the BC edge strength rises above 0, the Bethe marginals (given by the derivative) improve while the $\log Z$ approximation deteriorates. We remark that the exactness of the Bethe approximation on a tree can be very fragile in the sense that adding a very weak edge between variables to complete a cycle may expose that pairwise marginal as being (perhaps highly) inaccurate.

5 GENERAL HOMOGENEOUS GRAPHS

We discuss how the Bethe entropy approximation leads to a ‘phase shift’ in behavior for graphs with more than one cycle when W is above a positive threshold.

The true entropy is always maximized at $q_i = \frac{1}{2}$ for all variables. This also holds for the TRW approximation. However, in densely connected attractive models, the Bethe approximation pulls singleton marginals towards 0 or 1. This behavior has been discussed previously (Heskes, 2004; Mooij and Kappen, 2005) and described in terms of algorithmic stability (Wainwright and Jordan, 2008, §7.4), or heuristically as a result of LBP over-counting information when going around cycles (Ihler, 2007), but here we

explain it as a consequence of the Bethe entropy approximation.

We focus on symmetric homogeneous models which are d -regular, i.e. each node has the same degree d . One example is the complete graph on n variables, K_n . For this model, $d = n - 1$. The following result is proved in the Appendix, using properties of the Hessian from (Weller and Jebara, 2013a).

Lemma 6. Consider a symmetric homogeneous MRF on n vertices with d -regular topology and edge weights W . $q = (\frac{1}{2}, \dots, \frac{1}{2})$ is a stationary point of the Bethe free energy but for W above a critical value, this is not a minimum. Specifically, let H be the Hessian of the Bethe free energy at q , x_B be the value from Lemma 4 and $\mathbf{1}$ be the vector of length n with 1 in each dimension; then $\mathbf{1}^T H \mathbf{1} = n[d - 4x_B(d - 1)]/x_B < 0$ if $x_B > \frac{1}{4} \frac{d}{d-1} \Leftrightarrow W > 2 \log \frac{d}{d-2}$.

To help understand this result, consider (2) for the Bethe entropy S_B , and recall that $\sum_i d_i = 2m$ (m is the number of edges, handshake lemma), hence $S_B = mS_{ij} - (2m - n)S_i$. For large W , all the probability mass for each edge is pulled onto the main diagonal, thus $S_{ij} \approx S_i$. For $m > n$, which interestingly is exactly the case of more than one cycle, in order to achieve the optimum S_B , each entropy term $\rightarrow 0$ by tending to pairwise marginal $\begin{pmatrix} 1 & 0 \\ 0 & 0 \end{pmatrix}$ or symmetrically $\begin{pmatrix} 0 & 0 \\ 0 & 1 \end{pmatrix}$. See the second row of Figure 3 for an illustration of how the Bethe entropy surface changes dramatically as W rises, even sometimes going negative, and the top row to see how the Bethe free energy surfaces changes rapidly as W moves through the critical threshold.

Reinforcing this pull of singleton marginals away from $\frac{1}{2}$ is the shape of the energy surface, when optimized for free energy subject to given singleton marginals. In the Bethe approximation, this is achieved by computing ξ_{ij} terms according to (4), as illustrated in the bottom row of Figure 3, but for any reasonable entropy term (including TRW), always $\xi_{ij} < \min(q_i, q_j)$, hence the energy is lower towards the extreme values 0 or 1.

Remarks: (i) This effect is specifically due to the Bethe entropy approximation, and is not affected by tightening the polytope relaxation, as we shall see in §6. (ii) To help appreciate the consequences of Lemma 6, observe that $\log \frac{d}{d-2}$ is positive, monotonically decreasing to 0 as d increases. Thus, for larger, more densely connected topologies, the threshold for this effect is at lower positive edge weights. Above the threshold, $q_i = \frac{1}{2}$ is no longer a minimum but becomes a saddle point.⁴ (iii) This explains the observation made after (Heinemann and Globerson, 2011,

⁴The Hessian at $q_i = \frac{1}{2}$ is neither positive nor negative definite. Moving away from the valley where all q_i are equal, the Bethe free energy rises quickly.

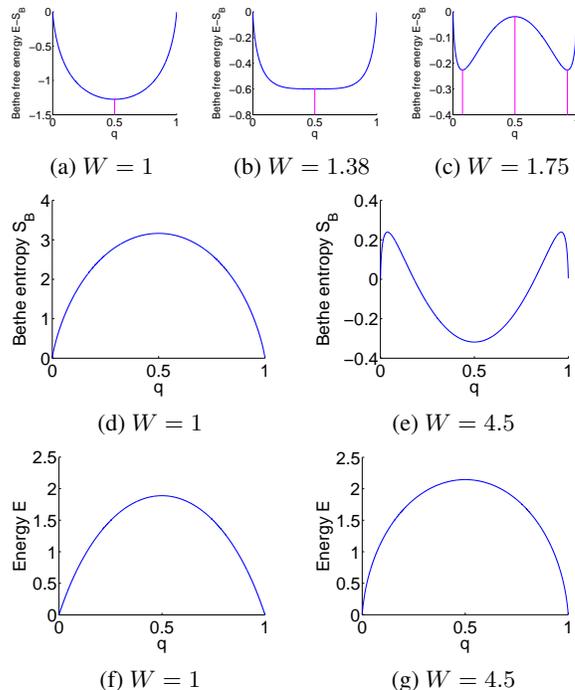

Figure 3: Bethe free energy $E - S_B$ with stationary points highlighted (top), then entropy S_B (middle) and energy E (bottom) vs $q_i = q \forall i$ for symmetric homogeneous complete graph K_5 . All quantities are evaluated at the optimum over pairwise marginals, i.e. $\{\xi_{ij}\}$ are computed as in (4). These figures are described in Lemma 6 and the text thereafter. $W \approx 1.38$ is the critical threshold, above which Bethe singleton marginals are rapidly pulled toward 0 or 1. $W = 4.5$ is sufficiently high that the Bethe entropy becomes negative at $q = \frac{1}{2}$ (middle row).

Lemma 3), where it is pointed out that for an attractive model as $n \rightarrow \infty$, if $n/m \rightarrow 0$, a marginal distribution (other than the extreme of all 0 or all 1) is unlearnable by the Bethe approximation (because the effect we have described pushes all singleton marginals to 0 or 1). (iv) As W rises, although the Bethe singleton marginals can be poor, the Bethe partition function does not perform badly: For a symmetric model, as $W \rightarrow \infty$, there are 2 dominating MAP states (all 0 or all 1) with equal probability. The true marginals are at $q_i = \frac{1}{2}$ which picks up the benefit of $\log 2$ entropy, whereas the Bethe approximation converges to one or other of the MAP states with 0 entropy, hence has $\log 2$ error.

To see why a similar effect does not occur as $W \rightarrow -\infty$, note that for $W < 0$ around a frustrated cycle, the minimum energy solution on the local polytope is at $q_i = \frac{1}{2}$. Indeed, this can pull singleton Bethe marginals toward $\frac{1}{2}$ in this case. See §5.1 in the Appendix for further analysis.

6 EXPERIMENTS

We are interested in the empirical performance of the optimum Bethe marginals and partition function, as the re-

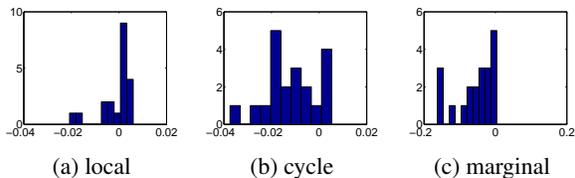

Figure 4: Histogram of differences observed in optimum returned Bethe free energy, FW-mesh primal, over the 20 models in the validation set (mesh using $\epsilon = 0.1$, less than ϵ is insignificant). Negative numbers indicate FW outperformed mesh.

laxation of the marginal polytope is tightened. Many methods have been developed to attempt the optimization over the local polytope, primarily addressing its non-convexity, though none is guaranteed to return the global optimum. Recently, an algorithm was derived to return an ϵ -approximation to the optimum $\log Z_B$ based on constructing a discretized mesh of pseudo-marginals (Weller and Jebara, 2013a, 2014). One method for optimizing over tighter relaxations is to use this algorithm as an inner solver in an iterative dual decomposition approach with subgradient updates (Sontag, 2010; Sontag et al., 2011), where it can be shown that, when minimizing the Bethe free energy, the dual returned less ϵ lower bounds $-\log Z_B$ over the tighter polytope. This would be our preferred approach, but for the models on which we would like to run experiments, the runtime is prohibitive.

Hence we explored two other methods: (i) We replaced the inner solver with a faster, convergent double-loop method, the HAK-BETHE option in libDAI (Heskes et al., 2003; Mooij, 2010), though this is guaranteed only to return a local optimum at each iteration, hence we have no guarantee on the quality of the final result; (ii) We applied the Frank-Wolfe algorithm (FW) (Frank and Wolfe, 1956; Jaggi, 2013; Belanger et al., 2013). At each iteration, a tangent hyperplane is computed at the current point, then a move is made to the best computed point along the line to the vertex (of the appropriate polytope) with the optimum score on the hyperplane. This proceeds monotonically, even on a non-convex surface such as the Bethe free energy, hence will converge (since it is bounded), though runtime is guaranteed only for a convex surface as in TRW.

FW can be applied directly to optimize over marginal, cycle or local polytopes, and performed much better than HAK: runtime was orders of magnitude faster, and the energy found was in line with HAK.⁵ To further justify using FW, which may only reach a local optimum, on our main test cases, we compared its performance on a small validation set against the benchmark of dual decomposition using the guaranteed ϵ -approximate mesh method (Weller and Jebara, 2014) as an inner solver.

⁵The average difference between energies found was < 0.1 .

6.1 IMPLEMENTATION AND VALIDATION

To validate FW for the Bethe approximations on each polytope, we compared log partition functions and pairwise marginals across 20 MRFs, each on a complete graph with 5 variables. Each edge potential was drawn $W_{ij} \sim [-8, 8]$ and each singleton potential $\theta_i \sim [-2, 2]$. To handle the tighter polytope relaxations using the mesh method, we used a dual decomposition approach as follows. For the cycle polytope, one Lagrangian variable was introduced for each cycle constraint (6) with projected subgradient descent updates. For the marginal polytope, rather than imposing each facet constraint, which would quickly become unmanageable⁶, instead a lift-and-project method was employed (Sontag, 2010). These algorithms may be of independent interest and are provided in the Supplement.

For all mesh runs, we used $\epsilon = 0.1$. Note that strong duality is not guaranteed for Bethe since the objective is non-convex, hence we are guaranteed only an upper bound on $\log Z_B$; yet we were able to monitor the duality gap by using rounded primals and observed that the realized gaps were typically within ϵ , see Figure 6.

For FW, we always initialized at the uniform distribution, i.e. $\mu_{ij} = \begin{pmatrix} \frac{1}{4} & \frac{1}{4} \\ \frac{1}{4} & \frac{1}{4} \end{pmatrix} \forall (i, j) \in \mathcal{E}$, note this is always within the marginal polytope. At each iteration, to determine how far to go along the line to the optimum vertex, we used Matlab’s `fminbnd` function. This induces a minimum move of 10^{-6} along the line to the optimum vertex, which was helpful in escaping from local minima. When we tried allowing zero step size, performance became worse. Our stopping criterion was to run for 10,000 iterations (which did not take long) or until the objective value changed by $< 10^{-6}$, at which point we output the best value found so far, and the corresponding pseudo-marginals.

Results on the validation set are shown in Figure 4, indicating that FW performed well compared to mesh + dual decomposition (the best standard we have for the Bethe optimum). Note, however, that good performance on $\log Z_B$ estimation does not necessarily imply that the Bethe optimal marginals were being returned for either method. There may be several local optima where the Bethe free energy has value close to the global optimum, and methods may return different locations. This is a feature of the non-convex surface which should be borne in mind when considering later results, hence we should not be surprised that in the validation set, although 17/20 of the runs had ℓ_1 error in singleton marginals under 0.05, there were 3 runs with larger differences, in one case as high as 0.7 (not shown).⁷

⁶The number of facets of the marginal polytope grows extremely rapidly (Deza and Laurent, 2009).

⁷Recall the example from §5, where a symmetric homogeneous MRF with complete graph K_n topology and high edge

Given this performance, we used FW for all Bethe optimizations on the test cases. FW was also used for all TRW runs, where edge appearance probabilities were obtained using the matrix-tree theorem with weights proportional to each edge’s coupling strength $|W_{ij}|$, as was used in (Sontag and Jaakkola, 2007).

6.2 TEST SETS

Models with 10 variables connected in a complete graph were drawn with random potentials. This allows comparison to earlier work such as (Sontag and Jaakkola, 2007) and (Meshi et al., 2009, Appendix). In addition to examining error in log partition functions and singleton marginals as was done in earlier work, given our theoretical observations in §3-5, we also explored the error in pairwise marginals. To do this, we report the ℓ_1 error in the estimated probability that a pair of variables is equal, averaged over all edges, i.e. we report average ℓ_1 error of $\mu_{ij}(0, 0) + \mu_{ij}(1, 1)$. We used FW to minimize the Bethe and TRW free energies over each of the local, cycle and marginal polytopes. For each maximum coupling value used, 100 models were generated and results averaged for plotting. Given the theoretical observations of §3-5, we are interested in behavior both for attractive and general (non-attractive) models.

For general models, potentials were drawn for single variables $\theta_i \sim U[-2, 2]$ and edges $W_{ij} \sim U[-y, y]$ where y was varied to observe the impact of coupling strength.⁸ Results are shown in Figure 5. Tightening the relaxation of the polytope from local to cycle or marginal, dramatically improves both Bethe and TRW approximations on all measures, with little difference between the cycle or marginal polytopes. This confirms observations in (Sontag and Jaakkola, 2007).

The relative performance of Bethe compared to TRW depends on the criteria used. Looking at the error of singleton marginals, Bethe is better than TRW for low coupling strengths, but for high coupling strengths the methods perform equally well on the local polytope, whereas on the cycle or marginal polytopes, TRW outperforms Bethe (though Bethe is still competitive). Thus, tightening the relaxation of the local polytope at high coupling does not lead to Bethe being superior on all measures. However, in terms of partition function and pairwise marginals, which are important in many applications, Bethe does consistently outperform TRW in all settings, and over all polytopes.

For attractive models, in order to explore our observations in §5, much lower singleton potentials were used. We drew

weights was shown to have 2 locations at the global minimum, with average ℓ_1 distance between them approaching 1.

⁸These settings were chosen to facilitate comparison with the results of (Sontag and Jaakkola, 2007), though in that paper, variables take values in $\{-1, 1\}$ so the equivalent singleton potential ranges coincide. To compare couplings, our y values should be divided by 4.

$\theta_i \sim U[-0.1, 0.1]$ and $W_{ij} \sim U[0, y]$ where y is varied. This is consistent with parameters used by Meshi et al. (2009). Results are shown in Figure 7. When coupling is high, the Bethe entropy approximation pushes singleton marginals away from $\frac{1}{2}$. This effect quickly becomes strong above a threshold. Hence, when singleton potentials are very low, i.e. true marginals are close to $\frac{1}{2}$, the Bethe approximation will perform poorly irrespective of polytope, as observed in our attractive experiments. We note, however, that this effect rarely causes singleton marginals to cross over to the other side of $\frac{1}{2}$. Further, as discussed in §5, the partition function approximation is not observed to deviate by more than $\log 2$ on average.

7 CONCLUSIONS

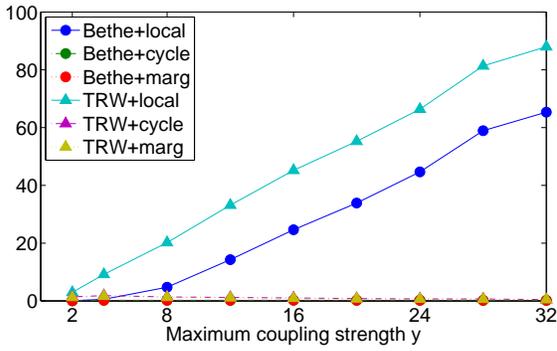

We have used analytic and empirical methods to explore the two aspects of the Bethe approximation: the polytope relaxation and the entropy approximation. We found Frank-Wolfe to be an effective method for optimization, and note that for the cycle polytope, the runtime of each iteration scales polynomially with the number of variables (see §6.1.3 in the Appendix for further details).

For general models with both attractive and repulsive edges, tightening the relaxation of the polytope from local to cycle or marginal, dramatically improves both Bethe and TRW approximations on all measures, with little difference between the cycle or marginal polytopes. For singleton marginals, except when coupling is low, there does not appear to be a significant advantage to solving the non-convex Bethe free energy formulation compared to convex variational approaches such as TRW. However, for log-partition function estimation, Bethe does provide significant benefits. Empirically, in both attractive and mixed models, Bethe pairwise marginals appear consistently better than TRW.

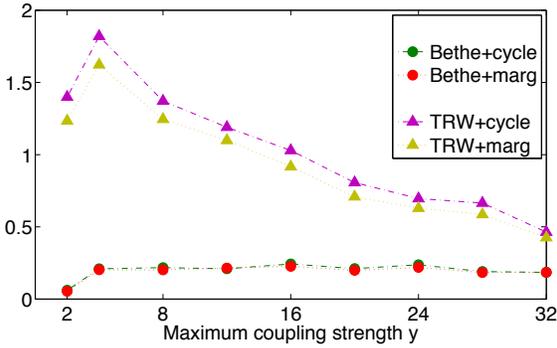

In our experiments with attractive models, the polytope approximation appears to make little difference. However, we have shown theoretically that in some cases it can cause a significant effect. In particular, our discussion of non-homogeneous attractive cycles in §4 shows that even in the attractive setting, tightening the polytope can affect the Bethe approximation - improving marginals but worsening the partition function. It is possible that to observe this phenomenon empirically, one needs a different distribution over models.

A Bayesian Nonparametric Model for Spectral Estimation of Metastable Systems

Hao Wu

Department of Mathematics and Computer Science
Free University of Berlin
Arnimallee 6, 14195 Berlin, Germany

Abstract

The identification of eigenvalues and eigenfunctions from simulation or experimental data is a fundamental and important problem for analysis of metastable systems, because the dominant spectral components usually contain a lot of essential information of the metastable dynamics on slow timescales. It has been shown that the dynamics of a strongly metastable system can be equivalently described as a hidden Markov model (HMM) under some technical assumptions and the spectral estimation can be performed through HMM learning. However, the spectral estimation with unknown number of dominant spectra is still a challenge in the framework of traditional HMMs, and the infinite HMMs developed based on stick-breaking processes cannot satisfactorily solve this problem either. In this paper, we analyze the difficulties of spectral estimation for infinite HMMs, and present a new nonparametric model called stick-breaking half-weighted model (SB-HWM) to address this problem. The SB-HWM defines a sparse prior of eigenvalues and can be applied to Bayesian inference of dominant eigenpairs of metastable systems in a nonparametric manner. We demonstrate by simulations the advantages of applying SB-HWM to spectral estimation.

1 INTRODUCTION

In a variety of scientific areas, we are confronted with the task of analyzing and modeling a complex system which can be described as a Markov process $\{x_t\}$ with time evolution equation

$$\begin{aligned}\rho_{t+\tau}(x) &= \mathcal{P}(\tau) \rho_t(x) \\ &\triangleq \int_{\Omega} p(x_{t+\tau} = x | x_t = x') \rho_t(x') dx\end{aligned}\quad (1)$$

where x_t denotes the system state at time t , Ω is the state space, ρ_t represents the probability density function of x_t , and \mathcal{P} represents the Markov propagator. For many real-world physical and chemical systems, e.g., conformational transitions in macromolecules (Noé and Fischer, 2008), autocatalytic chemical reactions (Biancalani et al., 2012) and climate changes (Berglund and Gentz, 2002), it is common and natural to further assume that $\{x_t\}$ is a time-reversible and metastable process. The reversibility means that $p(x_t = x', x_{t+\tau} = x) = p(x_t = x, x_{t+\tau} = x')$ and generally arises from the time symmetries of classical mechanics, thermodynamics and quantum mechanics, and the metastability of a dynamical system means that the state space of the system can be decomposed into a set of macrostates called *metastable states* so that the local equilibrium within a metastable state can be reached quickly and the transitions between different metastable states can only be observed on slow timescales. A large number of recent studies in statistical physics indicate that the dominant spectral components (or called dominant eigenpairs, i.e., the largest eigenvalues and the associated eigenfunctions) of the Markov propagator is a key to understand and characterize such a process, because they can provide a lot of essential and useful information for the computation of ensemble averages and correlation functions (Noé et al., 2011), detection of spatial structures of metastable states (Deuffhard and Weber, 2005), choice of reaction coordinates (Rohrdanz et al., 2011; Perez-Hernandez et al., 2013), and construction of low-dimensional approximate models (Kube and Weber, 2007; Noé and Nüske, 2013).

However, directly solving the eigenvalue problem of the Markov propagator is generally impossible except for some extremely simple cases (e.g., Ornstein-Uhlenbeck process), and the dominant spectral components can only be estimated from simulation or experimental data through statistical inference and numerical computation. The most

popular and successful method for the spectral estimation is the Markov state model (MSM) method (Prinz et al., 2011; Djurdjevic et al., 2010), which discretizes the state space into a set of discrete bins and calculates the dominant spectral components in a finite element manner by assuming transitions between the bins are Markovian. Obviously, the main difficulty of this method is the choice of the discretization. On the one hand the Markov assumption will be severely violated if the discretization is too coarse, and on the other hand too many bins may cause the problem of “curse of dimensionality” in the estimation of transition probabilities. A more general method is the variational method (Noé and Nüske, 2013; Nüske et al., 2013), which allows one to perform the spectral estimation by using “soft bins” defined by a set of smooth basis functions instead of the “crisp bins” used in MSMs. Numerical experiments show that the variational method can achieve more accurate estimation than the MSM method with the same number of bins. However, there is no systematic algorithm for the choice of basis functions, and the basis function set can only be determined by trial and error in practice. Moreover, in some literature, the diffusion maps is used to identify dominant spectral components in a nonparametric manner by treating each sample point as a discrete bin (Rohrdanz et al., 2011; Ferguson et al., 2011), but this method is applicable only if the Markov propagator is defined by a Brownian dynamics.

In (Noé et al., 2013; Prinz et al., 2014), a novel framework call projected Markov model (PMM) is proposed for spectral analysis of metastable processes without the Markov assumption on discrete bins. Within this framework, it is shown that if a metastable Markov process contains only m nonzero eigenvalues then the corresponding coarse-grained dynamics on the space of discrete bins is equivalent to an m -state hidden Markov model (HMM), and the equivalence is independent of the choice of the discretization. Then HMM learning methods can be utilized to identify dominant eigenvalues and projected eigenfunctions efficiently and effectively even in the case that the investigated system is only experimentally observable and some important dimensions of the system state cannot be directly observed. (See more details in Subsection 2.1.) The main disadvantage of the PMM approach is that the estimation performance strongly depends on the choice of m , and a small change of the value of m may lead to a great error on the estimation of spectral components because of the orthogonality of eigenfunctions (Noé et al., 2013).

The aim of this paper is to propose an infinite HMM based method to solve the spectral estimation problem of metastable processes with unknown dominant spectra. Infinite HMMs (Teh et al., 2006; Teh and Jordan, 2010; Paisley and Carin, 2009; Fox et al., 2011) are a generalization of classical HMMs, which contains infinite hidden states and provide a powerful tool for nonparametric dynamical

modeling of sequential data. In contrast with classical HMMs, infinite HMMs encourage sparse utilization of infinite state sets through defining suitable prior models, and can be used to infer both model parameters and state numbers from observation data in a pure Bayesian manner. However, our investigation (see Section 3) shows that a sparse prior on hidden states cannot guarantee that the eigenvalue set also has a sparse structure, and the spectral estimation is an “ill-posed” problem for the existing infinite HMMs. In this paper, we construct a new infinite HMM named stick-breaking half-weighted model (SB-HWM), which has a sparse prior distribution on eigenvalues and tends to approximate the underlying dynamics of an unknown system with a small number of dominant spectral components. Moreover, we develop a sampling inference algorithm for applying SB-HWMs to Bayesian nonparametric inference of spectral components.

The rest of the paper is organized as follows. In Section 2, we present the relevant mathematical background on PMMs and infinite HMMs, then Section 3 outlines the Bayesian nonparametric framework for solving the spectral estimation problem and explains the reason why the existing infinite HMMs cannot be directly applied. In Section 4 we introduce the SB-HWM and its sampling inference algorithm. Section 5 demonstrates through simulations the effectiveness of the proposed model and algorithm.

2 BACKGROUND

2.1 COARSE-GRAINED DYNAMICS AND PROJECTED MARKOV MODELS

Let $\{x_t\}$ be a Markov process with propagator \mathcal{P} and state space Ω as in (1) and $\{y_t\}$ is the corresponding observation process obtained from the spatial coarse-graining

$$\Pr(y_t = k | x_t = x) = \chi_k(x), \quad k \in \mathcal{O} \quad (2)$$

where $\mathcal{O} = \{1, \dots, K\}$ denotes the discrete observation space and $\chi_k(x)$ denotes the observation probability function for the observed value k . Often, the coarse-graining is employed by the Galerkin discretization and $\{\chi_k(x)\}$ is a set of indicator functions with each k representing a finite element space $\{x | x \in \Omega, \chi_k(x) = 1\}$. But in some practical cases, e.g. where $\{y_t\}$ obtained from noisy measurements, each $\chi_k(x)$ is a continuous probability density function and characterizes a soft finite element space.

It is obvious that (1) and (2) is in fact an HMM, but it is infeasible to reconstruct \mathcal{P} from $\{y_t\}$ by direct statistical inference because of the continuity of Ω and the complexity of the dynamics of $\{x_t\}$ in general cases. In order to overcome this difficulty, the PMM (Noé et al., 2013) provides a low-dimensional approximation of the coarse-grained dynamics based on the following metastability assumption:

Assumption 1. $\{x_t\}$ is ergodic and reversible w.r.t. the

unique stationary distribution $\mu(x)$, and there is a τ' such that $\mathcal{P}(\tau')$ has only m eigenvalues which are not close to 0.

Note that this assumption holds for most practical metastable systems and m is usually a small number depends on the number of metastable states in Ω .¹ Under this assumption, we can conclude that $\mathcal{P}(\tau)$ is a compact and self-adjoint operator w.r.t. the inner product inner product $\langle \cdot, \cdot \rangle_{\mu^{-1}}$ defined by

$$\langle u_1, u_2 \rangle_{\mu^{-1}} = \int \frac{u_1(x) u_2(x)}{\mu(x)} dx \quad (3)$$

and the dynamics of $\{x_t\}$ can be decomposed as

$$\rho_{t+\tau} = \sum_{i=1}^m \lambda_i(\tau) \langle \rho_t, \phi_i \rangle_{\mu^{-1}} \phi_i + \mathcal{P}_{\text{fast}}(\tau) \rho_t \quad (4)$$

with

$$\lambda_i(\tau) = \exp(-\kappa_i \tau) \quad (5)$$

Here $\lambda_i(\tau)$ denotes the i -th largest magnitude eigenvalue of $\mathcal{P}(\tau)$ with eigenfunction ϕ_i and decay rate $\kappa_i \geq 0$ ($\kappa_1 = 0 < \kappa_2$ and $\phi_1 = \mu$ due to the ergodicity). The operator $\mathcal{P}_{\text{fast}}(\tau)$ consists of spectral components of $\mathcal{P}(\tau)$ which decay to zero quickly and $\|\mathcal{P}_{\text{fast}}(\tau)\| \approx 0$ for $\tau \geq \tau'$. Omitting the second term on the r.h.s. of (4), the correlation matrix $\mathbf{C}(n\tau) = [c_{ij}(n\tau)] = [\Pr(y_t = i, y_{t+n\tau} = j)]$ of $\{y_t\}$ can be decomposed as

$$\mathbf{C}(n\tau) = \mathbf{Q} \mathbf{\Lambda}(\tau)^n \mathbf{Q}^\top \quad (6)$$

where $\mathbf{\Lambda}(\tau) = \text{diag}(\lambda_1(\tau), \dots, \lambda_m(\tau))$ contains the dominant eigenvalues of $\mathcal{P}(\tau)$, and the i -th column of $\mathbf{Q} \in \mathbb{R}^{K \times m}$ is the i -th projected eigenfunction

$$\mathbf{q}_i = \left(\int \chi_1(x) \phi_i(x) dx, \dots, \int \chi_K(x) \phi_i(x) dx \right)^\top \quad (7)$$

Therefore, we can characterize the coarse-grained dynamics of $\{y_t\}$ by low-dimensional PMM variables $\{\mathbf{Q}, \mathbf{\Lambda}(\tau)\}$ on a large timescale $\tau \geq \tau'$.

It is important to point out that we can also get a similar approximation of $\mathbf{C}(n\tau)$ by using a m -state HMM. Assume that $\{y_t\}$ are observations of an HMM with hidden states $\{s_t\}$, state set $\{1, \dots, m\}$, transition matrix $\mathbf{A} = [a_{ij}] = [\Pr(s_{t+\tau} = j | s_t = i)]$ and observation matrix $\mathbf{B} = [b_{ij}] = [\Pr(y_t = j | s_t = i)]$, then $\mathbf{C}(n\tau)$ can be

¹Generally speaking, a stochastic system with m metastable states only has m eigenvalues which are significantly larger than zero on a large timescale. It is worth pointing out that this assumption of sparse spectrum is a very important basis in the research of metastability (see, e.g., (Deuffhard and Weber, 2005; Djurdjevac et al., 2010; Noé and Nüske, 2013; Prinz et al., 2014)), and a large number of studies have shown the validity of this assumption for common physical processes which exhibits metastability.

expressed as

$$\begin{aligned} \mathbf{C}(n\tau) &= \mathbf{B}^\top \text{diag}(\boldsymbol{\pi}) \mathbf{A}^n \mathbf{B} \\ &= (\mathbf{B}^\top \mathbf{L}) \tilde{\mathbf{\Lambda}}^n (\mathbf{B}^\top \mathbf{L})^\top \end{aligned} \quad (8)$$

under the condition² that \mathbf{A} is a reversible transition matrix w.r.t. the stationary distribution $\boldsymbol{\pi}$, where $\tilde{\mathbf{\Lambda}}$ is a diagonal matrix containing eigenvalues of \mathbf{A} , \mathbf{L} consists of left eigenvectors of \mathbf{A} with $\mathbf{L}^\top \mathbf{A} = \tilde{\mathbf{\Lambda}} \mathbf{L}^\top$ and $\mathbf{L}^\top \text{diag}(\boldsymbol{\pi})^{-1} \mathbf{L} = \mathbf{I}$, and \mathbf{I} denotes the identity matrix. Based on the similarity between (6) and (8), the PMM theory provides the following conclusion: *Under the metastability assumption (Assumption 1) with $\|\mathcal{P}_{\text{fast}}(\tau)\| = 0$ and some technical assumptions, the dynamics of $\{y_t\}$ is equivalent to a m -state HMM with a reversible transition matrix.* Thus, if a suitable m is given, we can utilize HMM learning algorithms to efficiently estimate the dominant eigenvalues and projected eigenfunctions of $\mathcal{P}(\tau)$ from $\{y_t\}$ with $\mathbf{Q} = \mathbf{B}^\top \mathbf{L}$ and $\mathbf{\Lambda}(\tau) = \tilde{\mathbf{\Lambda}}$. However, the choice of m is still an unsatisfactorily solved problem for the PMM method, and the numerical experiments in (Noé et al., 2013) show that the estimation results of the PMM method is very sensitive to the value of m .

2.2 STICK-BREAKING PROCESSES AND INFINITE HIDDEN MARKOV MODELS

Roughly speaking, a stick-breaking process (SBP) (Ishwaran and James, 2001) is a prior for discrete distributions, and the realization of an SBP with parameters α', α and base distribution G_0 can be expressed by the following probability density function:

$$G = \sum_{i=1}^{\infty} w_i \delta_{\theta_i} \quad (9)$$

where δ_θ denotes the Dirac point measure concentrated on θ , θ_i is the i -th component of the discrete distribution with $\theta_i \stackrel{\text{iid}}{\sim} G_0$, and w_i denotes the corresponding weight which are drawn by $w_i = V_i \prod_{j=1}^{i-1} (1 - V_j)$ and $V_i \stackrel{\text{iid}}{\sim} \text{Beta}(\alpha', \alpha)$. Obviously, the SBP model is a generalization of the finite-dimensional Dirichlet distribution (Gelman et al., 2003), and allows one to easily construct discrete distributions with infinite components. For convenience of computation and notation, in this paper we only consider a special class³ of SBPs with $\alpha' = 1$, and denote by DP(α, G_0) and GEM(α) the prior distributions of G and $\{w_i\}$ defined in (9).

The SBP model provides a powerful and flexible tool for nonparametric estimation of multi-modal mixture models, and can be applied to building HMMs with infinite

²This condition means $\text{diag}(\boldsymbol{\pi}) \mathbf{A}$ is a symmetric matrix, which is a sufficient condition for reversibility of $\{y_t\}$.

³An SBP with $\alpha' = 1$ is equivalent to a Dirichlet process (Ferguson, 1973).

states for sequential statistical modeling. The most commonly used infinite HMM is the HDP-HMM (Teh et al., 2006), which constructs prior distributions of the infinite-dimensional transition matrix $\mathbf{A} = [a_{ij}]$ and observation matrix $\mathbf{B} = [b_{ij}]$ by organizing multiple SBPs in a hierarchical structure as

$$\begin{aligned} G_0 &= \sum_{k=1}^{\infty} \beta_k \delta_{\mathbf{b}_k} \sim \text{DP}(\gamma, H) \\ G_i &= \sum_{j=1}^{\infty} a_{ij} \delta_{\mathbf{b}_j} \stackrel{\text{iid}}{\sim} \text{DP}(\alpha, G_0) \end{aligned} \quad (10)$$

where \mathbf{b}_i denotes the i -th row of \mathbf{B} and represents the observation probability distribution of the i -th state, H represents the prior distribution of each \mathbf{b}_i and is usually a Dirichlet distribution, and α, γ are hyperparameters. In (Fox et al., 2011), a modified HDP-HMM called “sticky HDP-HMM” is proposed to encourage large self-transition probabilities and avoids “unphysically” fast switching between different states, which can be expressed as

$$\begin{aligned} G_0 &= \sum_{k=1}^{\infty} \beta_k \delta_{\mathbf{b}_k} \sim \text{DP}(\gamma, H) \\ G_i &= \sum_{j=1}^{\infty} a_{ij} \delta_{\mathbf{b}_j} \stackrel{\text{ind}}{\sim} \text{DP}(\alpha + \kappa, G_0^{(i)}) \end{aligned} \quad (11)$$

with

$$G_0^{(i)} = \frac{\alpha G_0 + \kappa \delta_{\mathbf{b}_i}}{\alpha + \kappa} \quad (12)$$

where $\kappa > 0$ is the sticky factor and $\lim_{\kappa \rightarrow \infty} a_{ii} = 1$. Furthermore, it is worthwhile to point out that for most of the SBP based infinite HMMs, including HDP-HMM, sticky HDP-HMM and stick-breaking HMM proposed in (Paisley and Carin, 2009), the infinite-dimensional prior distributions can be approximated by high- but finite-dimensional ones for convenience of implementing sampling inference.

3 BAYESIAN NONPARAMETRIC FRAMEWORK FOR SPECTRAL ESTIMATION

The main purpose of this paper is to develop a Bayesian nonparametric framework for spectral estimation of metastable Markov processes with unknown number m of dominant eigenpairs. In the rest of paper, unless otherwise stated, the lagtime τ is set to be fixed, and $\{x_t\}$ and $\{y_t\}$ are separately defined as $\{x_{n\tau}\}_{n=0}^N$ and $\{y_{n\tau}\}_{n=0}^N$.

Suppose that $\{x_t\}$ is a metastable process with the available observation process $\{y_t\}$ as described in Subsection 2.1 and $\{x_t\}$ satisfies Assumption 1. Based on the discussion in Section 2, the Bayesian estimation of the i -th largest eigenvalue λ_i and the corresponding projected eigenfunction \mathbf{q}_i of the Markov propagator $\mathcal{P}(\tau)$ of $\{x_t\}$ can be achieved by the following steps with m not given a priori: First, the dynamics of $\{y_t\}$ is described by an infinite HMM consisting of a infinite-dimensional transition matrix \mathbf{A} and observation matrix \mathbf{B} with prior $p(\mathbf{A}, \mathbf{B})$. Second, a large number of samples $\{(\mathbf{A}^{(k)}, \mathbf{B}^{(k)})\}$ of (\mathbf{A}, \mathbf{B}) are

drawn from the posterior distribution

$$\begin{aligned} &p(\mathbf{A}, \mathbf{B} | \{y_t\}) \\ &\propto p(\mathbf{A}, \mathbf{B}) \sum_{\{s_t\}} p(\{s_t\} | \mathbf{A}) p(\{y_t\} | \{s_t\}, \mathbf{B}) \end{aligned} \quad (13)$$

where s_t denotes the discrete hidden state of the infinite HMM at time t . Finally, the i -th eigenvalue $\lambda_i^{(k)}$ and left eigenvector $\mathbf{l}_i^{(k)\top}$ of $\mathbf{A}^{(k)}$ are calculated for each k such that the posterior distribution of $(\lambda_i, \mathbf{q}_i)$ can be approximated by the ensemble $\{(\lambda_i^{(k)}, \mathbf{q}_i^{(k)})\}$ with $\mathbf{q}_i^{(k)} = \mathbf{B}^{(k)\top} \mathbf{l}_i^{(k)}$.

It is natural for us to utilize one of infinite HMMs such as the HDP-HMM and sticky HDP-HMM mentioned in Subsection 2.2 to design the prior distribution of (\mathbf{A}, \mathbf{B}) within the above framework. However, the following simple example shows that the existing SBP based infinite HMMs are *not* applicable to the spectral estimation problem.

Example 2. Let $\{s_t\} = \{s_{n\tau}\}_{n=0}^{1000}$ be a realization of a reversible 3-state Markov chain with transition matrix

$$\mathbf{A}_0 = \begin{bmatrix} 0.8462 & 0.0769 & 0.0769 \\ 0.1250 & 0.7500 & 0.1250 \\ 0.1818 & 0.1818 & 0.6364 \end{bmatrix} \quad (14)$$

It is clear that $\{s_t\}$ is a Markov chain with large self-transition probabilities and has only three nonzero eigenvalues. We use the prior models of infinite-dimensional transition matrices defined in the HDP-HMM and sticky HDP-HMM to approximate the first 5 eigenvalues of $\{s_t\}$ based on the posterior distribution

$$\begin{aligned} p(\mathbf{A} | \{s_t\}) &\propto p(\mathbf{A}) p(\{s_t\} | \mathbf{A}) \\ &\propto p(\mathbf{A}) \prod_{n=1}^{1000} a_{s_{(n-1)\tau}, s_{n\tau}} \end{aligned} \quad (15)$$

Fig. 1a illustrates the estimation results obtained by the Markov chain Monte Carlo (MCMC) sampling. It can be observed that both the HDP-HMM and the sticky HDP-HMM give poor estimates of eigenvalues and fail to detect the spectral gap between λ_3 and λ_4 .

In a strict sense, the estimation problem in Example 2 is not an “HMM problem” since the hidden state sequence $\{s_t\}$ is exactly known, rather, it is an effective toy example for illustrating the difficulty of nonparametric spectral estimation for the existing infinite HMMs. Roughly speaking, each infinite HMM provides a “sparse” prior distribution of the stationary distribution $\pi = [\pi_i]$ of the transition matrix \mathbf{A} , which means for most samples of π we can find a small set \mathcal{S} of hidden states such that $\sum_{i \notin \mathcal{S}} \pi_i \approx 0$. Thus, there are only a small number of distinct hidden states that can be detected by the Bayesian inference in general although the prior model contains infinite states. However, the sparsity of π cannot guarantee the sparsity of the eigenvalue set, because the transition dynamics between hidden

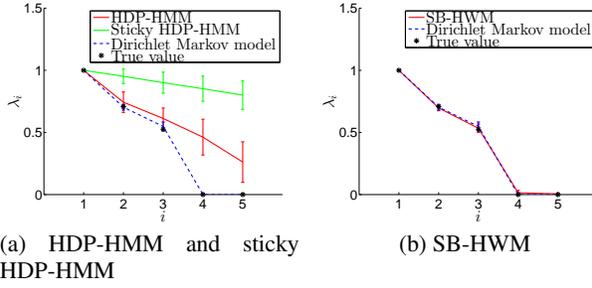

Figure 1: Estimation results of the first 5 eigenvalues of $\{s_t\}$ based on different prior models of \mathbf{A} , where error bars represent one standard deviation confidence intervals, and dashed lines represent the estimation results obtained by assuming that \mathbf{A} is a transition matrix with size 3×3 and the prior of each row of \mathbf{A} is $\text{Dir}(1/3, 1/3, 1/3)$. Truncated-model-based samplers (see Subsection 4.3 and (Fox et al., 2008)) are applied to sampling \mathbf{A} of infinite HMMs, which approximate \mathbf{A} by a finite-dimensional matrix with size 20×20 , and the posterior means and standard deviations are calculated from 5000 MCMC samples with 5000 burn-in samples.

states with small stationary probabilities may also contain large eigenvalues. This is also the reason why the infinite HMMs overestimate the eigenvalues in Example 2. (In fact, for any stationary distribution π and $i > 0$ we can construct a sequence of matrices $\{\mathbf{A}^{(k)}\}$ which are reversible w.r.t. π and satisfy $\lim_{k \rightarrow \infty} \lambda_i^{(k)} \rightarrow 1$. See the supplementary material for details.) Note that in contrast with the HDP-HMM, the sticky HDP-HMM encourages longer residence time for each state and tends to generate more “pseudo-dominant eigenvalues”, so it performs worse than the HDP-HMM in this example. Furthermore, it is difficult for both HDP-HMM and sticky HDP-HMM to incorporate the reversibility constraint.

In order to overcome disadvantages of existing infinite HMMs in the application of spectral estimation, we present in next section a novel infinite HMM, which approximates the “half-weighted matrix” instead of the transition matrix in a nonparametric way and can provide a sparse prior for eigenvalues.

4 STICK-BREAKING HALF-WEIGHTED MODELS

4.1 HALF-WEIGHTED MATRICES

Before developing our infinite HMM for spectral estimation, we first introduce the definition and some important properties of half-weighted matrices for the purpose of self-containedness. For a Markov chain with transition matrix $\mathbf{A} = [a_{ij}]$ and stationary distribution $\pi = [\pi_i]$, the half-

weighted matrix $\mathbf{H} = [h_{ij}]$ is defined by⁴

$$\mathbf{H} = \text{diag}(\pi)^{\frac{1}{2}} \mathbf{A} \text{diag}(\pi)^{-\frac{1}{2}} \quad (16)$$

(Note dimensions of \mathbf{A} , π and \mathbf{H} may be infinite here.)

The following two theorems summarize important properties of the half-weighted matrix and provide a criterion for checking if a matrix is a valid half-weighted matrix. (The proofs are in the supplementary material.)

Theorem 3. *If \mathbf{A} is a reversible and positive transition matrix and all eigenvalues $\{\lambda_i\}$ of \mathbf{A} are square summable, then (1) \mathbf{H} is a positive and symmetric matrix. (2) $\|\mathbf{H}\|_F < \infty$. (3) \mathbf{H} and \mathbf{A} have the same eigenvalues, and the i -th eigenvector ψ_i of \mathbf{H} and the i -th left eigenvector \mathbf{l}_i of \mathbf{A} satisfy $\psi_i = \text{diag}(\pi)^{-\frac{1}{2}} \mathbf{l}_i$. (4) $\sum_{i=m+1}^{\infty} \lambda_i^2 \leq \sum_{i>m \vee j>m} h_{ij}^2$ for all $m > 1$.*

Theorem 4. *If \mathbf{H} is a positive and symmetric matrix with $\|\mathbf{H}\|_F < \infty$, and the spectral radius of \mathbf{H} is 1, then \mathbf{H} is a half-weighted matrix of a Markov chain.*

According to (16), the likelihood of a half-weighted matrix \mathbf{H} of a given state sequence $\{s_t\} = \{s_{n\tau}\}_{n=0}^N$ is

$$p(\{s_t\}|\mathbf{H}) = p(s_0) \sqrt{\frac{\pi_{s_{N\tau}}}{\pi_{s_0}}} \prod_{n=1}^N h_{s_{(n-1)\tau}, s_{n\tau}} \quad (17)$$

From the above, it can be seen that the half-weighted matrix \mathbf{H} can be used to describe the dynamics of state transitions instead of \mathbf{A} , and \mathbf{H} is more numerically stable for eigenvalue decomposition than \mathbf{A} due to the symmetry of \mathbf{H} . Moreover, it is interesting to observe that (17) is in fact a Boltzmann chain model (Saul and Jordan, 1995) with the transition energy from state i to state j being $-\ln h_{ij}$.

4.2 MODEL DEFINITION

From the fourth property of half-weighted matrices stated in Theorem 3, it can be seen that if a Markov chain has a half-weighted matrix with all elements except the ones in a small number of rows and columns are close to zero, then there are only a few eigenvalues of the Markov chain that can be significantly larger than zero. This suggests a natural way of constructing a prior distribution over infinite HMMs which encourages the sparsity of eigenvalue sets and satisfies the reversibility.

Based on the above discussion, we now propose the following infinite HMM called stick-breaking half-weighted model (SB-HWM) for spectral estimation:

$$\begin{aligned} \mathbf{H} &= \frac{1}{r} \bar{\mathbf{H}} \\ \mathbf{B} &= (\mathbf{b}_1^\top, \mathbf{b}_2^\top, \dots)^\top \end{aligned} \quad (18)$$

⁴The definition of half-weighted matrix is in fact a discrete version of the “half-weighted correlation density” proposed in (Noé and Nüske, 2013) for analysis of Markov processes.

with

$$\begin{aligned}
\mathbf{w} = [w_i] &\sim \text{GEM}(\alpha_w) \\
\gamma_{ij} &\stackrel{\text{iid}}{\sim} \text{Gamma}(\alpha_\gamma, \beta_\gamma), \quad \text{for } i \geq j \\
\gamma_{ji} &= \gamma_{ij}, \quad \text{for } i < j \\
w_i^d &\stackrel{\text{iid}}{\sim} \text{Gamma}(\alpha_d, \beta_d) \\
\bar{\mathbf{H}} = [\bar{h}_{ij}] &= [\gamma_{ij} (w_i w_j + w_i w_i^d \cdot 1_{i=j})] \quad (19)
\end{aligned}$$

and

$$\mathbf{b}_i \stackrel{\text{iid}}{\sim} \text{Dir}(\alpha_b, \dots, \alpha_b) \quad (20)$$

where r denotes the spectral radius of the “unnormalized half-weighted matrix” $\bar{\mathbf{H}}$, $(\alpha_w, \alpha_\gamma, \beta_\gamma, \alpha_d, \beta_d, \alpha_b)$ are hyperparameters, and it is easy to verify by Theorem 4 that the realization of $\bar{\mathbf{H}}$ is a valid half-weighted matrix with probability 1. Note that $\bar{\mathbf{H}}$ can be expressed in a more compact form as

$$\bar{\mathbf{H}} = \mathbf{\Gamma} \circ (\mathbf{w}\mathbf{w}^\top + \text{diag}(\mathbf{w} \circ \mathbf{w}^d)) \quad (21)$$

where $\mathbf{\Gamma} = [\gamma_{ij}]$, $\mathbf{w}^d = [w_i^d]$ and \circ denotes the element-wise product. It can be seen that \mathbf{w} employs a “template vector” to encourage rows and columns of the half-weighted matrix to have the similar sparse structures⁵. Furthermore, it is known that for a metastable Markov process, the hidden states of the equivalent HMM mentioned in Subsection 2.1 often have long residence times since they arise from metastable states of the original process (Noé et al., 2013). So we use \mathbf{w}^d to enhance probabilities of self-transitions of hidden states, which plays the similar role as the sticky factor κ in (11). The following theorem gives a theoretical description of the sparsity of π and eigenvalue set $\{\lambda_i\}$ in the SB-HWM (see the supplementary material for the proof):

Theorem 5. *For an SB-HWM (\mathbf{H}, \mathbf{B}) generated by the prior defined by (18)-(20), the i -th largest magnitude eigenvalue λ_i and the stationary probability π_i of the i -th hidden satisfy $\mathbb{E}[|\lambda_i|] = O\left(\left(\frac{\alpha_w}{1+\alpha_w}\right)^{\frac{i}{3}}\right)$ and $\mathbb{E}[\pi_i] = O\left(\left(\frac{\alpha_w}{1+\alpha_w}\right)^{\frac{i}{3}}\right)$ as $i \rightarrow \infty$.*

As a comparison, we also apply the SB-HWM to the data in Example 2 and the estimation results are shown in Fig. 1b. (See Subsection 4.3 for the sampling algorithm.) It can be seen that the SB-HWM achieves the similar estimation performance as the HMM with state number given, and the correct number of dominant spectral components can be easily obtained from samples of the SB-HWM.

⁵For example, if w_i is about zero, the elements in the i -th row and column of $\bar{\mathbf{H}}$ will also be close to zero with high probabilities.

4.3 SAMPLING INFERENCE

For convenience of computation, we first construct a truncated model to approximate the SB-HWM by replacing the prior distribution of \mathbf{w} in (19) with the following truncated SBP prior (Ishwaran and James, 2002):

$$w_i = V_i \prod_{j=1}^{i-1} (1 - V_j) \quad (22)$$

with

$$\begin{cases} V_i \stackrel{\text{iid}}{\sim} \text{Beta}(1, \alpha), & i < L \\ V_i = 1, & i = L \end{cases} \quad (23)$$

The truncated model is obviously a finite HMM with L states since $w_i = 0$ for $i > L$, and according to Theorem 5, the influence of the truncation on the dynamics of SB-HWM is slight if L is sufficiently large⁶. Then the Markov chain Monte Carlo approach can be utilized to draw samples of (\mathbf{H}, \mathbf{B}) from the posterior distribution $p(\mathbf{H}, \mathbf{B} | \{y_t\})$ based on the truncated prior. Considering that the presented prior distribution of $\bar{\mathbf{H}}$ is not a conjugate distribution for the state sequence, here we combine the Metropolis-within-Gibbs algorithm with the block sampling algorithm of classical HMMs to generate samples (see the supplementary material for details) based on the assumption that $\{s_t\}$ is a stationary process, i.e., $p(s_0) = \pi_{s_0}$.

5 APPLICATIONS

In this section, we demonstrate the performance of the SB-HWM based Bayesian spectral estimation method on three examples of stochastic systems including an HMM, a diffusion process governed by a Brownian dynamics and the molecular dynamics of alanine dipeptide. The detailed settings of simulations and estimation algorithms are provided in the supplementary material.

5.1 HMM DATA

Here we apply the SB-HWM to the simulation data generated by a 3-state HMM with lagtime $\tau = 1$ and 8, and compare its performance with HDP-HMM and sticky HDP-HMM. Estimation results are summarized in Fig. 2. Obviously, both HDP-HMM and sticky HDP-HMM severely overestimate the eigenvalues and result in large errors in estimation of projected eigenfunctions, because their samples contain a lot of “pseudo-dominant spectral components” as mentioned in Section 3. (All the three models achieve small

⁶According to our experience, the empirical performance of truncated SB-HWMs is not sensitive to the choice of L if it is larger than twice or three times of the number of the dominant eigenvalues. We simply set L to be 20 in experiments of this paper, and the theoretical analysis of the truncation error will be published elsewhere.

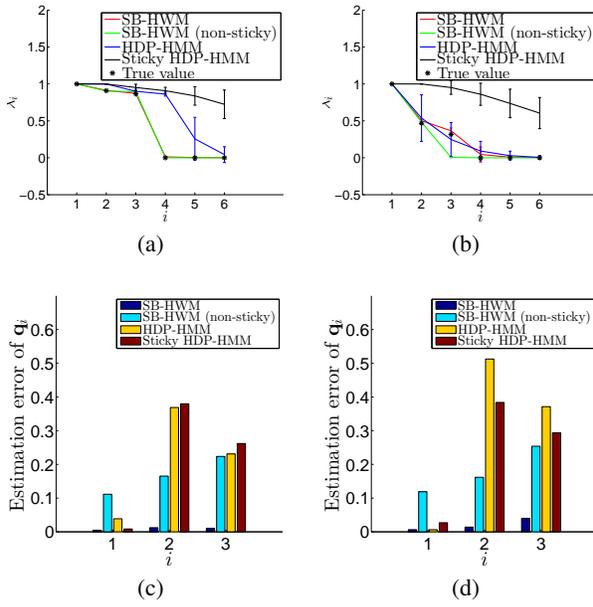

Figure 2: Infinite HMMs applied to data from an HMM. (a,b) Estimates of the first 6 eigenvalues with $\tau = 1$ and 8, where error bars represent one standard deviation confidence intervals. (c,d) Estimation errors of the first 3 projected eigenfunctions with $\tau = 1$ and 8, where the error between the estimate $\hat{\mathbf{q}}_i$ and the true value \mathbf{q}_i is defined by $\|\hat{\mathbf{q}}_i - \mathbf{q}_i\|$.

estimation errors on \mathbf{q}_1 as it can easily be estimated as the stationary distribution of $\{y_t\}$. Of the above three models, only the SB-HWM provides accurate estimates of eigenvalues and dominant eigenfunctions, which allows us to correctly detect the spectral gap and total number of dominant spectral components. Furthermore, we apply a specific SB-HWM with $w_i^d \equiv 0$ for all i to the HMM data in order to verify the usefulness of the sticky term in (19), and the estimates obtained by the non-sticky SB-HWM are also shown in Fig. 2 (see green lines and bars). It can be observed that the estimates of projected eigenfunctions obtained by the non-sticky SB-HWM are much worse than that obtained by the proposed SB-HWM and the non-sticky SB-HWM fails to identify the third dominant spectral component when applied to the HMM data with $\tau = 8$. The main reason for the poor performance of the non-sticky SB-HWM is that it tends to underestimate residence times of hidden states which are key parameters affecting the spectral properties especially for HMMs of metastable systems. (Note that $a_{ii} = O(w_i^2)$ as $i \rightarrow \infty$ in the non-sticky SB-HWM, whereas $a_{ii} = O(w_i)$ in the SB-HWM.)

5.2 BROWNIAN DYNAMICS DATA

In this subsection, we consider a two-dimensional system of Brownian dynamics on the domain $\Omega = [-2, 2] \times$

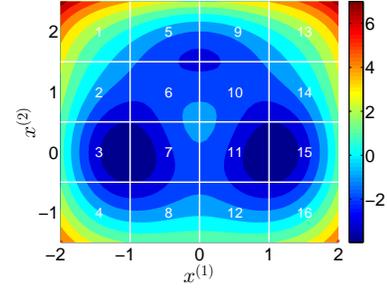

Figure 3: Illustration of the potential function and observation model of a Brownian dynamics system, where each grid represents a bin of the observation model.

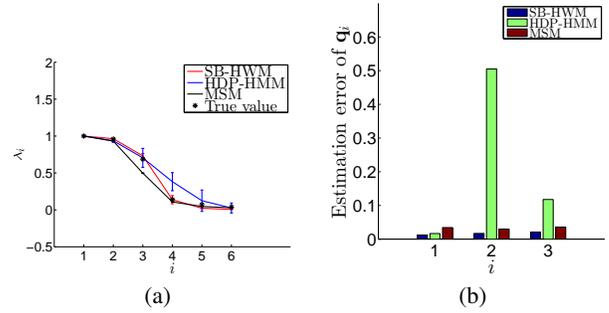

Figure 4: Infinite HMMs and an MSM applied to data from a Brownian dynamics simulation. (a) Estimates of the first 6 eigenvalues, where error bars represent one standard deviation confidence intervals. (b) Estimation errors of the first 3 projected eigenfunctions.

$[-1.5, 2.5]$ with a three-well potential and a Galerkin discretization observation model which are depicted in Fig. 3. The three potential wells implies that the system contains the same number of metastable states and dominant spectral components. Fig. 4 plots spectral estimation results obtained by the SB-HWM, HDP-HMM and MSM, where the MSM estimates spectral components by simply assuming that each bin in Fig. 3 is a discrete state in a Markov chain. It is obvious that the discrete bins cannot accurately capture boundaries between the metastable states in this example, and the poor coarse-graining causes large estimation errors of eigenvalues. (The detailed theoretical analysis on the relationship between the spectral estimation error and the choice of the discretization is reported in (Sarich et al., 2010).) From Fig. 4, we can also see that the HDP-HMM performs even much worse than the simple MSM, which again demonstrates the difficulty of spectral estimation for the existing infinite HMMs. The SB-HWM significantly outperforms the other two models on the spectral estimation in this example.

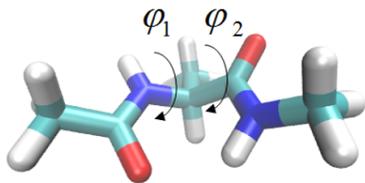

Figure 5: Illustration of the structure of alanine dipeptide

5.3 MOLECULAR DYNAMICS DATA

Alanine dipeptide (sequence acetyl-alanine-methylamide) is a small molecule which consists of two alanine amino acid units. The structural and dynamical properties of this molecule have been thoroughly studied, and it is well known that the configuration space of the alanine dipeptide can be conveniently described by two backbone dihedral angles (see Fig. 5) and contains three metastable states (see Fig. 6). We utilize the SB-HWM, HDP-HMM, 5-state MSM and 23-state MSM to perform the spectral estimation based on a molecular dynamics simulation with length 0.05 millisecond, where the discretization of all models are designed by using the kmeans algorithm and the first three models share the same discretization shown in Fig. 6. Moreover, for convenience of comparison, we construct a very finely discretized MSM with 129 states to estimate spectral components from a molecular dynamics simulation with length 1 millisecond, and use the corresponding estimates as “true values” in this example. It can be observed from Fig. 7 that the HDP-HMM cannot provide any valuable information on spectral components in this example except the first component, and the SB-HWM with observation space $\{1, \dots, 5\}$ obviously outperforms the MSMs with 5 states and 23 states.

Fig. 8 shows the estimated eigenfunctions calculated according to the estimated projected eigenfunctions provided by the SB-HWM and 129-state MSM respectively. (The calculation details are give in the supplementary material.) By comparing them, it is interesting to note that the SB-HWM is able to well reconstruct dominant eigenfunctions in a low-dimensional function space, which also demonstrates the effectiveness of the proposed spectral estimation method.

6 CONCLUSION

We introduce in this paper a novel infinite HMM, “stick-breaking half-weighted model” (SB-HWM) for identification of dominant spectral components of metastable systems. The main idea is to construct a SBP based infinite-dimensional half-weighted matrix to describe transition dynamics of hidden states. In contrast with the other infinite HMMs, the SB-HWM provides a sparse prior on eigen-

values so that both the values and the numbers of dominant spectral components can be estimated by the Bayesian non-parametric inference. Furthermore, a truncated approximation based sampling inference algorithm for SB-HWMs is developed. Interesting directions of future research include developing a more efficient sampling algorithm and extending the algorithm to non-reversible systems.

Abstract

We present a new algorithmic approach to the group fused lasso, a convex model that approximates a multi-dimensional signal via an approximately piecewise-constant signal. This model has found many applications in multiple change point detection, signal compression, and total variation denoising, though existing algorithms typically using first-order or alternating minimization schemes. In this paper we instead develop a specialized projected Newton method, combined with a primal active set approach, which we show to be substantially faster than existing methods. Furthermore, we present two applications that use this algorithm as a fast subroutine for a more complex outer loop: segmenting linear regression models for time series data, and color image denoising. We show that on these problems the proposed method performs very well, solving the problems faster than state-of-the-art methods and to higher accuracy.

1 Introduction

Given a multivariate signal y_1, y_2, \dots, y_T , with $y_t \in \mathbb{R}^n$, the (weighted) group fused lasso (GFL) estimator (Bleakley and Vert, 2011; Alaíz et al., 2013) attempts to find a roughly “piecewise-constant” approximation to this signal. It determines this approximation by solving the optimization problem

$$\underset{x_1, x_2, \dots, x_T}{\text{minimize}} \quad \frac{1}{2} \sum_{t=1}^T w_t \|x_t - y_t\|_2^2 + \sum_{t=1}^{T-1} \lambda_t \|x_t - x_{t+1}\|_2 \quad (1)$$

where x_1, x_2, \dots, x_T are the optimization variables, $w \in \mathbb{R}_+^T$ are weights for each time point, $\lambda \in \mathbb{R}_+^{T-1}$ are regularization parameters, and $\|\cdot\|_2$ denotes the Euclidean norm. Intuitively, the ℓ_2 norm on the *difference* between consecutive points encourages sparsity in

this difference: each difference $x_t - x_{t+1}$ will typically be either full or identically zero at the solution, i.e., the signal x will be approximately piecewise-constant. This approach generalizes the 1D total variation norm (Tibshirani et al., 2005; Barbero and Sra, 2011), which considers only univariate signals. Owing to the piecewise-constant nature of the approximate signals formed by the group fused lasso, the approach has found applications in signal compression, multiple change-point detection, and total variation denoising. Though several algorithms have been proposed to solve (1), to the best of our knowledge these have involved, at their foundation, first-order methods such as projected gradient, block coordinate descent, or splitting methods. Although such algorithms can sometimes obtain reasonable performance, they often fail to quickly find accurate solutions, especially when one wants to solve (1) to high precision as a “subroutine” (or prox-operator) in a larger algorithm (Barbero and Sra, 2011).

In this paper, we develop a fast algorithm for solving the optimization problem (1), based upon a projected Newton approach. Our method can solve group fused lasso problems to high numerical precision, often several orders of magnitude faster than existing state-of-the-art approaches. At its heart, our method involves dualizing the optimization problem (1) *twice*, in a particular manner, to eliminate the non-differentiable ℓ_2 norm and replace it by simple nonnegativity constraints; we solve the reformulated problem to high accuracy via a projected Newton approach. In order to fully exploit the sparsity of large-scale instances, we combine the above ideas with a primal active-set method that iteratively solves reduced-size problems to find the final set of non-zero differences for the original GFL problem.

Although our fast fused group lasso method is valuable in its own right, its real power comes when used as a proximal subroutine in a more complex algorithm, an operation that often needs to be solved thousands of times. With this motivation in mind, we apply our approach to two applications: segmenting linear regression models, and color total variation image denoising.

We demonstrate the power of our approach in experiments with real and synthetic data, both for the basic group fused lasso and these applications, and show substantial improvement over the state of the art.

2 A fast Newton method for the GFL

We begin by adopting slightly more compact notation, and rewrite (1) (the *primal* problem) as

$$\underset{X}{\text{minimize}} \quad \frac{1}{2} \|(X - Y)W^{1/2}\|_F^2 + \|XD\Lambda\|_{1,2} \quad (\text{P})$$

where $X, Y \in \mathbb{R}^{n \times T}$ denote the matrices

$$X = [x_1 \ \cdots \ x_T], \quad Y = [y_1 \ \cdots \ y_T]; \quad (2)$$

$W := \text{diag}(w)$ and $\Lambda := \text{diag}(\lambda)$; $\|\cdot\|_F$ denotes the Frobenius norm; $\|\cdot\|_{1,2}$ denotes the mixed $\ell_{1,2}$ -norm

$$\|A\|_{1,2} := \sum_i \|a_i\|_2, \quad (3)$$

where a_i is the i th column of A ; and $D \in \mathbb{R}^{T, T-1}$ denotes the first order differencing operator

$$D = \begin{bmatrix} 1 & 0 & 0 & \cdots \\ -1 & 1 & 0 & \cdots \\ 0 & -1 & 1 & \cdots \\ \vdots & \vdots & \vdots & \ddots \end{bmatrix} \quad (4)$$

so that XD takes the difference of the columns of X .

2.1 Dual problems

To solve (P), it is useful to look at its dual and (for our algorithm) a modified dual of this dual. To derive these problems, we transform (P) slightly by introducing the constraint $V = XD$, and corresponding dual variables $U \in \mathbb{R}^{n \times T-1}$. The Lagrangian is then given by

$$\mathcal{L}_P(X, U, V) := \frac{1}{2} \|(X - Y)W^{1/2}\|_F^2 + \|V\Lambda\|_{1,2} + \text{tr} U^T (V - XD). \quad (5)$$

Minimizing (5) analytically over X and V gives

$$X^* = Y - UD^T W^{-1}, \quad V^* = 0 \text{ iff } \|u_t\|_2 \leq \lambda_t \quad (6)$$

where u_t is the t -th column of U ; this leads to the dual

$$\underset{U}{\text{maximize}} \quad -\frac{1}{2} \|UD^T W^{-1/2}\|_F^2 + \text{tr} UD^T Y^T \quad (\text{D})$$

subject to $\|u_t\|_2 \leq \lambda_t, \quad t = 1, \dots, T-1.$

Indeed, several past algorithmic approaches have solved (D) directly using projected gradient methods, see e.g., (Alaíz et al., 2013).

The basis of our algorithm is to form the dual of (D), but in a manner that leads to a different problem than

the original primal. In particular, noting that the constraint $\|u_t\|_2 \leq \lambda_t$ is equivalent to the constraint that $\|u_t\|_2^2 \leq \lambda_t^2$, we can remove the non-differentiable ℓ_2 norm, and form the Lagrangian

$$\mathcal{L}_D(U, z) = -\frac{1}{2} \|UD^T W^{-1/2}\|_F^2 + \text{tr} UD^T Y^T + \sum_{t=1}^{T-1} z_t (\|u_t\|_2^2 - \lambda_t^2). \quad (7)$$

Minimizing over U analytically yields

$$U^* = YD(D^T W^{-1}D + Z)^{-1}, \quad (8)$$

where $Z := \text{diag}(z)$, and leads to the dual problem (the dual of the dual of (P))

$$\underset{z \geq 0}{\text{min}} \quad \frac{1}{2} YD(D^T W^{-1}D + Z)^{-1} D^T Y^T + \frac{1}{2} (\lambda^2)^T z, \quad (\text{DD})$$

where λ^2 denotes squaring λ elementwise. This procedure, taking the dual of the dual of the original optimization problem, has transformed the original, non-smooth problem into a smooth optimization problem subject to a non-negativity constraint, a setting for which there are several efficient algorithms. Although (DD) is not easily solved via a standard form semidefinite program—it involves a matrix fractional term, for which the standard semidefinite programming form is computationally unattractive—it can be solved efficiently by a number of methods for smooth, bound-constrained optimization. However, as we will see below, the Hessian for this problem is typically poorly conditioned, so the choice of algorithm for minimizing (DD) has a large impact in practice. Furthermore, because the z dual variables are non-zero only for the change points of the original X variables, we expect that for many regimes we will have very few non-zero z values. These points motivate the use of projected Newton methods (Bertsekas, 1982), which perform Newton updates on the variables not bound ($z \neq 0$).

2.2 A projected Newton method for (DD)

Denote the objective of (DD) as $f(z)$; the gradient and Hessian of f are given by

$$\begin{aligned} \nabla_z f(z) &= -\frac{1}{2} (U^2)^T \mathbf{1} + \frac{1}{2} \lambda^2, \\ \nabla_z^2 f(z) &= U^T U \circ (D^T W^{-1}D + Z)^{-1}, \end{aligned} \quad (9)$$

where as above $U = YD(D^T W^{-1}D + Z)^{-1}$, U^2 denotes elementwise squaring of U , and \circ denotes the elementwise (Hadamard) product. The projected Newton method proceeds as follows: at each iteration, we construct the set of *bound* variables

$$\mathcal{I} := \{i : z_i = 0 \text{ and } (\nabla_z f(z))_i > 0\}. \quad (10)$$

We then perform a Newton update only on those variables that are *not* bound ($\bar{\mathcal{I}}$, referred to as the *free set*), and project back onto the feasible set

$$z_{\bar{\mathcal{I}}} \leftarrow [z_{\bar{\mathcal{I}}} - \alpha (\nabla_z^2 f(z))_{\bar{\mathcal{I}}, \bar{\mathcal{I}}}^{-1} (\nabla_z f(z))_{\bar{\mathcal{I}}}]_+, \quad (11)$$

Algorithm 1 Projected Newton for GFL

input signal $Y \in \mathbb{R}^{n \times T}$; weights $w \in \mathbb{R}_+^T$; regularization parameters $\lambda \in \mathbb{R}_+^{T-1}$; tolerance ϵ

output: optimized signal $X \in \mathbb{R}^{n \times T}$

initialization: $z \leftarrow 0$

repeat

1. Form dual variables and gradient

$$U \leftarrow YD(DW^{-1}D + Z)^{-1}$$
$$\nabla_z f(z) \leftarrow -\frac{1}{2}(U^2)^T \mathbf{1} + \frac{1}{2}\lambda^2$$

2. Compute active constraints

$$\mathcal{I} \leftarrow \{i : z_i = 0 \text{ and } (\nabla_z f(z))_i > 0\}$$

3. Compute reduced Hessian and Newton direction

$$H \leftarrow U_{\bar{\mathcal{I}}}^T U_{\bar{\mathcal{I}}} \circ (D^T W^{-1} D + Z)_{\bar{\mathcal{I}}, \bar{\mathcal{I}}}^{-1}$$
$$\Delta z_{\bar{\mathcal{I}}} \leftarrow -H^{-1}(\nabla_z f(z))_{\bar{\mathcal{I}}}$$

4. Update variables

$$z_{\bar{\mathcal{I}}} \leftarrow [z_{\bar{\mathcal{I}}} + \alpha \Delta z_{\bar{\mathcal{I}}}]_+$$

where α is chosen by line search

until $\|(\nabla_z f(z))_{\bar{\mathcal{I}}}\|_2 \leq \epsilon$

where α is a step size (chosen by backtracking, interpolation, or other line search), and $[\cdot]_+$ denotes projection onto the non-negative orthant. The full method is shown in Algorithm 1. Although the projected Newton method is conceptually simple, it involves inverting several (possibly $T \times T$ matrices), which is impractical if these were to be computed as general matrix operations. Fortunately, there is a great amount of structure that can be exploited in this problem.

Efficiently solving $YD(D^T W^{-1} D + Z)^{-1}$. One key operation for the weighted GFL problem is to solve linear systems of the form $D^T W^{-1} D + Z$, where W and Z are diagonal. Fortunately, the first matrix is highly structured: it is a symmetric tridiagonal matrix

$$D^T W^{-1} D = \begin{bmatrix} \frac{1}{w_1} + \frac{1}{w_2} & -\frac{1}{w_2} & 0 & \cdots \\ -\frac{1}{w_2} & \frac{1}{w_2} + \frac{1}{w_3} & -\frac{1}{w_3} & \cdots \\ 0 & -\frac{1}{w_3} & \frac{1}{w_3} + \frac{1}{w_4} & \cdots \\ \vdots & \vdots & \vdots & \ddots \end{bmatrix}, \quad (12)$$

and adding Z to it only affects the diagonal. LAPACK has customized routines for solving problems of this form: `dpttrf` (which computes the LDL^T factorization of the matrix) and `dptts2` (which computes the solution to $LDL^T X = B$ via backsubstitution). For

our work, we modified this latter code slightly to solve systems with the unknown on the left hand side, as is required for our setting; this lends a slight speedup by exploiting the memory locality of column-based matrices. The methods factor $T - 1 \times T - 1$ matrix in $O(T)$ time, and solve n left hand sides in time $O(Tn)$.

Computing entries of $(D^T W^{-1} D + Z)^{-1}$. The projected Newton method also requires more than just solving equations of the form above: to compute the Hessian, we must actually also compute entries of the inverse $(D^T W^{-1} D + Z)^{-1}$ — we need to compute the entries with rows and columns in $\bar{\mathcal{I}}$. Naively, this would require solving $k = |\bar{\mathcal{I}}|$ left hand sides, corresponding to the unit bases for the entries in $\bar{\mathcal{I}}$; even using the fast solver above, this takes time $O(Tk)$. To speed up this operation, we instead use a fast method for computing the actual entries of the inverse of this tridiagonal, using an approach based upon (Usmani, 1994); this ultimately lets us compute the k^2 entries in $O(k^2)$ time, which can be much faster for small free sets.

Specifically, let $a \in \mathbb{R}^{T-1}$ and $b \in \mathbb{R}^{T-2}$ denote the diagonal and the negative off-diagonal entries of $D^T W^{-1} D + Z$ respectively (that is, $a_i = \frac{1}{w_i} + \frac{1}{w_{i+1}} + z_i$ and $b_i = \frac{1}{w_{i+1}}$), we can compute individual entries of $(D^T W^{-1} D + Z)^{-1}$ as follows (the following adapts the algorithm in (Usmani, 1994), but has enough simplifications for our case that we state it explicitly here). Define $\theta, \phi \in \mathbb{R}^T$ via the recursions

$$\begin{aligned} \theta_{i+1} &= a_i \theta_i - b_{i-1}^2 \theta_{i-1}, \quad i = 2, \dots, T-1 \\ \theta_1 &= 1, \quad \theta_2 = a_1, \\ \phi_i &= a_i \phi_{i+1} - b_i^2 \phi_{i+2}, \quad i = T-2, \dots, 1 \\ \phi_T &= 1, \quad \phi_{T-1} = a_{T-1}. \end{aligned} \quad (13)$$

Then, the (i, j) entry of $(D^T W^{-1} D + Z)^{-1}$ for $j \leq i$ is given by

$$(D^T W^{-1} D + Z)_{ij}^{-1} = \frac{1}{\theta_T} \left(\prod_{k=i}^{j-1} b_k \right) \theta_i \phi_{j+1}. \quad (14)$$

Finally, we can compute all the needed running products $\prod_{k=i}^{j-1} b_k$ by computing a single cumulative sum of the logs of the b_i terms $c_i = \sum_{j=1}^i \log b_i$ and then using the equality $\prod_{k=i}^{j-1} b_k = \exp(c_j - c_i)$.

2.3 A primal active set approach

Using the two optimizations mentioned above, the projected Newton method can very quickly find a solution accurate to numerical precision for medium sized problems (T and n on the order of thousands). However, for problems with substantially larger T , which are precisely those we are most interested in for many GFL applications, the approach above begins to break down. There are two reasons for this: 1) The size of the free

set $k = |\mathcal{I}|$, though often small at the final solution, can be significantly larger at intermediate iterations; since the Newton method ultimately does involve an $O(k^3)$ time to invert the Hessian restricted to the free set, this can quickly render the algorithm impractical. 2) Even with small free sets, the basic $O(Tn)$ cost required for a single pass over the data at each Newton iteration starts to dominate, especially since a significant number of iterations to find the correct free set may be required (only after finding the correct free set does one obtain quadratic convergence rates).

To overcome these problems, we consider a further layer to the algorithm, which wraps our fast projected Newton solver inside a primal active-set method. The basic intuition is that, at the optimal solution to the original GFL problem, there will typically be very few change points in the solution X^* (these correspond exactly to those z variables that are non-zero). If we knew these changes points ahead of time, we could solve a substantially reduced (weighted) GFL problem that was equivalent to the original problem. Specifically, let $\mathcal{J} \subseteq \{1, \dots, T-1\}$ denote the optimal set of change point locations for the primal problem. By the relationship of dual problems, this will be identical to the set of free variables $\tilde{\mathcal{I}}$ at the optimal solution, but since we treat these differently in the algorithmic design we use different notation. Then the original problem

$$\underset{X}{\text{minimize}} \quad \|(X - Y)W^{1/2}\|_F^2 + \|XDA\|_{1,2}, \quad (15)$$

where $X \in \mathbb{R}^{n \times T}$, is equivalent to the reduced problem

$$\underset{X'}{\text{minimize}} \quad \|(X' - Y')W'^{1/2}\|_F^2 + \|X'D'\Lambda_{\mathcal{J},\mathcal{J}}\|_{1,2} \quad (16)$$

with optimization variable $X' \in \mathbb{R}^{n \times k+1}$ for $k = |\mathcal{J}|$, where $D' \in \mathbb{R}^{k+1 \times k}$ denotes the same first order differences matrix but now over only $k+1$ -sized vectors, and where Y' and $W' = \text{diag}(w')$ are defined by

$$w'_i = \sum_{j \in \mathcal{J}'_i} w_j, \quad y'_i = \frac{1}{w'_i} \sum_{j \in \mathcal{J}'_i} w_j y_j, \quad (17)$$

where we define $\mathcal{J}'_i = \{\mathcal{J}_{i-1} + 1, \dots, \mathcal{J}_i\}$ for $i = 1, \dots, k+1$ (i.e., \mathcal{J}'_i denotes the list of indices within the i th segment, there being $k+1$ segments for k change points). Furthermore, all these terms can be computed in time $O(nk)$ via cumulative sums similar to the cumulative sum used for b above (which take $O(Tn)$ to compute once, but which thereafter only require $O(kn)$ to form the reduced problem).

To see this equivalence, note first that since X only changes at the points $|\mathcal{J}|$, it immediately holds that $\|XDA\|_{1,2} = \|X'D'\Lambda_{\mathcal{J},\mathcal{J}}\|_{1,2}$. To show that the other

term in the objective is also equivalent, we have that

$$\begin{aligned} & \|(X - Y)W^{1/2}\|_F^2 \\ &= \sum_{i=1}^{k+1} \|(x'_i 1^T - Y_{\mathcal{J}'_i})W_{\mathcal{J}'_i, \mathcal{J}'_i}^{1/2}\|_F^2 \\ &= \sum_{i=1}^{k+1} \left((w_{\mathcal{J}'_i}^T 1) x'^T_i x'_i - 2x'^T_i Y_{\mathcal{J}'_i} w_{\mathcal{J}'_i} + \|Y_{\mathcal{J}'_i} W_{\mathcal{J}'_i, \mathcal{J}'_i}^{1/2}\|_F^2 \right) \\ &= \sum_{i=1}^{k+1} w'_i \|x'_i - y'_i\|_2^2 + c. \end{aligned}$$

This equivalence motivates a primal active set method where we iteratively guess the active set \mathcal{J} (with some fixed limit on its allowable size), use the projected Newton algorithm to solve the reduced problem, and then use the updated solution to re-estimate the active set. This is essentially equivalent to a common “block pivoting” strategy for non-negative least squares (Portugal et al., 1994) or ℓ_1 methods (Lee et al., 2007), and has been shown to be very efficient in practice (Kim and Park, 2010). The full algorithm, which we refer to as Active Set Projected Newton (ASPN, pronounced “aspen”), is shown in Algorithm 2. In total, the algorithm is extremely competitive compared to past approaches to GFL, as we show in Section 4, often outperforming the existing state of the art by orders of magnitude.

3 Applications

Although the ASPN algorithm for the group fused lasso is a useful algorithm in its own right, part of the appeal of a fast solver for this type of problem is the possibility of using it as a “subroutine” within solvers for more complex problems. In this section we derive such algorithms for two instances: segmentation of time-varying linear regression models and multi-channel total variance image denoising. Both models have been considered in the literature previously, and the method presented here offers a way of solving these optimization problems to a relatively high degree of accuracy using simple methods.

3.1 Linear model segmentation

In this setting, we observe a sequence of input/output pairs $(a_t \in \mathbb{R}^n, y_t \in \mathbb{R})$ over time and the goal is to find model parameters x_t such that $y_t \approx a_t^T x_t$ (it is more common to denote the input itself as x_t and model parameters θ_t , but the notation here is more in keeping with the rest of this paper). Naturally, if x_t is allowed to vary arbitrarily, we can always find (an infinite number of) x_t 's that fit the output perfectly, but if we constrain the sum of norms $\|x_t - x_{t-1}\|_2$, then we will instead look for piecewise constant segments in the parameter space; this model was apparently first proposed in Ohlsson et al. (2010).

Algorithm 2 Active Set Projected Newton (ASPN)

input signal $Y \in \mathbb{R}^{n \times T}$; weights $w \in \mathbb{R}_+^T$; regularization parameters $\lambda \in \mathbb{R}_+^{T-1}$; maximum active set size k_{\max} ; tolerance ϵ

output: optimized signal $X \in \mathbb{R}^{n \times T}$

initialization: $z \leftarrow 0$

repeat

1. Form dual variables and gradient

$$U \leftarrow YD(DW^{-1}D + Z)^{-1}$$

$$\nabla_z f(z) \leftarrow -\frac{1}{2}(U^2)^T 1 + \frac{1}{2}\lambda^2$$

2. Compute active set, containing all non-zero z_i 's and additional element with negative gradients, up to size k_{\max}

$$\mathcal{J}^0 \leftarrow \{i : z_i > 0\}$$

$$\mathcal{J}^1 \leftarrow \{i : z_i = 0, \nabla_z f(z) < 0\}$$

$$\mathcal{J} \leftarrow \mathcal{J}^0 \cup \mathcal{J}_{1:k_{\max}-|\mathcal{J}^0|}^1$$

3. Form reduced problem (Y', w') for \mathcal{J} using (17) and solve using projected Newton

$$z_{\mathcal{J}} \leftarrow \text{Projected-Newton}(Y', w', \lambda_{\mathcal{J}})$$

until $\|(\nabla_z f(z))_{\mathcal{J}}\|_2 \leq \epsilon$

This model may be cast as the optimization problem

$$\underset{X}{\text{minimize}} \|A \text{vec } X - y\|_2^2 + \|XD\Lambda\|_{1,2}, \quad (18)$$

where $X \in \mathbb{R}^{n \times T}$ is the same optimization variable as previously, $y \in \mathbb{R}^T$ denotes the vector of outputs, vec denotes the vectorization of a matrix (stacking its columns into a single column vector), and $A \in \mathbb{R}^{T \times Tn}$ is the block diagonal matrix

$$A = \begin{bmatrix} a_1^T & 0 & 0 & \cdots \\ 0 & a_2^T & 0 & \cdots \\ 0 & 0 & a_3^T & \cdots \\ \vdots & \vdots & \vdots & \ddots \end{bmatrix}. \quad (19)$$

While this problem looks very similar to the ordinary GFL setting, the introduction of the additional matrix A renders it substantially more complex. While it is possible to adapt the Newton methods above to solve the problem directly, much of the special problem structure is lost, and it requires, for examples, forming $Tn \times Tn$ block tridiagonal matrices, which is substantially more computationally intensive, especially for large n (the methods scale like $O(n^3)$). While optimization may still be possible with such approaches, we instead adopt a different approach that builds on the

alternating direction method of multipliers (ADMM), an algorithm that has attracted great attention recently (e.g. Boyd et al. (2011)). Briefly, ADMM solves problems of the form

$$\underset{x,z}{\text{minimize}} f(x) + g(z), \quad \text{subject to } Ax + Bz = c, \quad (20)$$

via a sequence of alternating minimizations over x and z and dual variable updates.

The “standard” ADMM algorithm. The simplest way to apply ADMM to (18), considered for the pure group fused lasso e.g., in Wahlberg et al. (2012), is to introduce variables $Z = XD$, and formulate the problem as

$$\underset{X,Z}{\text{minimize}} \|A \text{vec } X - Y\|_2^2 + \|Z\Lambda\|_{1,2}$$

$$\text{subject to } XD = Z. \quad (21)$$

After some derivations, this leads to the updates

$$X^{k+1} \leftarrow \underset{X}{\text{argmin}} \|A \text{vec } X - y\|_2^2 + \frac{\rho}{2}\|XD - Z^k + U^k\|_F^2$$

$$Z^{k+1} \leftarrow \underset{Z}{\text{argmin}} \|Z\Lambda\|_{1,2} + \frac{\rho}{2}\|X^{k+1}D - Z + U^k\|_F^2$$

$$U^{k+1} \leftarrow U^k + X^{k+1}D - Z^{k+1}, \quad (22)$$

where ρ acts effectively like a stepsize for the problem. This set of updates is particularly appealing because minimization over X and Z can both be computed in closed form: the minimization over X is unconstrained quadratic optimization, and has the solution

$$(A^T A + \rho F^T F)^{-1} (A^T y + \rho F^T \text{vec}(Z^k - U^k)) \quad (23)$$

where $F = (D^T \otimes I)$. Furthermore, these updates can be computed very efficiently, since $(A^T A + \rho F^T F)$ is block tridiagonal, and since this matrix does not change at each iteration, we can precompute its (sparse) Cholesky decomposition once, and use it for all iterations; using these optimizations, the X update takes time $O(Tn^2)$. Similarly, the Z update is a proximal operator that can be solved by *soft thresholding* the columns of $X^{k+1}D + U^k$ (an $O(Tn)$ operation). Although these elements make the algorithm appealing, they hide a subtle issue: the matrix $(A^T A + \rho F^T F X)$ is poorly conditioned (owing to the poor conditioning of $D^T D$), even for large ρ . Because of this, ADMM needs a large number of iterations for converging to a reasonable solution; even if each iteration is quite efficient, the overall algorithm can still be impractical.

ADMM using the GFL proximal operator. Alternatively, we can derive a different ADMM algorithm by considering instead the formulation

$$\underset{X,Z}{\text{minimize}} \|A \text{vec } X - Y\|_2^2 + \|ZD\Lambda\|_{1,2}$$

$$\text{subject to } X = Z, \quad (24)$$

which leads to the iterative updates

$$\begin{aligned} X^{k+1} &\leftarrow \underset{X}{\operatorname{argmin}} \|A \operatorname{vec} X - y\|_2^2 + \frac{\rho}{2} \|X - Z^k + U^k\|_F^2 \\ Z^{k+1} &\leftarrow \underset{Z}{\operatorname{argmin}} \|ZDA\|_{1,2} + \frac{\rho}{2} \|X^{k+1} - Z + U^k\|_F^2 \\ U^{k+1} &\leftarrow U^k + X^{k+1} - Z^{k+1}. \end{aligned} \quad (25)$$

The X update can still be computed in closed form

$$\operatorname{vec} X^{k+1} = (A^T A + \rho I)^{-1} (A^T y + \rho \operatorname{vec}(Z^k - U^k)),$$

which is even simpler to compute than in the previous case, since $A^T A + \rho I$ is block diagonal with blocks $a_i a_i^T + \rho I$, which can be solved for in $O(n)$ time; thus the entire X update takes times $O(Tn)$. The downside is that the Z update, of course, can no longer be solved with soft-thresholding. But the Z update here is precisely in the form of the group fused lasso; thus, we can use ASPN directly to perform the Z update. The main advantage here is that the matrix $A^T A + \rho I$ is much better conditioned, which translates into many fewer iterations of ADMM. Indeed, as we show below, this approach can be many orders of magnitude faster than straight ADMM, which is already a very competitive algorithm for solving these problems.

3.2 Color total variation denoising

Next, we consider color total variation denoising example. Given an $m \times n$ RGB image represented as a third order tensor, $Y \in \mathbb{R}^{3 \times m \times n}$, total variation image denoising (Rudin et al., 1992; Blomgren and Chan, 1998) attempts to find an approximation $X \in \mathbb{R}^{3 \times m \times n}$ such that differences between pixels in X favor being zero. It does this by solving the optimization problem

$$\begin{aligned} \underset{X}{\operatorname{minimize}} \quad & \frac{1}{2} \|X - Y\|_F^2 + \lambda \sum_{i=1}^m \sum_{j=1}^{n-1} \|X_{:,i,j} - X_{:,i,j+1}\|_2 \\ & + \lambda \sum_{i=1}^{m-1} \sum_{j=1}^n \|X_{:,i,j} - X_{:,i+1,j}\|_2, \end{aligned} \quad (26)$$

corresponding to an ℓ_2 norm penalty on the difference between all adjacent pixels, where each pixel $X_{:,i,j}$ is represented as a 3 dimensional vector. We can write this as a sum of $m + n$ group fused lasso problems

$$\begin{aligned} \underset{X}{\operatorname{minimize}} \quad & \sum_{i=1}^m (\|X_{:,i,:} - Y_{:,i,:}\|_F^2 + \lambda \|X_{:,i,:} D\|_{1,2}) \\ & + \sum_{j=1}^n (\|X_{:,:,j} - Y_{:,:,j}\|_F^2 + \lambda \|X_{:,:,j} D\|_{1,2}), \end{aligned}$$

where $X_{:,i,:} \in \mathbb{R}^{3 \times n}$ denotes the slice of a single row of the image and $X_{:,:,j} \in \mathbb{R}^{3 \times m}$ denotes the slice of a single column.

Unfortunately, this optimization problem cannot be solved directly via the group fused lasso, as the difference penalties on the rows and columns for the same matrix X render the problem quite different from the basic GFL. We can, however, adopt an approach similar to the one above, and create separate variables corresponding to the row and column slices, plus a constraint that they be equal; formally, we solve

$$\begin{aligned} \underset{X,Z}{\operatorname{minimize}} \quad & \sum_{i=1}^m (\|X_{:,i,:} - Y_{:,i,:}\|_F^2 + \lambda \|X_{:,i,:} D\|_{1,2}) \\ & + \sum_{j=1}^n (\|Z_{:,:,j} - Y_{:,:,j}\|_F^2 + \lambda \|Z_{:,:,j} D\|_{1,2}) \\ \text{subject to} \quad & X = Z. \end{aligned} \quad (27)$$

The major advantage of this approach is that it decomposes the problem into $m + n$ independent GFL tasks, plus a meta-algorithm that adjusts each sub-problem to make the rows and columns agree. Several such algorithms are possible, including ADMM; we present here a slightly simpler scheme known as the ‘‘proximal Dykstra’’ method (Combettes and Pesquet, 2011), which has been previously applied to the case of (single channel, i.e., black and white) total variation denoising (Barbero and Sra, 2011). Starting with $X^0 = Y$, $P^0 = 0$, $Q^0 = 0$, the algorithm iterates as follows:

$$\begin{aligned} Z_{:,j}^{k+1} &\leftarrow \operatorname{GFL}(X_{:,j}^k + P_{:,j}^k, \lambda), \quad j = 1, \dots, n \\ P^{k+1} &\leftarrow P^k + X^k - Z^{k+1} \\ X_{:,i}^{k+1} &\leftarrow \operatorname{GFL}(Z_{:,i}^{k+1} + Q_{:,i}^k, \lambda), \quad i = 1, \dots, m \\ Q^{k+1} &\leftarrow Q^k + Z^{k+1} - X^{k+1}. \end{aligned} \quad (28)$$

Typically, very few iterations (on the order of 10) of this outer loop are need to converge to high accuracy. Furthermore, because each of the m or n GFL problems solved in the first and third steps are independent, they can be trivially parallelized.

4 Experimental results

We present experimental results for our approaches, both on the basic group fused lasso problem, where we compare to several other potential approaches, and on the two applications of linear model segmentation and color total variation denoising. C++ and MATLAB code implementing our methods is available at <http://www.cs.cmu.edu/~mwytock/gfl/>.

4.1 Group fused lasso

Here we evaluate the ASPN algorithm versus several alternatives to solving the group fused lasso problem, evaluated on both synthetic and real data. Figure 1

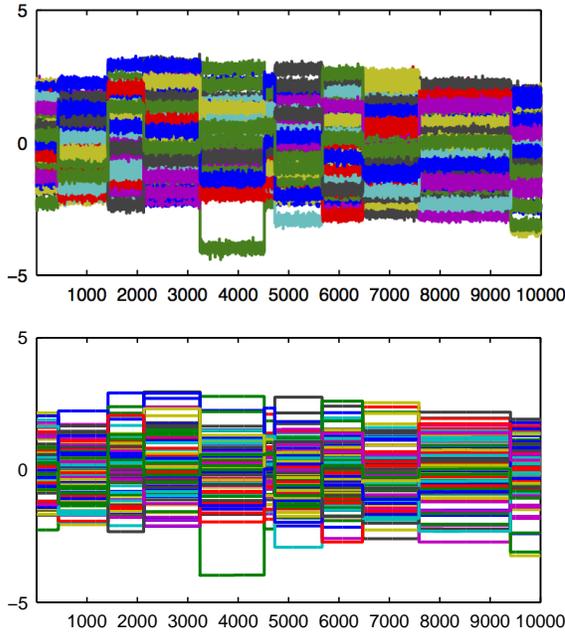

Figure 1: Above: synthetic change point data, with $T = 10000$, $n = 100$, and 10 true change points. Below: recovered signal.

shows a synthetic time series with $T = 10,000$, $n = 100$, and 10 discrete change points in the data; the data was generated by uniformly sampling the change points, sampling the mean of each segment from $\mathcal{N}(0, I)$, and then additional Gaussian noise. Figure 1 shows the recovered signal using the group fused lasso with $w_t = 1$, $\lambda_t = 20$. In Figure 2, we show timing results for this problem as well as a smaller problem with $T = 1000$ and $n = 10$; we compare ASPN to GFLseg (Bleakley and Vert, 2011) (which uses coordinate descent on the primal problem), an accelerated projected gradient on the dual (i.e., the FISTA algorithm) (Beck and Teboulle, 2009), Douglas-Rachford splitting (Combettes and Pesquet, 2007) (a generalization of ADMM that performs slightly better here), a projected gradient on the dual (Alaíz et al., 2013), and LBFGS-B (Byrd et al., 1995) applied to the dual of the dual. In all cases, ASPN performs as well as (often much better than) the alternatives.

Next, we evaluate how the ASPN algorithm scales as a function of the number of time points T and the number of change points at the solution, k . In Figure 3, the first set of experiments shows that when the number of change points at the solution is fixed ($k = 10$), the amount of time required for a highly accurate solution remains small even for large T , agreeing with analysis that shows the number of operations required is $O(T)$. In particular, a solution accurate to 10^{-6} is found in 4.8 seconds on a problem with $T = 10^6$ time points.

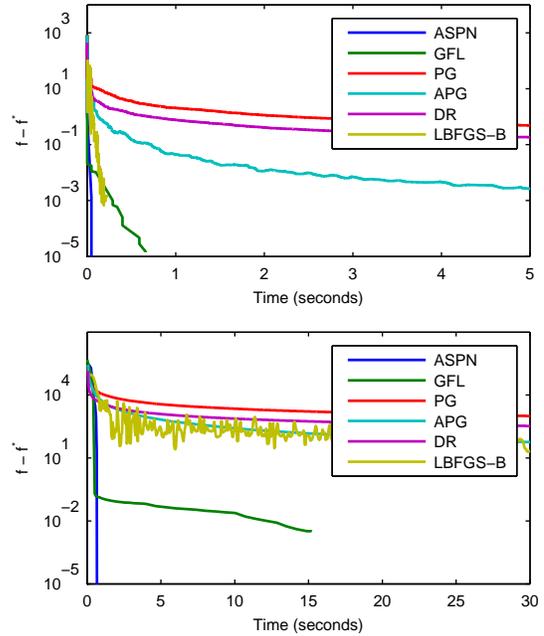

Figure 2: Above: timing results on synthetic problem with $T = 1000$, $n = 10$. Below: timing results on synthetic problem with $T = 10000$, $n = 100$.

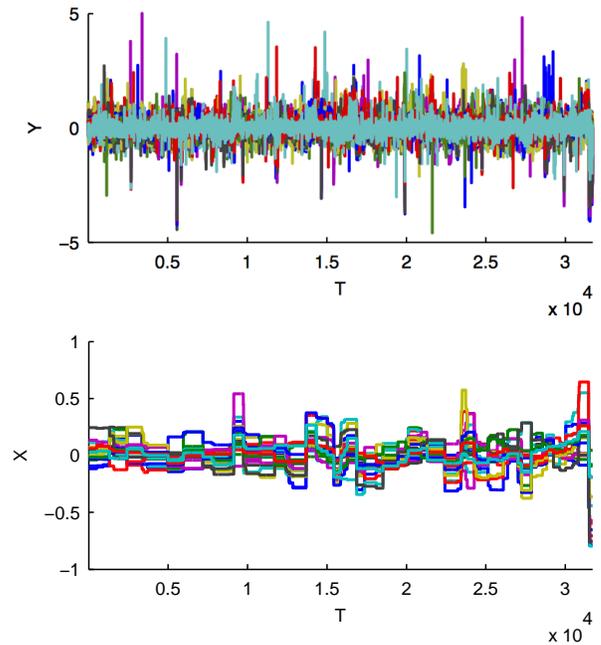

Figure 4: Above: Lung data from (Bleakley and Vert, 2011). Below: recovered signal using group fused lasso.

However, in the next set of experiments, we see that compute time grows rapidly as a function of k due to the $O(k^3)$ operations required to compute the Newton step, suggesting that the proposed method is most appropriate for problems with sparse solutions.

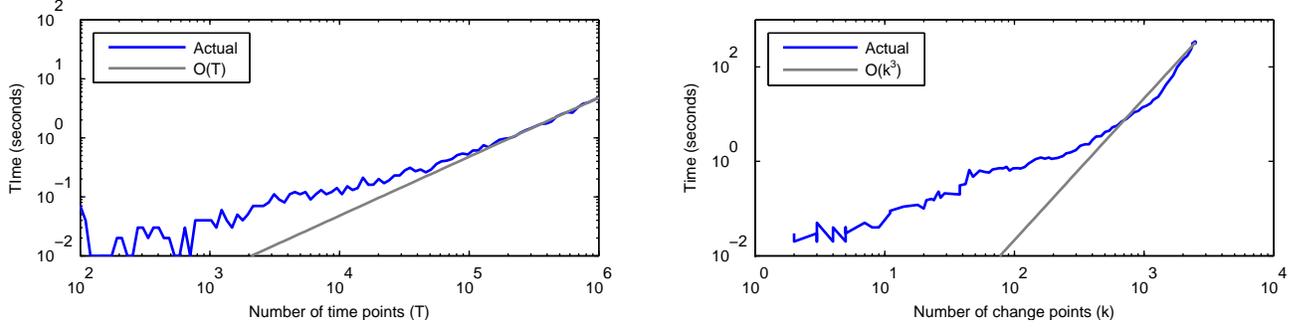

Figure 3: Left: timing results vs. number of change points at solution for synthetic problem with $T = 10000$ and $n = 10$. Right: timing results for varying T , $n = 10$, and sparse solution with 10 change points.

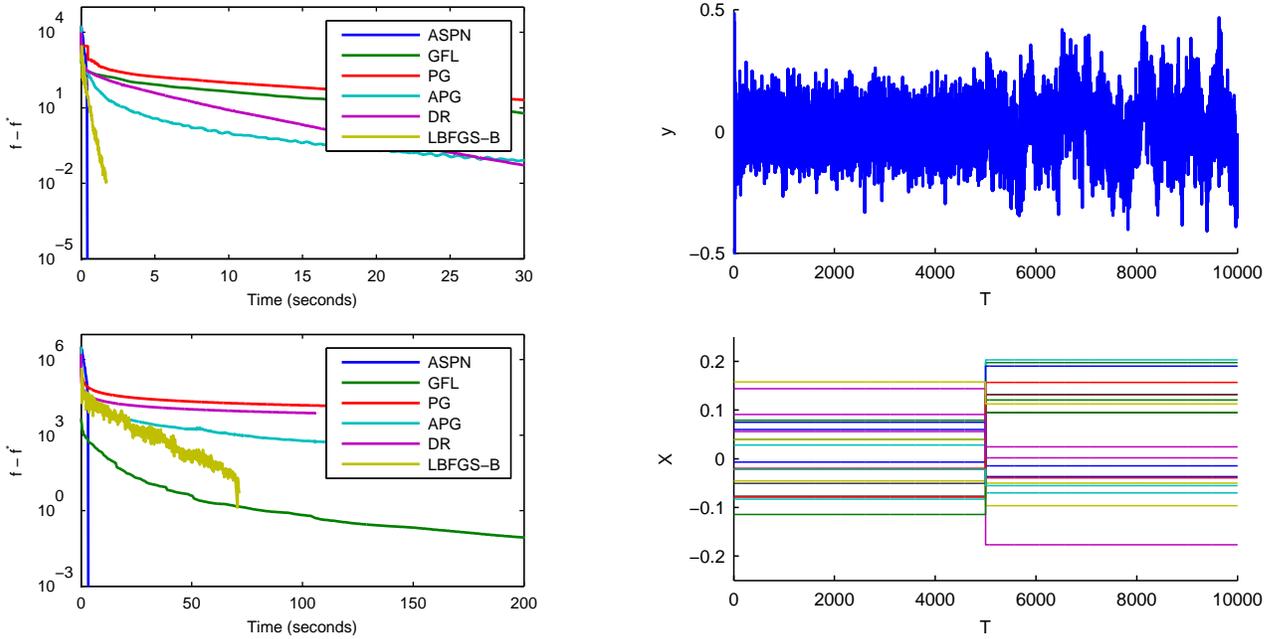

Figure 5: Above: Timing results on bladder problem, $T = 2143$, $n = 57$. Below: Timing results on lung problem, $T = 31708$, $n = 18$.

Figure 6: Above: Observed autoregressive signal z_t . Below: true autoregressive model parameters.

Finally, we evaluate the algorithm on two real time series previously used with the group fused lasso (Bleakley and Vert, 2011), from DNA profiles of bladder and lung cancer sequences. Figure 4 shows one of these two series, along with the approximation produced by the group fused lasso. Figure 5 shows timing results for the above methods again on this problem: here we observe the same overall behavior, that ASPN typically dominates the other approaches.

4.2 Linear regression segmentation

Here we apply the two different ADMM methods discussed in Section 3.1 to the task of segmenting auto-

regressive time series models. In particular, we observe some time series z_1, \dots, z_T , and we fit a linear model to this data $z_t \approx a_t^T x_t$ where $a_t = (z_{t-1}, z_{t-2}, \dots, z_{t-n})$. Figure 6 shows an example time series generated by this process, as well as the true underlying model that generated the data (with additional noise). This is the rough setting used in (Ohlsson et al., 2010), which was the first example we are aware of that uses such regularization techniques within a linear regression framework. Figure 7 shows the model parameters recovered using the method from Section 3.1, which here match the ground truth closely.

Of more importance, though, is the comparison between the two different ADMM approaches. Figure 8

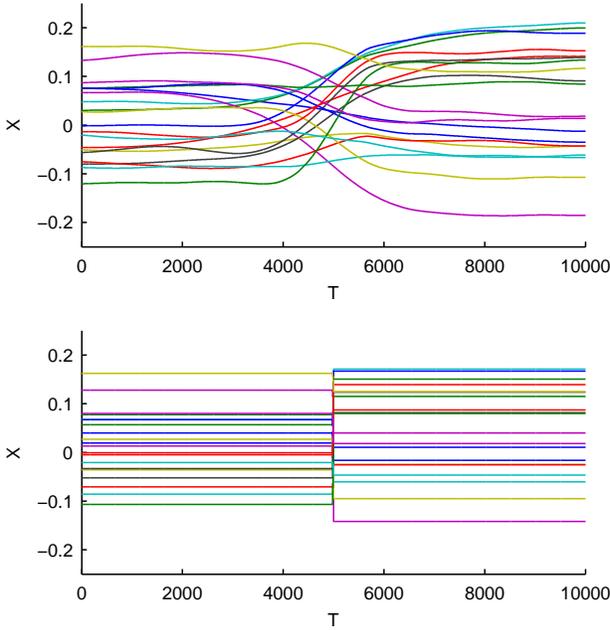

Figure 7: Above: Autoregressive parameters recovered with “simple” ADMM algorithm. Below: parameters recovered using alternative ADMM w/ ASPN.

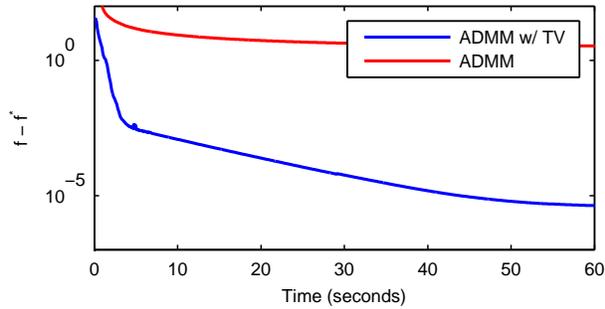

Figure 8: Convergence of simple ADMM versus alternative ADMM w/ ASPN.

shows convergence versus running time and here the “simple” ADMM approach, which encodes the difference operator in the constraints (and thus has simpler updates), converges significantly slower than our alternative. Importantly, the X axis in this figure is measured in time, and we emphasize that even though the “simple” ADMM updates are individually slightly faster (they do not involve GFL subproblems), their overall performance is much poorer. Further, as illustrated in Figure 7, the “simple” ADMM approach never actually obtains a piecewise constant X except at the optimum, which is never reached in practice.

Figure 9: Left: original image. Middle: image corrupted with Gaussian noise. Right: image recovered with total variation using proximal Dykstra and ASPN.

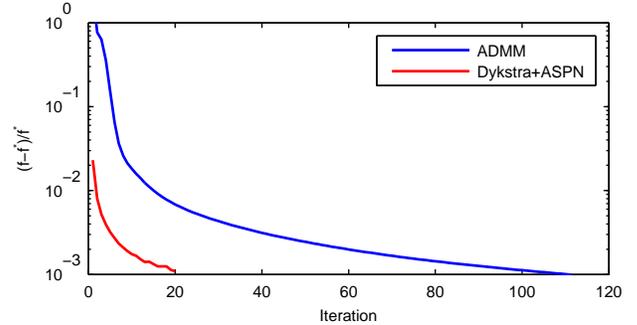

Figure 10: Comparison of proximal Dykstra method to ADMM for TV denoising of color image.

4.3 Color total variation denoising

Finally, as described in Section 3.2, we apply the proximal Dykstra algorithm, using ASPN as a fast subroutine, to color image denoising. Figure 9 shows a 256x256 image generated by combining various solid-colored shapes, corrupted with per-RGB-component noise of $\mathcal{N}(0, 0.1)$, and then recovered with total variation denoising. There has been enormous work on total variation denoising, and while a full comparison is beyond the scope of this paper, ADMM or methods such as those used by the FTVd routines in Yang et al. (2009), for instance, are considered to be some of the fastest for this problem. In Figure 10, we show the performance of our approach and ADMM versus iteration number, and as expected observe better convergence; for single-core systems, ADMM is ultimately a better solution for this problem, since each iteration of ADMM takes about 0.767 seconds in our implementation whereas 512 calls to ASPN take 20.4 seconds. However, the advantage to the ASPN approach is that all these calls can be trivially parallelized for a 256X speedup (the calls are independent and all code is CPU-bound), whereas parallelizing a generic sparse matrix solve, as needed for ADMM-based approaches, is much more challenging and thus per-iteration performance highlights the potential benefits of the ASPN approach.

Abstract

Many objects can be represented as sets of multi-dimensional points. A common approach to learning from these point sets is to assume that each set is an *i.i.d.* sample from an unknown underlying distribution, and then estimate the similarities between these distributions. In realistic situations, however, the point sets are often subject to sampling biases due to variable or inconsistent observation actions. These biases can fundamentally change the observed distributions of points and distort the results of learning. In this paper we propose the use of conditional divergences to correct these distortions and learn from biased point sets effectively. Our empirical study shows that the proposed method can successfully correct the biases and achieve satisfactory learning performance.

1 INTRODUCTION

Traditional learning algorithms deal with fixed, finite dimensional vectors/points, but many real objects are actually sets of points that are multi-dimensional, real-valued vectors. For instance, in computer vision an image is often treated as a set of patches with each patch described by a fixed length feature vector (Li and Perona, 2005). In monitoring problems, each sensor produces one set of measurements for a particular region within a time period. In a social network, a community is a set of people. It is important to devise algorithms that can effectively process and learn from these data.

A convenient and often adopted way to deal with point sets is to construct a feature vector for each set so that standard learning techniques can be applied. However, this conversion process often relies on human effort and domain expertise and is prone to information loss. Recently, several algorithms were proposed to directly learn from point sets

based on the assumption that each set is a sample from an underlying distribution. (Póczos et al., 2011, 2012) proposed novel kernels between point sets based on efficient and consistent divergence estimators. (Gretton et al., 2007; Muandet et al., 2012) designed a class of set kernels based on the kernel embedding of distributions. (Boiman et al., 2008; McCann and Lowe, 2012) developed simple classifiers for point sets based on divergences between the sets and the classes. Some parametric methods have also been proposed (Jaakkola and Haussler, 1998; Jebara et al., 2004). These methods achieved impressive empirical successes, thus showing the advantage of learning directly from point sets.

One factor that can significantly affect the effectiveness of learning is sampling bias. Sampling bias comes from the way we collect points from the underlying distributions, and makes the observed sample not representative of the true distribution. It undermines the fundamental validity of learning because the points are no longer iid samples from a distribution conditioned only on the object's type. Though it has been extensively studied in statistics, this key problem has been largely ignored by the previous research on learning from sets. The goal of this paper is to alleviate the impact of sampling bias when measuring similarities between point sets.

We consider point sets with the following structure. Let each point be described by two groups of random variables: the independent variables (*i.v.*) and dependent variables (*d.v.*). A point is collected by first specifying the value of the *i.v.*, and then observing a sample from the distribution of the *d.v.* conditioned on the given *i.v.* Figure 1 shows a synthetic example where the *i.v.* is sampled uniformly, and the *d.v.* is from the Gaussian distribution whose mean is proportional to the value of *i.v.*, forming the black line-shaped point set. Many real world situations, including surveys and mobile sensing, produce point sets of this type. In patch-based image analysis, we first specify the location of the patches as the *i.v.* and then extract their features as the *d.v.* In traffic monitoring, a helicopter is sent to specific locations at specific times (*i.v.*) and measures the traffic

volume ($d.v.$).

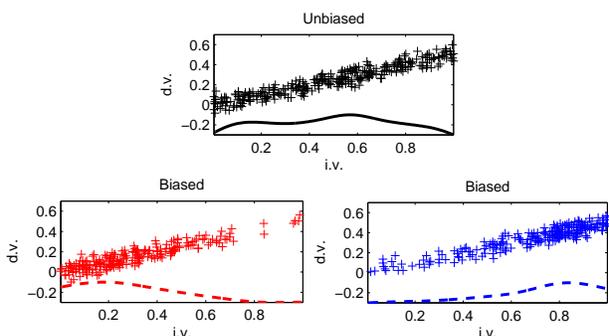

Figure 1: The observation biases.

We assume that the sampling bias affects the way we observe $i.v.$, yet the observation of $d.v.$ given $i.v.$ remains intact. This assumption is compatible with the covariate shift model (Shimodaira, 2000; Huang et al., 2007). As shown in Figure 1, an unbiased observer will sample $i.v.$ uniformly and get the black set. Biased observers might focus more on the smaller or larger values of the $i.v.$ and create the biased red and blue sets, where the curves show the observed marginal densities of the $i.v.$. The joint and marginal distributions of the biased sets now look very different from each other and the unbiased set. Nevertheless, no matter what the distribution of $i.v.$ is, the distribution of $d.v.$ given $i.v.$ is always the same Gaussian that does not change with the observer. In traffic monitoring, the helicopter may be tasked with other, non-traffic, jobs that create different patrol schedules each day, thus creating an uneven profile of the city’s traffic. But the measured traffic volumes at the patrolled locations are still accurate.

To correct sampling biases of this kind, we propose to use conditional divergences. Existing divergence-based methods use the joint distribution of the $i.v.$ and the $d.v.$ to measure the differences between point sets. On the other hand, conditional divergences focus on the conditional distributions of $d.v.$ given $i.v.$ and are insensitive to the distribution of $i.v.$, which is distorted by the sampling bias in our setting. As long as the conditional distributions are intact, the conditional divergences will be reliable. Moreover, it can be shown that the divergence between joint distributions is a special case of the conditional divergence. A fast and consistent estimator is developed for the conditional divergences. We also discuss specific examples of correcting sampling biases, including some extreme cases.

We evaluate the effectiveness of conditional divergences on both synthetic and real world data sets. On synthetic data sets, we show that the proposed estimator is accurate and the conditional divergences are capable of correcting sampling biases. We also demonstrate their performance on real-world climate and image classification problems.

The rest of this paper is organized as follows. The back-

ground and some related work is introduced in Section 2. Section 3 defines the conditional divergence and describes its properties and estimation. Section 4 describes how to use conditional divergence to correct various sampling biases. In Section 5 we make a discussion about the conditional divergences. In Section 6, we evaluate the effectiveness of the proposed methods on both synthetic and real data sets. We conclude the paper in Section 7.

2 BACKGROUND AND RELATED WORK

We consider a data set that consists of M point sets $\{G_m\}_{m=1,\dots,M}$, and each point set G_m is a set of d -dimensional vectors, $G_m = \{z_{mn}\}_{n=1,\dots,N_m}$, $z_{mn} \in \mathbb{R}^d$. Each point $z_{mn} = [x_{mn}; y_{mn}]$ is a concatenation of two shorter vectors $x_{mn} \in \mathbb{R}^{d_x}$ and $y_{mn} \in \mathbb{R}^{d_y}$ representing the independent variables $i.v.$ and the dependent variables $d.v.$ respectively. We assume that each G_m has an underlying distribution $f_m(z) = f_m(x, y)$, and the points $\{z_{mn}\}$ are *i.i.d.* samples from $f_m(z)$. f_m can be written as $f_m(z) = f_m(y|x)f_m(x)$. In the context of image classification, each G_m is an image, and x_{mn} is the location of the n th patch and y_{mn} is the feature of that patch.

We can learn from these sets by estimating the divergence between the f_m ’s as the dissimilarity between the G_m ’s. Having the dissimilarities, various problems can be solved by using similarity based learning algorithms, including *k-nearest neighbors* (KNN), *spectral clustering* (Ng et al., 2001), and *support vector machines* (SVM). In this direction, several divergence-based methods have been proposed (Boiman et al., 2008; Póczos et al., 2012; Muandet et al., 2012), and both empirical and theoretical successes were achieved.

In the presence of sampling bias that affects the distribution of $i.v.$, $f_m(x)$ is transformed into $f'_m(x)$. Consequently the observed G_m ’s represent the biased joint distribution $f'_m(z) = f_m(y|x)f'_m(x)$. Therefore naively learning from the point sets using joint distributions will lead us to the distorted f'_m ’s instead of the true f_m ’s. To correct the sampling bias, we need to either 1) modify the point sets to restore $f(z)$, or 2) use similarity measures that are insensitive to $f(x)$.

Existing correction methods often reweigh the points in the training set so that its effective distribution matches the distribution in the test set (Shimodaira, 2000; Huang et al., 2007; Cortes et al., 2008). Our proposed conditional divergences are insensitive to the biased distributions of the independent variables and thus robust against sampling biases.

Traditionally in statistics and machine learning, sampling bias is considered between the training set and the test set. In contrast, we consider problems consisting of a large

number of point sets, and our goal is to learn from the sets themselves. This extension raises many important challenges, including how to find a common basis to compare all pairs of distributions, how to deal with unobserved segments of distributions, and how to design efficient algorithms.

To our knowledge, this is first time sampling bias is addressed in the context of learning from sets of points. Algorithms such as (Póczos et al., 2011, 2012; Gretton et al., 2007; Muandet et al., 2012; Boiman et al., 2008; McCann and Lowe, 2012; Jebara et al., 2004) all directly compare the joint distributions of the observed points, making them susceptible to sample bias. (Póczos, 2012) proposed the use of conditional divergence, yet sampling bias was still not considered.

3 CONDITIONAL DIVERGENCES

We propose to measure the dissimilarity between two distributions $p(z) = p(x, y)$ and $q(z) = q(x, y)$ using the *conditional divergence (CD)* based on the *Kullback-Leibler (KL)* divergence:

$$\text{CD}_{c(x)}(p(z)||q(z)) = \mathbb{E}_{c(x)} [\text{KL}(p(y|x)||q(y|x))] \quad (1)$$

where $c(x)$ is a user-specified distribution over which the expectation is taken. CD is the average KL divergence between the conditional distributions $p(y|x)$ and $q(y|x)$ over possible values of x , and $c(x)$ can be considered as the importance of the divergences at different x 's. CD's definition is free of the *i.v.* distributions $p(x)$ and $q(x)$, which are vulnerable to sampling biases. By definition, CD has a lot in common with the KL divergence: it is non-negative, and equals zero if and only if $p(y|x) = q(y|x)$ for every x within the support of $c(x)$. CD is also not a metric and not even symmetric.

In the form of (1), CD is hard to compute because the divergences $\text{KL}(p(y|x)||q(y|x))$ are not available for arbitrary continuous distributions. Also note that $c(x)$ is a distribution specified by the user. To make CD more accessible, we can rewrite it as

$$\begin{aligned} \text{CD}_{c(x)}(p(z)||q(z)) &= \mathbb{E}_{p(z)} \left[\frac{c(x)}{p(x)} \left(\ln \frac{p(z)}{q(z)} - \ln \frac{p(x)}{q(x)} \right) \right]. \end{aligned} \quad (2)$$

Now, CD is defined in terms of the density ratios of the input distributions and the expectation over $p(z)$.

An interesting case of (2) occurs when we choose $c(x) = p(x)$, which gives the result

$$\begin{aligned} \text{CD}_{p(x)}(p(z)||q(z)) &= \text{KL}(p(z)||q(z)) - \text{KL}(p(x)||q(x)). \end{aligned} \quad (3)$$

We can see this special CD is equal to the *joint divergence* (divergence between joint distributions) minus the divergence between the marginal distributions of x . Intuitively, CD is removing the effect of $p(x)$ and $q(x)$ from the joint divergence, so that the net results are free from the sampling bias. Moreover, when $p(x)$ and $q(x)$ are the same, $\text{KL}(p(x)||q(x))$ vanishes and this CD equals the joint divergence. In other words, when there is no sampling bias, $\text{CD}_{p(x)}(p(z)||q(z)) = \text{KL}(p(z)||q(z))$.

3.1 ESTIMATION

In this section we give an estimator for CD (2). Suppose we have two sets G_p and G_q with underlying distributions $p(z)$ and $q(z)$ respectively. We can approximate the expectation (2) with the empirical mean and estimated densities:

$$\begin{aligned} \widehat{\text{CD}}_{c(x)}(p(z)||q(z)) &= \frac{1}{N_p} \sum_{n=1}^{N_p} \frac{c(x_{p,n})}{\hat{p}(x_{p,n})} \left(\ln \frac{\hat{p}(z_{p,n})}{\hat{q}(z_{p,n})} - \ln \frac{\hat{p}(x_{p,n})}{\hat{q}(x_{p,n})} \right), \end{aligned} \quad (4)$$

where N_p is the size of G_p , \hat{p}, \hat{q} are the estimates of p, q .

$c(t)$ is an arbitrary input from the user and we can see that its role is to reweight the log-density-ratios at different points in G_p . To generalize this notion, we define the *generalized conditional divergence (GCD)* and its estimator as the weighted average of the log-density-ratios:

$$\begin{aligned} \text{GCD}_w(p(z)||q(z)) &= \sum_{n=1}^{N_p} w(x_{p,n}) \left(\ln \frac{p(z_{p,n})}{q(z_{p,n})} - \ln \frac{p(x_{p,n})}{q(x_{p,n})} \right) \end{aligned} \quad (5)$$

$$\begin{aligned} \widehat{\text{GCD}}_w(p(z)||q(z)) &= \sum_{n=1}^{N_p} w(x_{p,n}) \left(\ln \frac{\hat{p}(z_{p,n})}{\hat{q}(z_{p,n})} - \ln \frac{\hat{p}(x_{p,n})}{\hat{q}(x_{p,n})} \right) \end{aligned} \quad (6)$$

$$\sum_{n=1}^{N_p} w(x_{p,n}) = 1, w(x_{p,n}) \geq 0,$$

where $w(x)$ is the weight function and the constraint $\sum_n w(x_n) = 1$ is induced by the fact that

$$\begin{aligned} \lim_{N_p \rightarrow \infty} \sum_{n=1}^{N_p} w(x_{p,n}) &= \lim_{N_p \rightarrow \infty} \frac{1}{N_p} \sum_{n=1}^{N_p} \frac{c(x_{p,n})}{p(x_{p,n})} \\ &= \mathbb{E}_{p(x)} \left[\frac{c(x)}{p(x)} \right] = \int \frac{c(x)}{p(x)} p(x) dx = 1. \end{aligned}$$

To obtain the density estimates \hat{p}, \hat{q} , we use the *k-nearest-neighbor (KNN)* based estimator (Loftsgaarden and Quesenberry, 1965). Let the $f(z)$ be the d -dimensional density function to be estimated and $Z = \{z_n\}_{n=1, \dots, N} \in \mathbb{R}^d$ be samples from $f(z)$. Then the density estimate at the point

z' is

$$\hat{f}(z') = \frac{k}{N c_1(d) \phi_{Z,k}^d(z')}, \quad (7)$$

where $c_1(d)$ is the volume of the unit ball in the d -dimensional space, and $\phi_{Z,k}(z')$ denotes the distance from z' to its k th nearest neighbor in Z (if z' is already in Z then it is excluded). This estimator is chosen over other options such as the *kernel density estimation* because it is simple, fast, and leads to a provably convergent estimator as shown below.

By plugging in (7) into (6), we can get the following estimator for GCD:

$$\begin{aligned} \widehat{\text{GCD}}_w(p(z)||q(z)) & \quad (8) \\ &= \sum_{n=1}^{N_p} w(x_{p,n}) \left(d \ln \frac{\phi_{G_q,k}(z_{p,n})}{\phi_{G_p,k}(z_{p,n})} - d_x \ln \frac{\phi_{G_q,k}(x_{p,n})}{\phi_{G_p,k}(x_{p,n})} \right), \end{aligned}$$

where d_x is the dimensionality of the x . We can see that the resulting estimator has a simple form and can be calculated based only on the KNN statistics ϕ , which are efficient to compute using space-dividing trees or even approximate KNN algorithms such as (Muja and Lowe, 2009). Also note that even though the estimator (8) is obtained using the density estimator (7), its final form only involves simple combinations of the log-KNN-statistics $\ln \phi$. Thus, this GCD estimator effectively avoids explicit density estimation which is notoriously difficult, especially in high dimensions.

More importantly, the GCD estimator (8) has stronger convergence properties than the density estimator from which it is derived. Standard convergence results have that the density estimator (7) is statistically consistent only if $k/n \rightarrow 0, k \rightarrow \infty$ simultaneously. However, for estimator (8) convergence can be achieved even for a fixed finite k . This means that we can always use a small k to keep the nearest neighbor search fast and still get good estimates. Specifically, following the work of (Wang et al., 2009; Póczos and Schneider, 2011), the following theorem can be proved:

Theorem 1. *Suppose the density function pairs $(p(z), q(z))$ and $(p(x), q(x))$ are both 2-regular (as defined in (Wang et al., 2009)). Also suppose that the weight function satisfies $\lim_{N_p \rightarrow \infty} w(x_{p,n}) = 0, \forall n$. Then the estimator (8) is L^2 consistent for any fixed k . That is*

$$\begin{aligned} \lim_{N_p, N_q \rightarrow \infty} \mathbb{E} \left[\widehat{\text{GCD}}_w(p(z)||q(z)) - \text{GCD}_w(p(z)||q(z)) \right]^2 \\ = 0 \end{aligned}$$

The proof of Theorem 1 is similar to what was used in (Wang et al., 2009). The condition $\lim_{N_p \rightarrow \infty} w(x_{p,n}) = 0$ ensures that the weight function does not concentrate on only a few points. We omit the detailed proof here. Note

that the convergence of GCD does not carry to CD (4) because the weight function $w(x_{p,n}) = \frac{c(x_{p,n})}{\hat{p}(x_{p,n})}$ is no longer deterministic. However, empirically we found that (4) exhibits the behavior of a consistent estimator and produces satisfactory results.

4 CHOOSING $c(x)$

To use CD, we have to choose the appropriate $c(x)$ or $w(x)$. When learning from point sets, it is preferable to use the same $c(x)$ to compute the CDs between all pairs of sets, so that they have a common basis to compare. However, this is not always necessary or possible. Even though the choice of $c(x)$ and $w(x)$ can be arbitrary, we consider 3 options below.

First, we can let $c(x) \propto 1$ so that $w(x_{p,n}) \propto p^{-1}(x_{p,n})$ to treat every value of x equally. The disadvantage is that $p^{-1}(x_{p,n})$ has to be estimated, which is error prone. We can also use $c(x) = p(x)$ and $w(x_{p,n}) \propto 1$, leading to (3). In this case, different pairs of sets can have different $c(x)$'s. When the sampling bias is small, these differences might be acceptable considering the possible errors in $w(x)$ otherwise. Thirdly, $c(x) \propto p(x)q(x)$ and $w(x_{p,n}) \propto q(x_{p,n})$ puts the focus on regions where both $p(x)$ and $q(x)$ are high. It means that we should put larger weights in dense regions and avoid scarce regions to get reliable estimates.

One caveat is that the weight function and the log-density-ratios in CD should not use the same density estimate, otherwise the estimation errors will correlate and cause systematic overestimations. Using different estimators can help decouple the errors and avoid accumulation. In practice, we use the estimator (7) with a different k .

Some extreme cases of sampling biases are when whole segments of the distribution are missing from the sample and therefore unobserved. Two sets can even have disjoint supports of x . With the CD, we can choose $c(x) \propto p(x)q(x)$ or $c(x) \propto I(p(x)q(x) > 0)$, where $I(\cdot)$ is the indicator function, and only compare two sets in their overlapping regions. The resulting quantity may not be accurate with respect to the true unbiased divergence, but it is still a valid measurement of the differences between conditional distributions. When $f(y|x)$ only weakly depends on x , this estimate can be an adequate approximation to the original divergence. If $f(y|x)$ varies drastically for different x 's without any regularity then only comparing the overlapping regions might be the best we can do.

When two sets have disjoint supports in x , no useful information can be extracted and the corresponding divergence has to be regarded as missing without further assumptions. Nevertheless, in our settings where a large number of point sets are available, it is likely that each set will share its support in x with at least some others to provide a few reliable divergence estimates. We might be able to infer the diver-

gence between disjoint sets using the idea of triangulation. We shall leave this possibility for future investigation.

5 DISCUSSION

In CD, $c(x)$ conveys prior knowledge about the importance of different x 's. It should be carefully chosen based on the data, and poor results can happen when the assumptions made in $c(x)$ are not valid. For example, $c(x) \propto 1$ assumes that all the x 's are equally important. This could be a bad assumption when the supports of two sets do not overlap, because at some x 's one of the densities will be zero, making the conditional densities $f(y|x)$ not well-defined. Similar problems might occur in regions where one of the densities is very low. Numerically the estimator can still work but usually produces poor results. In this scenario, $c(x) \propto p(x)q(x)$ suits the data better.

The CD estimator (8) relies on the KNN statistics ϕ which is the distance between nearest neighbors. Usually we use Euclidean distance to measure the difference between points and find nearest neighbors. However, the estimator does not prevent the use of other distances. In fact, (Loftsgaarden and Quesenberry, 1965) shows that alternative distances can be used and the consistency results will generally still hold. A common choice of adaptive distance measure is the *Mahalanobis distance* (Bishop, 2007), which is equivalent to applying a linear transformation to the random variables. It is even possible to learn the distance metric for ϕ in a supervised way to maximize the learning performance. We leave this possibility as future work.

The estimated conditional divergences can be used in many learning algorithms to accomplish various tasks. In this paper, we use kernel machines to classify point sets as in (Póczos et al., 2011, 2012). Having the divergence estimates, we convert them into Gaussian kernels and then use SVM for classification. When constructing kernels, all the divergences are symmetrized by taking the average $\mu(p, q) = \frac{d(p||q)+d(q||p)}{2}$. The symmetrized divergences μ are then exponentiated to get the Gaussian kernel $k(p, q) = \exp(-\gamma\mu(p, q))$ and the kernel matrix \mathbf{K} , where γ is the width parameter. Unfortunately, \mathbf{K} usually does not represent a valid Mercer kernel because the divergence is not a metric and random estimation errors exist. As a remedy, we discard the negative eigenvalues from the kernel matrix \mathbf{K} to convert it to its closest *positive semi-definite* (PSD) matrix $\tilde{\mathbf{K}}$. This $\tilde{\mathbf{K}}$ then is a valid kernel matrix and can be used in an SVM for learning.

6 EXPERIMENTS

We examine the empirical properties of the conditional divergences and their estimators. The tested divergences are listed below.

- **Full D**: Divergence between full unbiased sets as the groundtruth.
- **D**: Divergence between biased sets.
- **D-DV**: Divergence between biased sets while ignoring the *i.v.*
- **CD-P, CD-U, CD-PQ**: conditional divergences with $c(x) \propto p(x)$, $c(x) \propto 1$, $c(x) \propto p(x)q(x)$ respectively between biased sets.

Full D, D, D-DV are estimated using the KL divergence estimator proposed by (Wang et al., 2009). Unless stated otherwise, we use $k = 3$ for GCD estimation using (8), and use k values between 30 and 50 to compute the weight function.

We consider two types of sampling biases. The first type creates different $f(x)$'s for different sets, yet they still share the same support of x as the original unbiased data. Based on the first type, the second type of sampling bias is more extreme and can hide certain segments of the true distributions, and thus causes different sets to have different supports of x . We call the resulting test sets from these two sampling biases *uneven sets* and *partial sets* respectively.

In order to evaluate the quality of the bias correction by the CDs, we use controlled sampling biases in our experiments. The original point set data are collected from real problems without any sampling bias. Then we resample each set to create artificial sampling biases. By doing this, we can compare the results using the biased sets to the divergences using the unbiased data which is the groundtruth.

An SVM is used to classify the point sets using the method described in Section 5. When using the SVM, we tune the width parameter γ and the slack penalty C by 3-fold cross-validation on the training set.

6.1 SYNTHETIC DATA

6.1.1 Estimation Accuracy

We generate synthetic data to test the accuracy of the proposed conditional divergence estimators. The data set consists of 2-dimensional (one as *i.v.* and one as *d.v.*) Gaussian noise along two horizontal lines as the two classes, as shown in Figure 2 and 3. The Gaussians have fixed spherical covariance, and the mean of the blue class is slightly higher than the red class, resulting in an analytical KL divergence of 0.5. Then the *i.v.* (x axis) is resampled to create sampling bias and the red and blue curves show the resulting marginal densities $f_{\text{red}}(x)$, $f_{\text{blue}}(x)$. The task is to recover the true divergence value 0.5 from this biased sample. We vary the sample size to see the empirical convergence, and the results of 10 random runs are reported. The shortcut for this problem is to ignore the *i.v.*, but we do not let the estimators take it and force them to recover from the sampling bias.

Figure 2 shows the results on the uneven sets. As expected, the joint divergences are corrupted by the sampling bias and are far from the truth. The three CDs all converge to the true value. Figure 3 shows the results on the partial sets. The joint divergence diverges in this case. CD-P and CD-U are closer but not converging to the correct value, and the reason is that the non-overlapping supports violate the assumptions made by them. CD-PQ successfully achieved the true value. This shows the advantage of only measuring CD within the overlapping region in this example. Overall, the CDs are effective against sampling bias and the estimators converge to the true values.

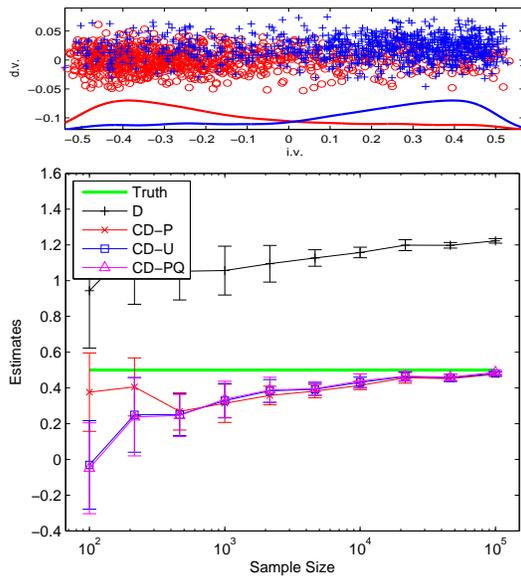

Figure 2: Divergences on the uneven synthetic data.

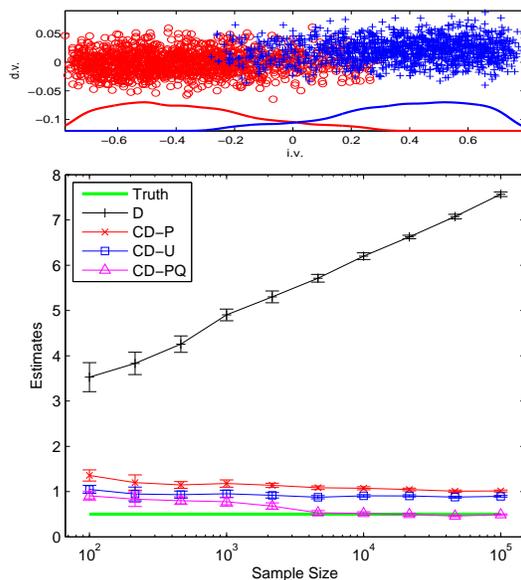

Figure 3: Divergences on the partial synthetic data.

6.1.2 Handling Point Sets

Here we test the estimators using a large number of point sets. The full data of two classes are shown in Figure 5a. To create partial sets, we use a sliding window, whose width is half of the data’s span, to scan the full data and at each position put the points within the window together as a set. The uneven sets are then created by combining the partial sets with a small number of random samples from the original data. 100 sets are created for each class and each set contains 200 – 300 points.

This data set is more challenging: the marginal distribution of $d.v.$ cannot differentiate the two classes; the conditional distributions $f(y|x)$ are dependent on x ; near the center of the data the conditional distributions of the two classes are very close. The different divergence matrices on the uneven sets are shown in Figure 4, in which we sorted the sets according to their classes and window positions to show the structures. We see that the joint divergence is severely affected by the sampling bias, while the CDs are quite insensitive. The result of CD-U is especially impressive: the similarity structure of the original data is perfectly recovered. Figure 5 shows the results on the partial sets. The joint divergence is now dominated by the sampling bias. CDs again are able to recover from this severe disruption and achieve reasonable results. The result of CD-PQ is the cleanest on this data set.

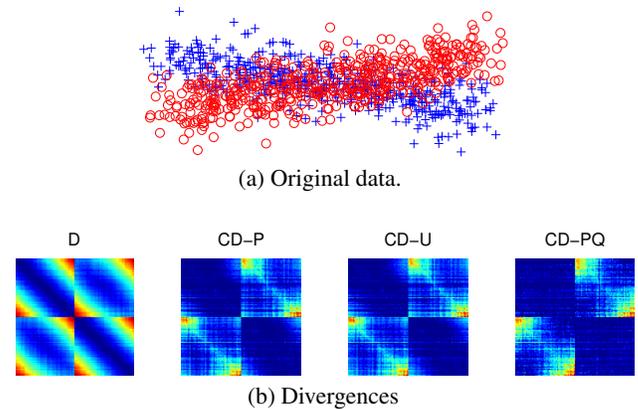

Figure 5: Divergences on the partial sets. The goal is to recover the “Full D” result shown in Figure 4.

6.2 SEASON CLASSIFICATION

In this section we use the divergences in SVM to classify real world point sets generated by sensor networks. We gathered the data from the QCLCD climate database at NCDC ¹. We use a subset of QCLCD that contains daily climatological data from May 2007 to May 2013 measured by 1,164 weather stations in the continental U.S. Each of these weather station produces various measurements such

¹<http://www.ncdc.noaa.gov>

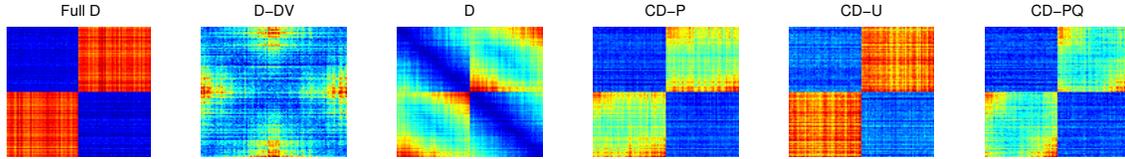

Figure 4: Divergences on the uneven sets. The goal is to recover the “Full D” given only the biased sets.

as the temperature, humidity, precipitation, *etc.*, at its location. We aggregate these data into point sets, so that each set contains the measurements from all stations in one week.

We consider the problem of predicting the season of a set based on the average temperature measurement. Specifically, we want to know if a set corresponds to Spring or Fall based on the average temperatures over the U.S. Note that classifying Summer and Winter would be too easy, while differentiating Spring and Fall can be challenging since they have similar average temperatures. Nevertheless, it is still possible based on the geographical distribution of the temperatures. Figure 6 shows the temperature maps in a first week of March and a first week of November.

Again, we create uneven and partial sets based on the original data by randomly positioning a full-width window whose height is 20% of the data’s vertical span, as shown in Figure 6. This injection of sampling bias is simulating the scenario where we only have a sensing satellite orbiting parallel to the equator. In this problem, the location is the *i.v.* and the temperature is the *d.v.* This procedure gives us 160 3-dimensional (latitude, longitude, temperature) point sets with sizes around 2,000.

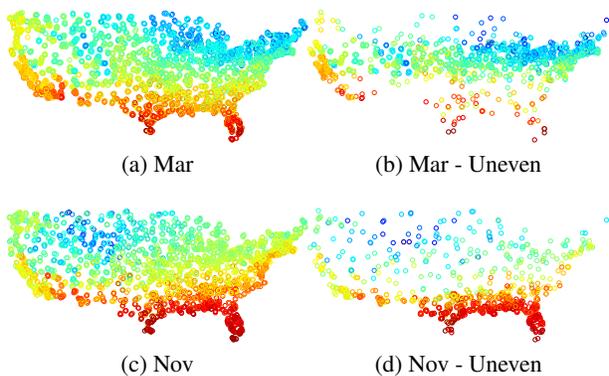

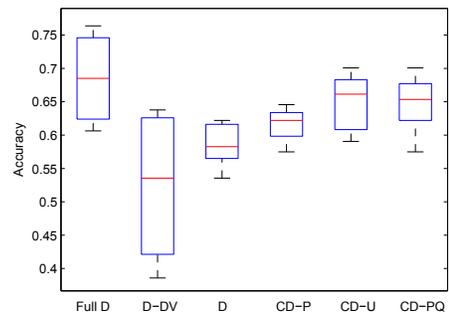

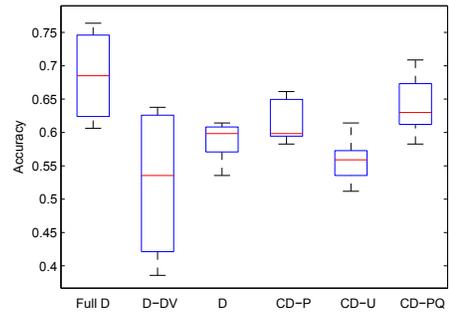

Figure 6: Example temperature maps of the U.S. from the QCLCD. (a) and (c) are the original data. (b) and (d) are the artificially created uneven data.

In each run, 20% of the random point sets are used for training and the rest are used for testing. Classification results of 10 runs are reported in Figure 7. On the uneven sets, we see that both CD-U and CD-PQ are able to recover from the sampling bias and achieve results that are only 3% worse

than the full divergence. On the partial sets, however, the performance CD-U dropped significantly. This indicates that it can be risky to apply CD in regions where two sets do not overlap. It is interesting to see that D-DV, which ignores the locations, barely does better than random since Spring and Fall indeed have similar temperatures. Yet by considering the geographical distribution of temperatures we can achieve 70% accuracy.

(a) QCLCD, uneven.

(b) QCLCD, partial.

Figure 7: Season classification results on the QCLCD weather data.

6.3 IMAGE CLASSIFICATION

We can also use CDs to classify scene images. We construct one point set for each image, where each point describes one patch including its location (*i.v.*) and the feature (*d.v.*). The OT (A.Oliva and Torralba, 2001) scene images are used, which contain 2,688 grayscale images of size 256×256 from 8 categories. The patches are sampled densely on a grid and multiscale SIFT features are extracted using VLFeat (Vedaldi and Fulkerson, 2008). The points are reduced to 20-dimensions using PCA, preserving 70%

of variance.

Again, we create both uneven and partial point sets by randomly positioning a full-width window whose height is 60% of the image. By doing this, the injected sampling bias forces a set to focus on a specific horizontal part of the scene. For instance in a beach scene, the biased observer focuses either on the sky or the sand, and only see a small part of the rest of the scene. After the above processing, the full data set contains 2,688 sets of 20-dimensional points, and the sets' sizes are around 1,600. In the biased data, each partial set has about 950 points and each uneven set has about 1,100. In each run, we randomly select 50 images per class for training and another 50 for testing.

Results of 10 random runs are shown in Figure 8. In these results, CDs again successfully restore the accuracies to a high level even in the face of harsh sampling biases. We see that CD-U impressively beats the other methods by a large margin on the uneven sets, and is only 1% worse than the full divergence. CD-PQ is the best on partial sets. These results show the CDs' corrective power when the correct assumptions are made about the sampling biases.

We also observe that CD-U and CD-P did not perform well on the partial sets, which is expected since their assumptions were invalid on the data. In general, the impact of sampling bias on this data set is small (less than 10% decrease in accuracies) because the patch features (*d.v.*) only weakly depend on the patch locations (*i.v.*). In fact, many patch-based image analyses such as (Li and Perona, 2005) do not include the locations. This might explain why both D-DV and D-P did reasonably well in this task and the corrected results by CD-PQ are only slightly better.

7 CONCLUSION

In this paper we described various aspects of dealing with sampling bias when learning from point sets. We proposed the conditional divergence (CD) to measure the difference between point sets and alleviate the impact of sampling bias. An efficient and convergent estimator of CD was provided. We then discussed how to deal with various types of sampling biases using CD. In the experiments we show that these methods are effective against sampling bias on both synthetic and real data.

Several directions can be explored in the future. We can extend the definition of conditional divergence from KL divergence to the more general Rényi divergences. The generalized conditional divergences provide the possibility of learning the weights of the density ratios in a supervised ways in order to maximize the discriminative power of the resulting divergences. The distance between points used in estimating the CDs could also be learned. Finally for extreme cases that cause missing divergences, we may infer them by exploiting the relationships among the sets using

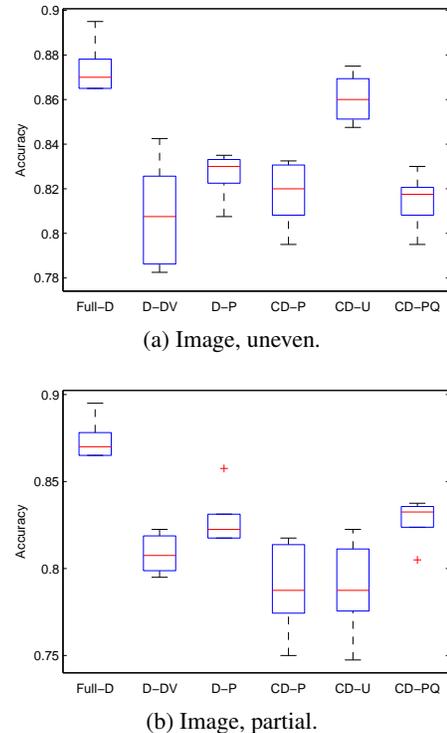

Figure 8: Image classification results on OT.

matrix completion techniques.

Abstract

Ancestral graphs (AGs) are graphical causal models that can represent uncertainty about the presence of latent confounders, and can be inferred from data. Here, we present an algorithmic framework for efficiently testing, constructing, and enumerating m -separators in AGs. Moreover, we present a new constructive criterion for covariate adjustment in directed acyclic graphs (DAGs) and maximal ancestral graphs (MAGs) that characterizes adjustment sets as m -separators in a subgraph. Jointly, these results allow to find all adjustment sets that can identify a desired causal effect with multivariate exposures and outcomes in the presence of latent confounding. Our results generalize and improve upon several existing solutions for special cases of these problems.

1 INTRODUCTION

Graphical causal models endow researchers with a language to codify assumptions about a data generating process (Pearl, 2009; Elwert, 2013). Using graphical criteria, one can assess whether the assumptions encoded in such a model allow estimation of a causal effect from observational data, which is a key issue in Epidemiology (Rothman et al., 2008), the Social Sciences (Elwert, 2013) and other fields where controlled experimentation is typically impossible. Specifically, the famous back-door criterion by Pearl (2009) can identify cases where causal effect identification is possible by standard covariate adjustment, and other methods like the front-door criterion or do-calculus can even permit identification even if the back-door criterion fails (Pearl, 2009). In current practice, however, covariate adjustment is highly preferred to such alternatives because its statistical properties are well understood, giving access to useful methodology like robust estimators and confidence intervals. In contrast, knowledge about the sta-

tistical properties of e.g. front-door estimation is still considerably lacking (VanderWeele, 2009; Glynn and Kashin, 2013)¹. Unfortunately, the back-door criterion is not complete, i.e., it does not find all possible options for covariate adjustment that are allowed by a given graphical causal model.

In this paper, we aim to efficiently find a definitive answer for the following question: Given a causal graph \mathcal{G} , which covariates \mathbf{Z} do we need to adjust for to estimate the causal effect of the exposures \mathbf{X} on the outcomes \mathbf{Y} ? To our knowledge, no efficient algorithm has been shown to answer this question, not even when \mathcal{G} is a directed acyclic graph (DAG), though constructive solutions do exist for special cases like singleton $\mathbf{X} = \{X\}$ (Pearl, 2009), and a subclass of DAGs (Textor and Liškiewicz, 2011). Here, we provide algorithms for adjustment sets in DAGs as well as in maximal ancestral graphs (MAGs), which extend DAGs allowing to account for unspecified latent variables. Our algorithms are guaranteed to find all valid adjustment sets for a given DAG or MAG with polynomial delay, and we also provide variants to list only those sets that minimize a user-supplied cost function or to quickly construct a simple adjustment set if one exists. Modelling multiple, possibly interrelated exposures \mathbf{X} is important e.g. in case-control studies that screen several putative causes of a disease (Greenland, 1994). Likewise, the presence of unspecified latent variables often cannot be excluded in real-world settings, and the causal structure between the observed variables may not be completely known. We hope that the ability to quickly deduce from a given DAG or MAG whether and how covariate adjustment can render a causal effect identifiable will benefit researchers in such areas.

We have two main contributions. First, in Section 3, we present algorithms for verifying, constructing, and listing m -separating sets in AGs. This subsumes a number of earlier solutions for special cases of these problems, e.g.

¹Quoting VanderWeele (2009), “Time will perhaps tell whether results like Pearl’s front-door path adjustment theorem and its generalizations are actually useful for epidemiologic research or whether the results are simply of theoretical interest.”

the Bayes-Ball algorithm for verification of d -separating sets (Shachter, 1998), the use of network flow calculations to find minimal d -separating sets in DAGs (Tian et al., 1998; Acid and de Campos, 2003), and an algorithm to list minimal adjustment sets for a certain subclass of DAGs (Textor and Liškiewicz, 2011). Our verification and construction algorithms for single separators are asymptotically runtime-optimal. Although we apply our algorithms only to adjustment set construction, they are likely useful in other settings as separating sets are involved in most graphical criteria for causal effect identification. Moreover, the separators themselves constitute statistically testable implications of the causal assumptions encoded in the graph.

Second, we give a graphical criterion that characterizes adjustment sets in terms of separating sets, and is sound and complete for DAGs and MAGs without selection variables. This generalizes the sound and complete criterion for DAGs by Shpitser et al. (2010), and the sound but incomplete adjustment criterion for MAGs without selection variables by Maathuis and Colombo (2013). Our criterion exhaustively addresses adjustment set construction in the presence of latent covariates and with incomplete knowledge of causal structure if at least a MAG can be specified. We give the criterion separately for DAGs (Section 4) and MAGs (Section 5) because the same graph usually admits more adjustment options if viewed as a DAG than if viewed as a MAG.

2 PRELIMINARIES

We denote sets by bold upper case letters (\mathbf{S}), and sometimes abbreviate singleton sets as $\{S\} = S$. Graphs are written calligraphically (\mathcal{G}), and variables in upper-case (X).

Mixed graphs and paths. We consider mixed graphs $\mathcal{G} = (\mathbf{V}, \mathbf{E})$ with nodes (vertices, variables) \mathbf{V} and directed ($A \rightarrow B$), undirected ($A-B$), and bidirected ($A \leftrightarrow B$) edges \mathbf{E} . Nodes linked by an edge are *adjacent*. A *walk* of length n is a node sequence V_1, \dots, V_{n+1} such that there exists an edge sequence E_1, E_2, \dots, E_n for which every edge E_i connects V_i, V_{i+1} . Then V_1 is called the *start node* and V_{n+1} the *end node* of the walk. A *path* is a walk in which no node occurs more than once. Given a node set \mathbf{X} and a node set \mathbf{Y} , a walk from $X \in \mathbf{X}$ to $Y \in \mathbf{Y}$ is called *proper* if only its start node is in \mathbf{X} . Given a graph $\mathcal{G} = (\mathbf{V}, \mathbf{E})$ and a node set \mathbf{V}' , the *induced subgraph* $\mathcal{G}_{\mathbf{V}'} = (\mathbf{V}', \mathbf{E}')$ contains the edges \mathbf{E}' from \mathcal{G} that are adjacent only to nodes in \mathbf{V}' .

Ancestry. A walk of the form $V_1 \rightarrow \dots \rightarrow V_n$ is *directed*, or *causal*. If there is a directed walk from U to V , then U is called an *ancestor* of V and V a *descendant* of U . A graph is *acyclic* if no directed walk from a node to itself is longer than 0. All directed walks in an acyclic graph are paths. A walk is *anterior* if it were directed after replacing all edges $U - V$ by $U \rightarrow V$. If there is an anterior path

from U to V , then U is called an *anterior* of V . All ancestors of V are anteriors of V . Every node is its own ancestor, descendant, and anterior. For a node set \mathbf{X} , the set of all of its ancestors is written as $An(\mathbf{X})$. The descendant and anterior sets $De(\mathbf{X}), Ant(\mathbf{X})$ are analogously defined. Also, we denote by $Pa(\mathbf{X}), (Ch(\mathbf{X}))$, the set of parents (children) of \mathbf{X} .

m -Separation. A node V on a walk w is called a *collider* if two arrowheads of w meet at V , e.g. if w contains $U \leftrightarrow V \leftarrow Q$. There can be no collider if w is shorter than 2. Two nodes U, V are called *collider connected* if there is a path between them on which all nodes except U and V are colliders. Adjacent vertices are collider connected. Two nodes U, V are called *m -connected* by a set \mathbf{Z} if there is a path π between them on which every node that is a collider is in $An(\mathbf{Z})$ and every node that is not a collider is not in \mathbf{Z} . Then π is called an *m -connecting path*. The same definition can be stated simpler using walks: U, V are called *m -connected* by \mathbf{Z} if there is a walk between them on which all colliders and only colliders are in \mathbf{Z} . If U, V are *m -connected* by the empty set, we simply say they are *m -connected*. If U, V are not *m -connected* by \mathbf{Z} , we say that \mathbf{Z} *m -separates* them or *blocks* all paths between them. Two node sets \mathbf{X}, \mathbf{Y} are *m -separated* by \mathbf{Z} if all their nodes are pairwise *m -separated* by \mathbf{Z} . In DAGs, *m -separation* is equivalent to the well-known *d -separation* criterion (Pearl, 2009).

Ancestral graphs and DAGs. A mixed graph $\mathcal{G} = (V, E)$ is called an *ancestral graph* (AG) if the following two conditions hold: (1) For each edge $A \leftarrow B$ or $A \leftrightarrow B$, A is not an ancestor of B . (2) For each edge $A - B$, there are no edges $A \leftarrow C, A \leftrightarrow C, B \leftarrow C$ or $B \leftrightarrow C$. There can be at most one edge between two nodes in an AG (Richardson and Spirtes, 2002). Syntactically, all DAGs are AGs and all AGs containing only directed edges are DAGs. An AG $\mathcal{G} = (\mathbf{V}, \mathbf{E})$ is a *maximal ancestral graph* (MAG) if every non-adjacent pair of nodes U, V can be *m -separated* by some $\mathbf{Z} \subseteq \mathbf{V} \setminus \{U, V\}$. Every AG \mathcal{G} can be turned into a MAG \mathcal{M} by adding bidirected edges between node pairs that cannot be *m -separated* (Richardson and Spirtes, 2002).

3 ALGORITHMS FOR m -SEPARATION

In this section, we compile an algorithmic framework for solving a host of problems related to verification, construction, and enumeration of *m -separating sets* in AGs. The problems are defined in Fig. 1, which also shows the asymptotic runtime of their solutions. Throughout, n stands for the number of nodes and m for the number of edges in a graph. All of these problems except LISTSEP can be solved by rather straightforward modifications of existing algorithms (Acid and Campos, 1996; Shachter, 1998; Tian et al., 1998; Textor and Liškiewicz, 2011). We there-

fore refrain in this paper from presenting them in detail, Pseudocodes of these algorithms are shown for reference and implementation in the online version of this paper². The online version also contains proof details that had to be omitted from this paper for space reasons.

An important tool for solving similar problems for d -separation is *moralization*, by which d -separation can be reduced to a vertex cut in an undirected graph. This reduction allows to solve problems like FINDMINSEP using standard network flow algorithms (Acid and Campos, 1996). Moralization can be generalized to AGs in the following manner.

Definition 3.1 (Moralization of AGs (Richardson and Spirtes, 2002)). *Given an AG \mathcal{G} , the augmented graph $(\mathcal{G})^a$ is an undirected graph with the same node set as \mathcal{G} such that $X - Y$ is an edge in $(\mathcal{G})^a$ if and only if X and Y are collider connected in \mathcal{G} .*

Theorem 3.2 (Reduction of m -Separation to vertex cuts (Richardson and Spirtes, 2002)). *Given an AG \mathcal{G} and three node sets X, Y and Z , Z m -separates X and Y if and only if Z is an X - Y node cut in $(\mathcal{G}_{Ant(X \cup Y \cup Z)})^a$.*

A direct implementation of Definition 3.1 would lead to a suboptimal algorithm. Therefore, we first give an asymptotically optimal (linear time in output size) moralization algorithm for AGs. We then solve TESTMINSEP, FINDMINSEP, FINDMINCOSTSEP and LISTMINSEP by generalizing existing correctness proofs of the moralization approach for d -separation (Tian et al., 1998).

Not all our solutions are based on moralization, however. Moralization takes time $O(n^2)$, and TESTSEP and FINDSEP can be solved faster, i.e. in asymptotically optimal time $O(n + m)$.

Lemma 3.3 (Efficient AG moralization). *Given an AG \mathcal{G} , the augmented graph $(\mathcal{G})^a$ can be computed in time $O(n^2)$.*

Proof. The algorithm proceeds in four steps. (1) Start by setting $(\mathcal{G})^a$ to \mathcal{G} replacing all edges by undirected ones. (2) Identify all connected components in \mathcal{G} with respect to bidirected edges (two nodes are in the same such component if they are connected by a path consisting only of bidirected edges). Nodes without adjacent bidirected edges form singleton components. (3) For each pair U, V of nodes from the same component, add the edge $U - V$ to $(\mathcal{G})^a$ if it did not exist already. (4) For each component, identify all its parents (nodes U with an edge $U \rightarrow V$ where U is in the component) and link them all by undirected edges in $(\mathcal{G})^a$. Now two nodes are adjacent in $(\mathcal{G})^a$ if and only if they are collider connected in \mathcal{G} . All four steps can be performed in time $O(n^2)$. \square

Lemma 3.4. *Let X, Y, I, R be sets of nodes with $I \subseteq R$, $R \cap (X \cup Y) = \emptyset$. If there exists an m -separator Z_0 , with $I \subseteq Z_0 \subseteq R$ then $Z = Ant(X \cup Y \cup I) \cap R$ is an m -separator.*

²URL: theory.bio.uu.nl/textor/uai14.pdf

Corollary 3.5 (Ancestry of minimal separators). *Given an AG \mathcal{G} , and three sets X, Y, I , every minimal set Z over all m -separators containing I is a subset of $Ant(X \cup Y \cup I)$.*

Proof. Assume there is a minimal separator Z with $Z \not\subseteq Ant(X \cup Y \cup I)$. According to Lemma 3.4 we have that $Z' = Ant(X \cup Y \cup I) \cap Z$ is a separator with $I \subseteq Z'$. But $Z' \subseteq Ant(X \cup Y \cup I)$ and $Z' \subseteq Z$, so $Z \neq Z'$ and Z is not a minimal separator. \square

Corollary 3.5 applies to minimum-cost separators as well because every minimum-cost separator must be minimal. Now we can solve FINDMINCOSTSEP and FINDMINSIZESEP by using weighted min-cut, which takes time $O(n^3)$ using practical algorithms, and LISTMINSEP by using Takata’s algorithm to enumerate minimal vertex cuts with delay $O(n^3)$ (Takata, 2010).

However, for FINDMINSEP and TESTMINSEP, we can do better than using standard vertex cuts.

Proposition 3.6. *The task FINDMINSEP can be solved in time $O(n^2)$.*

Proof. Two algorithms are given in the online appendix, one with runtime $O(n^2)$ and one with runtime $O(nm)$. \square

Corollary 3.7. *The task TESTMINSEP can be solved in time $O(n^2)$.*

Proof. First verify whether Z is an m -separator using moralization. If not, return “no”. Otherwise, set $S = Z$ and solve FINDMINSEP. Return “yes” if the output is Z and “no”, otherwise. \square

Moralization can in the worst case quadratically increase the size of a graph. Therefore, in some cases, it may be preferable to avoid moralization if the task at hand is rather simple, as are the two tasks considered below.

Proposition 3.8. *The task FINDSEP can be solved in time $O(n + m)$.*

Proof. This follows directly from Lemma 3.4, and the fact that the set $Ant(X \cup Y \cup I) \cap R$ can be found in linear time from the MAG without moralization. Note that unlike in DAGs, two non-adjacent nodes cannot always be m -separated in ancestral graphs. \square

By modifying the Bayes-Ball algorithm (Shachter, 1998) appropriately, we get the following.

Proposition 3.9. *The task TESTSEP can be solved in time $O(n + m)$.*

Lastly, we consider the problem of listing all m -separators. Here is an algorithm to solve that problem with polynomial delay.

Verification: For given \mathbf{X}, \mathbf{Y} and \mathbf{Z} decide if . . .		
TESTSEP	\mathbf{Z} m -separates \mathbf{X}, \mathbf{Y}	$O(n + m)$
TESTMINSEP	\mathbf{Z} m -separates \mathbf{X}, \mathbf{Y} but no $\mathbf{Z}' \subsetneq \mathbf{Z}$ does	$O(n^2)$
Construction: For given \mathbf{X}, \mathbf{Y} and auxiliary \mathbf{I}, \mathbf{R} , output . . .		
FINDSEP	an m -separator \mathbf{Z} with $\mathbf{I} \subseteq \mathbf{Z} \subseteq \mathbf{R}$	$O(n + m)$
FINDMINSEP	a minimal m -separator \mathbf{Z} with $\mathbf{I} \subseteq \mathbf{Z} \subseteq \mathbf{R}$	$O(n^2)$
FINDMINCOSTSEP	a minimum-cost m -separator \mathbf{Z} with $\mathbf{I} \subseteq \mathbf{Z} \subseteq \mathbf{R}$	$O(n^3)$
Enumeration: For given $\mathbf{X}, \mathbf{Y}, \mathbf{I}, \mathbf{R}$ enumerate all . . .		
LISTSEP	m -separators \mathbf{Z} with $\mathbf{I} \subseteq \mathbf{Z} \subseteq \mathbf{R}$	$O(n(n + m))$ delay
LISTMINSEP	minimal m -separators \mathbf{Z} with $\mathbf{I} \subseteq \mathbf{Z} \subseteq \mathbf{R}$	$O(n^3)$ delay

Table 1: Definitions of algorithmic tasks related to m -separation. Throughout, $\mathbf{X}, \mathbf{Y}, \mathbf{R}$ are pairwise disjoint node sets, \mathbf{Z} is disjoint with \mathbf{X}, \mathbf{Y} which are nonempty, and $\mathbf{I}, \mathbf{R}, \mathbf{Z}$ can be empty. By a minimal m -separator \mathbf{Z} , with $\mathbf{I} \subseteq \mathbf{Z} \subseteq \mathbf{R}$, we mean a set such that no proper subset \mathbf{Z}' of \mathbf{Z} , with $\mathbf{I} \subseteq \mathbf{Z}'$, m -separates the pair \mathbf{X} and \mathbf{Y} . Analogously, we define a minimal and a minimum-cost m -separator. The construction algorithms will output \perp if no set fulfilling the listed condition exists. Delay complexity for e.g. LISTMINSEP refers to the time needed to output one solution when there can be exponentially many solutions (see Takata (2010)).

```

function LISTSEP( $\mathcal{G}, \mathbf{X}, \mathbf{Y}, \mathbf{I}, \mathbf{R}$ )
  if FINDSEP( $\mathcal{G}, \mathbf{X}, \mathbf{Y}, \mathbf{I}, \mathbf{R}$ )  $\neq \perp$  then
    if  $\mathbf{I} = \mathbf{R}$  then Output  $\mathbf{I}$ 
    else
       $V \leftarrow$  an arbitrary node of  $\mathbf{R} \setminus \mathbf{I}$ 
      LISTSEP( $\mathcal{G}, \mathbf{X}, \mathbf{Y}, \mathbf{I} \cup \{V\}, \mathbf{R}$ )
      LISTSEP( $\mathcal{G}, \mathbf{X}, \mathbf{Y}, \mathbf{I}, \mathbf{R} \setminus \{V\}$ )

```

Figure 1: ListSep

Proposition 3.10. *The task LISTSEP can be solved with polynomial delay $O(n(n + m))$.*

Proof. Algorithm LISTSEP performs backtracking to enumerate all \mathbf{Z} with $\mathbf{I} \subseteq \mathbf{Z} \subseteq \mathbf{R}$ aborting branches that will not find a valid separator. Since every leaf will output a separator, the tree height is at most n and the existence check needs $O(n + m)$, the delay time is $O(n(n + m))$. The algorithm generates every separator exactly once: if initially $\mathbf{I} \subsetneq \mathbf{R}$, with $V \in \mathbf{R} \setminus \mathbf{I}$, then the first recursive call returns all separators \mathbf{Z} with $V \in \mathbf{Z}$ and the second call returns all \mathbf{Z}' with $V \notin \mathbf{Z}'$. Thus the generated separators are pairwise disjoint. This is a modification of the enumeration algorithm for minimal vertex separators (Takata, 2010). \square

4 ADJUSTMENT IN DAGS

In this section, we leverage the algorithmic framework of the last section together with a new constructive, sound and complete criterion for covariate adjustment in DAGs to solve all problems listed in Table 1 for adjustment sets instead of m -separators in the same asymptotic time. First, however, we need to introduce some more notation pertaining to the causal interpretation DAGs.

Do-operator and adjustment sets. A DAG \mathcal{G} encodes the factorization of joint distribution π for the set of vari-

ables $\mathbf{V} = \{X_1, \dots, X_n\}$ as $p(\mathbf{v}) = \prod_{j=1}^n p(x_j | pa_j)$, where pa_j denotes a particular realization of the parent variables of X_j in \mathcal{G} . When interpreted causally, an edge $X_i \rightarrow X_j$ is taken to represent a direct causal effect of X_i on X_j . For disjoint $\mathbf{X}, \mathbf{Y} \subseteq \mathbf{V}$, the (total) causal effect of \mathbf{X} on \mathbf{Y} is $p(\mathbf{y} | do(\mathbf{x}))$ where $do(\mathbf{x})$ represents an intervention that sets $\mathbf{X} = \mathbf{x}$. In a DAG, this intervention corresponds to removing all edges into \mathbf{X} , disconnecting \mathbf{X} from its parents. We denote the resulting graph as $\mathcal{G}_{\overline{\mathbf{X}}}$. Given DAG \mathcal{G} and a joint probability density π for \mathbf{V} the post-intervention distribution can be expressed in a truncated factorization formula:

$$p(\mathbf{v} | do(\mathbf{x})) = \begin{cases} \prod_{x_j \in \mathbf{V} \setminus \mathbf{X}} p(x_j | pa_j) & \text{for } \mathbf{V} \text{ consistent with } \mathbf{x} \\ 0 & \text{otherwise.} \end{cases}$$

Definition 4.1 (Adjustment (Pearl, 2009)). *Given a DAG $\mathcal{G} = (\mathbf{V}, \mathbf{E})$ and pairwise disjoint $\mathbf{X}, \mathbf{Y}, \mathbf{Z} \subseteq \mathbf{V}$, \mathbf{Z} is called covariate adjustment for estimating the causal effect of \mathbf{X} on \mathbf{Y} , or simply adjustment, if for every distribution p consistent with \mathcal{G} we have $p(\mathbf{y} | do(\mathbf{x})) = \sum_{\mathbf{z}} p(\mathbf{y} | \mathbf{x}, \mathbf{z})p(\mathbf{z})$.*

Definition 4.2 (Adjustment criterion (Shpitser et al., 2010; Shpitser, 2012)³). *Let $\mathcal{G} = (\mathbf{V}, \mathbf{E})$ be a DAG, and $\mathbf{X}, \mathbf{Y}, \mathbf{Z} \subseteq \mathbf{V}$ be pairwise disjoint subsets of variables. The set \mathbf{Z} satisfies the adjustment criterion relative to (\mathbf{X}, \mathbf{Y}) in \mathcal{G} if*

- (a) *no element in \mathbf{Z} is a descendant in \mathcal{G} of any $W \in \mathbf{V} \setminus \mathbf{X}$ which lies on a proper causal path from \mathbf{X} to \mathbf{Y} and*
- (b) *all proper non-causal paths in \mathcal{G} from \mathbf{X} to \mathbf{Y} are blocked by \mathbf{Z} .*

Analogously to $\mathcal{G}_{\overline{\mathbf{X}}}$, by $\mathcal{G}_{\underline{\mathbf{X}}}$ we denote a DAG obtained from \mathcal{G} by removing all edges leaving \mathbf{X} .

³In Shpitser et al. (2010), the criterion is stated using $\mathcal{G}_{\overline{\mathbf{X}}}$ instead of \mathcal{G} . However, one can easily prove that both criteria are equivalent.

4.1 CONSTRUCTIVE BACK-DOOR CRITERION

Definition 4.3 (Proper back-door graph). Let $\mathcal{G} = (\mathbf{V}, \mathbf{E})$ be a DAG, and $\mathbf{X}, \mathbf{Y} \subseteq \mathbf{V}$ be pairwise disjoint subsets of variables. The proper back-door graph, denoted as $\mathcal{G}_{\mathbf{X}\mathbf{Y}}^{pbd}$, is obtained from \mathcal{G} by removing the first edge of every proper causal path from \mathbf{X} to \mathbf{Y} .

Note the difference between the back-door graph $\mathcal{G}_{\mathbf{X}}$ and the proper back-door graph $\mathcal{G}_{\mathbf{X}\mathbf{Y}}^{pbd}$: in $\mathcal{G}_{\mathbf{X}}$ all edges leaving \mathbf{X} are removed while in $\mathcal{G}_{\mathbf{X}\mathbf{Y}}^{pbd}$ only those that lie on a proper causal path. However, to construct $\mathcal{G}_{\mathbf{X}\mathbf{Y}}^{pbd}$ still only elementary operations are sufficient. Indeed, we remove all edges $X \rightarrow D$ in \mathbf{E} such that $X \in \mathbf{X}$ and D is in the subset, which we call $PCP(\mathbf{X}, \mathbf{Y})$, obtained as follows:

$$PCP(\mathbf{X}, \mathbf{Y}) = (De_{\overline{\mathbf{X}}}(\mathbf{X}) \setminus \mathbf{X}) \cap An_{\underline{\mathbf{X}}}(\mathbf{Y}) \quad (1)$$

where $De_{\overline{\mathbf{X}}}(\mathbf{W})$ denotes descendants of \mathbf{W} in $\mathcal{G}_{\overline{\mathbf{X}}}$. $An_{\underline{\mathbf{X}}}(\mathbf{W})$ is defined analogously for $\mathcal{G}_{\underline{\mathbf{X}}}$. Hence, the proper back-door graph can be constructed from \mathcal{G} in linear time $O(m + n)$.

Now we propose the following adjustment criterion. For short, we will denote the set $De(PCP(\mathbf{X}, \mathbf{Y}))$ as $Dpcp(\mathbf{X}, \mathbf{Y})$.

Definition 4.4 (Constructive back-door criterion (CBC)). Let $\mathcal{G} = (\mathbf{V}, \mathbf{E})$ be a DAG, and let $\mathbf{X}, \mathbf{Y}, \mathbf{Z} \subseteq \mathbf{V}$ be pairwise disjoint subsets of variables. The set \mathbf{Z} satisfies the constructive back-door criterion relative to (\mathbf{X}, \mathbf{Y}) in \mathcal{G} if

- (a) $\mathbf{Z} \subseteq \mathbf{V} \setminus Dpcp(\mathbf{X}, \mathbf{Y})$ and
- (b) \mathbf{Z} d -separates \mathbf{X} and \mathbf{Y} in the proper back-door graph $\mathcal{G}_{\mathbf{X}\mathbf{Y}}^{pbd}$.

Theorem 4.5. The constructive back-door criterion is equivalent to the adjustment criterion.

Proof. First observe that the conditions (a) of both criteria are identical. Assume conditions (a) and (b) of the adjustment criterion hold. We show that (b) of the constructive back-door criterion follows. Let π be any proper path from \mathbf{X} to \mathbf{Y} in $\mathcal{G}_{\mathbf{X}\mathbf{Y}}^{pbd}$. Because $\mathcal{G}_{\mathbf{X}\mathbf{Y}}^{pbd}$ does not contain causal paths from \mathbf{X} to \mathbf{Y} , π is not causal and has to be blocked by \mathbf{Z} in \mathcal{G} by the assumption. Since removing edges cannot open paths, π is blocked by \mathbf{Z} in $\mathcal{G}_{\mathbf{X}\mathbf{Y}}^{pbd}$ as well.

Now we show that (a) and (b) of the constructive back-door criterion together imply (b) of the adjustment criterion. If that were not the case, then there could exist a proper non-causal path π from \mathbf{X} to \mathbf{Y} that is blocked in $\mathcal{G}_{\mathbf{X}\mathbf{Y}}^{pbd}$ but open in \mathcal{G} . There can be two reasons why π is blocked in $\mathcal{G}_{\mathbf{X}\mathbf{Y}}^{pbd}$: (1) The path starts with an edge $X \rightarrow D$ that does not exist in $\mathcal{G}_{\mathbf{X}\mathbf{Y}}^{pbd}$. Then we have $D \in PCP(\mathbf{X}, \mathbf{Y})$. For π to be non-causal, it would have to contain a collider $C \in An(\mathbf{Z}) \cap De(D) \subseteq An(\mathbf{Z}) \cap Dpcp(\mathbf{X}, \mathbf{Y})$. But because of (a), $An(\mathbf{Z}) \cap Dpcp(\mathbf{X}, \mathbf{Y})$ is empty. (2) A collider C on π is an ancestor

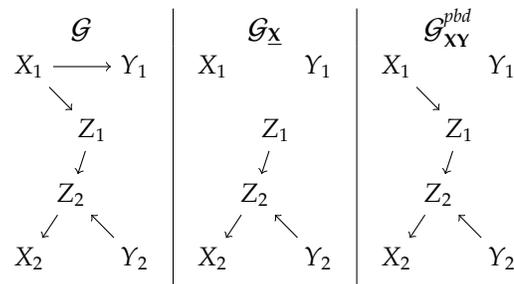

Figure 2: A DAG where for $\mathbf{X} = \{X_1, X_2\}$ and $\mathbf{Y} = \{Y_1, Y_2\}$, $\mathbf{Z} = \{Z_1, Z_2\}$ is a valid and minimal adjustment, but no set fulfills the back-door criterion (Pearl, 2009), and the parents of \mathbf{X} are not a valid adjustment set either.

of \mathbf{Z} in \mathcal{G} , but not in $\mathcal{G}_{\mathbf{X}\mathbf{Y}}^{pbd}$. Then there must be a directed path from C to \mathbf{Z} via an edge $X \rightarrow D$ with $D \in An(\mathbf{Z}) \cap PCP(\mathbf{X}, \mathbf{Y})$, contradicting (a). \square

4.2 ADJUSTING FOR MULTIPLE EXPOSURES

For a singleton set $\mathbf{X} = \{X\}$ of exposures we know that if a set of variables \mathbf{Y} is disjoint from $\{X\} \cup Pa(X)$ then one obtains easily an adjustment set with respect to X and \mathbf{Y} as $\mathbf{Z} = Pa(X)$ (Pearl, 2009, Theorem 3.2.2). The situation changes drastically if the effect of multiple exposures is estimated. Theorem 3.2.5 in Pearl (2009) claims that the expression for $P(\mathbf{y} \mid do(\mathbf{x}))$ is obtained by adjusting for $Pa(\mathbf{X})$ if \mathbf{Y} is disjoint from $\mathbf{X} \cup Pa(\mathbf{X})$, but, as the DAG in Fig. 2 shows, this is not true: the set $\mathbf{Z} = Pa(X_1, X_2) = \{Z_2\}$ is not an adjustment set according to $\{X_1, X_2\}$ and \mathbf{Y} . In this case one can identify the causal effect by adjusting for $\mathbf{Z} = \{Z_1, Z_2\}$ only. Indeed, for more than one exposure, no adjustment set may exist at all even without latent covariates and even though $\mathbf{Y} \cap (\mathbf{X} \cup Pa(\mathbf{X})) = \emptyset$, e.g. in the DAG

$$X_1 \overleftarrow{X_2} \overleftrightarrow{Z} \longleftarrow Y.$$

Using our criterion, we can construct a simple adjustment set explicitly if one exists. For a DAG $\mathcal{G} = (\mathbf{V}, \mathbf{E})$ we define the set

$$Adj(\mathbf{X}, \mathbf{Y}) = An(\mathbf{X}, \mathbf{Y}) \setminus (\mathbf{X} \cup \mathbf{Y} \cup Dpcp(\mathbf{X}, \mathbf{Y})).$$

Theorem 4.6. Let $\mathcal{G} = (\mathbf{V}, \mathbf{E})$ be a DAG and let $\mathbf{X}, \mathbf{Y} \subseteq \mathbf{V}$ be distinct node sets. Then the following statements are equivalent:

1. There exists an adjustment in \mathcal{G} w.r.t. \mathbf{X} and \mathbf{Y} .
2. $Adj(\mathbf{X}, \mathbf{Y})$ is an adjustment w.r.t. \mathbf{X} and \mathbf{Y} .
3. $Adj(\mathbf{X}, \mathbf{Y})$ d -separates \mathbf{X} and \mathbf{Y} in the proper back-door graph $\mathcal{G}_{\mathbf{X}\mathbf{Y}}^{pbd}$.

Proof. The implication (3) \Rightarrow (2) follows directly from the criterion Def. 4.4 and the definition of $Adj(\mathbf{X}, \mathbf{Y})$. Since

the implication (2) \Rightarrow (1) is obvious, it remains to prove (1) \Rightarrow (3).

Assume there exists an adjustment set \mathbf{Z}_0 w.r.t. \mathbf{X} and \mathbf{Y} . From Theorem 4.5 we know that $\mathbf{Z}_0 \cap Dpcp(\mathbf{X}, \mathbf{Y}) = \emptyset$ and that \mathbf{Z}_0 d -separates \mathbf{X} and \mathbf{Y} in $\mathcal{G}_{\mathbf{X}\mathbf{Y}}^{pbd}$. Our task is to show that $Adj(\mathbf{X}, \mathbf{Y})$ d -separates \mathbf{X} and \mathbf{Y} in $\mathcal{G}_{\mathbf{X}\mathbf{Y}}^{pbd}$. This follows from Lemma 3.4 used for the proper back-door graph $\mathcal{G}_{\mathbf{X}\mathbf{Y}}^{pbd}$ if we take $\mathbf{I} = \emptyset$, $\mathbf{R} = \mathbf{V} \setminus (\mathbf{X} \cup \mathbf{Y} \cup Dpcp(\mathbf{X}, \mathbf{Y}))$. \square

From Equation 1 and the definition $Dpcp(\mathbf{X}, \mathbf{Y}) = De(PCP(\mathbf{X}, \mathbf{Y}))$ we then obtain immediately:

Corollary 4.7. *Given two distinct sets $\mathbf{X}, \mathbf{Y} \subseteq \mathbf{V}$, $Adj(\mathbf{X}, \mathbf{Y})$ can be found in $O(n + m)$ time.*

4.3 TESTING, COMPUTING, AND ENUMERATING ADJUSTMENT SETS

Using our criterion, every algorithm for m -separating sets \mathbf{Z} between \mathbf{X} and \mathbf{Y} can be used for adjustment sets with respect to \mathbf{X} and \mathbf{Y} , by requiring that \mathbf{Z} not contain any node in $Dpcp(\mathbf{X}, \mathbf{Y})$. This allows solving all problems listed in Table 1 for adjustment sets in DAGs instead of m -separators. Below, we name those problems analogously as for m -separation, e.g. the problem to decide whether \mathbf{Z} is an adjustment set w.r.t. \mathbf{X}, \mathbf{Y} is named TESTADJ in analogy to TESTSEP.

TESTADJ can be solved by testing if $\mathbf{Z} \cap Dpcp(\mathbf{X}, \mathbf{Y}) = \emptyset$ and \mathbf{Z} is a d -separator in the proper back-door graph $\mathcal{G}_{\mathbf{X}\mathbf{Y}}^{pbd}$. Since $\mathcal{G}_{\mathbf{X}\mathbf{Y}}^{pbd}$ can be constructed from \mathcal{G} in linear time, the total time complexity of this algorithm is $O(n + m)$.

TESTMINADJ can be solved with an algorithm that iteratively removes nodes from \mathbf{Z} and tests if the resulting set remains an adjustment set w.r.t. \mathbf{X} and \mathbf{Y} . This can be done in time $O(n(n + m))$. Alternatively, one can construct the proper back-door graph $\mathcal{G}_{\mathbf{X}\mathbf{Y}}^{pbd}$ from \mathcal{G} and test if \mathbf{Z} is a minimal d -separator, with $\mathbf{Z} \subseteq \mathbf{V} \setminus Dpcp(\mathbf{X}, \mathbf{Y})$ between \mathbf{X} and \mathbf{Y} . This can be computed in time $O(n^2)$. The correctness of these algorithms follows from the proposition below, which is a generalization of the result in Tian et al. (1998).

Proposition 4.8. *If no single node Z can be removed from an adjustment set \mathbf{Z} such that the resulting set $\mathbf{Z}' = \mathbf{Z} \setminus Z$ is no longer an adjustment set, then \mathbf{Z} is minimal.*

The remaining problems like FINDADJ, FINDMINADJ etc. can be solved using corresponding algorithms for finding, resp. listing m -separations applied for proper back-door graphs. Since the proper back-door graph can be constructed in linear time the time complexities to solve the problems above are as listed in Table 1.

5 ADJUSTMENT IN MAGS

We now generalize the results from the previous section to MAGs. Two examples may illustrate why this generalization is not trivial. First, take $\mathcal{G} = X \rightarrow Y$. If \mathcal{G} is interpreted as a DAG, then the empty set is valid for adjustment. If \mathcal{G} is however taken as a MAG, then there exists no adjustment set as \mathcal{G} represents among others the DAG $U \rightarrow X \rightarrow Y$ where U is an unobserved confounder. Second, take $\mathcal{G} = A \rightarrow X \rightarrow Y$. In that case, the empty set is an adjustment set regardless of whether \mathcal{G} is interpreted as a DAG or a MAG. The reasons will become clear as we move on. First, let us recall the semantics of a MAG. The following definition can easily be given for AGs in general, but we do not need this generality for our purpose.

Definition 5.1 (DAG representation by MAGs (Richardson and Spirtes, 2002)). *Let $\mathcal{G} = (\mathbf{V}, \mathbf{E})$ be a DAG, and let $\mathbf{S}, \mathbf{L} \subseteq \mathbf{V}$. The MAG $\mathcal{M} = \mathcal{G}_{\mathbf{S}}^{\mathbf{L}}$ is a graph with nodes $\mathbf{V} \setminus (\mathbf{S} \cup \mathbf{L})$ and defined as follows. (1) Two nodes U and V are adjacent in $\mathcal{G}_{\mathbf{S}}^{\mathbf{L}}$ if they cannot be m -separated by any \mathbf{Z} with $\mathbf{S} \subseteq \mathbf{Z} \subseteq \mathbf{V} \setminus \mathbf{L}$ in \mathcal{G} . (2) The edge between U and V is*

$$U - V \text{ if } U \in An(\mathbf{S} \cup V) \text{ and } V \in An(\mathbf{S} \cup U);$$

$$U \rightarrow V \text{ if } U \in An(\mathbf{S} \cup V) \text{ and } V \notin An(\mathbf{S} \cup U);$$

$$U \leftrightarrow V \text{ if } U \notin An(\mathbf{S} \cup V) \text{ and } V \notin An(\mathbf{S} \cup U).$$

We call \mathbf{L} latent variables and \mathbf{S} selection variables. We say there is selection bias if $\mathbf{S} \neq \emptyset$.

Hence, every MAG represents an infinite set of underlying DAGs that all share the same ancestral relationships. For a given MAG \mathcal{M} , we can construct a represented DAG \mathcal{G} by replacing every edge $X - Y$ by a path $X \rightarrow S \leftarrow Y$, and every edge $X \leftrightarrow Y$ by $X \leftarrow L \rightarrow Y$, where S and L are new nodes; then $\mathcal{M} = \mathcal{G}_{\mathbf{S}}^{\mathbf{L}}$ where \mathbf{S} and \mathbf{L} are all new nodes. \mathcal{G} is called the *canonical DAG* of \mathcal{M} (Richardson and Spirtes, 2002), which we write as $C(\mathcal{M})$.

Lemma 5.2 (Preservation of separating sets (Richardson and Spirtes, 2002)). *\mathbf{Z} m -separates \mathbf{X}, \mathbf{Y} in $\mathcal{G}_{\mathbf{S}}^{\mathbf{L}}$ if and only if $\mathbf{Z} \cup \mathbf{S}$ m -separates \mathbf{X}, \mathbf{Y} in \mathcal{G} .*

We now extend the concept of adjustment to MAGs in the usual way (Maathuis and Colombo, 2013).

Definition 5.3 (Adjustment in MAGs). *Given a MAG $\mathcal{M} = (\mathbf{V}, \mathbf{E})$ and two variable sets $\mathbf{X}, \mathbf{Y} \subseteq \mathbf{V}$, $\mathbf{Z} \subseteq \mathbf{V}$ is an adjustment set for \mathbf{X}, \mathbf{Y} in \mathcal{M} if for every probability distribution $p(\mathbf{v}')$ consistent with a DAG $\mathcal{G} = (\mathbf{V}', \mathbf{E}')$ for which $\mathcal{G}_{\mathbf{S}}^{\mathbf{L}} = \mathcal{M}$, for some $\mathbf{S}, \mathbf{L} \subseteq \mathbf{V}' \setminus \mathbf{V}$, we have*

$$p(\mathbf{y} \mid do(\mathbf{x})) = \sum_{\mathbf{z}} p(\mathbf{y} \mid \mathbf{x}, \mathbf{z}, \mathbf{s}) p(\mathbf{z} \mid \mathbf{s}). \quad (2)$$

Selection bias (i.e., $\mathbf{S} \neq \emptyset$) substantially complicates adjustment, and in fact nonparametric causal inference in general (Zhang, 2008)⁴. Due to these limitations, we restrict ourselves to the case $\mathbf{S} = \emptyset$ in the rest of this section. Note however that recovery from selection bias is sometimes possible with additional population data, and graphical conditions exist to identify such cases (Barenboim et al., 2014).

5.1 ADJUSTMENT AMENABILITY

In this section we first identify a class of MAGs in which adjustment is impossible because of causal ambiguities – e.g., the simple MAG $X \rightarrow Y$ falls into this class, but the larger MAG $A \rightarrow X \rightarrow Y$ does not.

Definition 5.4 (Visible edge (Zhang, 2008)). *Given a MAG $\mathcal{M} = (\mathbf{V}, \mathbf{E})$, an edge $X \rightarrow Y \in \mathbf{E}$ is called visible if in all DAGs $\mathcal{G} = (\mathbf{V}', \mathbf{E}')$ with $\mathcal{G}_{\mathbf{S}}^{\mathbf{L}} = \mathcal{M}$ for some $\mathbf{S}, \mathbf{L} \subseteq \mathbf{V}'$, all d -connected walks between X and Y in \mathcal{G} that contain only nodes of $\mathbf{S} \cup \mathbf{L} \cup X \cup Y$ are directed paths.*

Intuitively, an invisible directed edge $X \rightarrow Y$ means that there may still hidden confounding factors between X and Y , which is guaranteed not to be the case if the edge is visible.

Lemma 5.5 (Graphical conditions for edge visibility (Zhang, 2008)). *In a MAG $\mathcal{M} = (\mathbf{V}, \mathbf{E})$, an edge $X \rightarrow Y$ is visible if and only if there is a node A not adjacent to Y where (1) $A \rightarrow X \in \mathbf{E}$ or $A \leftrightarrow X \in \mathbf{E}$, or (2) there is a collider path $A \leftrightarrow V_1 \leftrightarrow \dots \leftrightarrow V_n \leftrightarrow X$ or $A \rightarrow V_1 \leftrightarrow \dots \leftrightarrow V_n \leftrightarrow X$ where all V_i are parents of Y .*

Definition 5.6. *We call a MAG $\mathcal{M} = (\mathbf{V}, \mathbf{E})$ adjustment amenable w.r.t. $\mathbf{X}, \mathbf{Y} \subseteq \mathbf{V}$ if all proper causal paths from \mathbf{X} to \mathbf{Y} start with a visible directed edge.*

Lemma 5.7. *If a MAG $\mathcal{M} = (\mathbf{V}, \mathbf{E})$ is not adjustment amenable w.r.t. $\mathbf{X}, \mathbf{Y} \subseteq \mathbf{V}$ then there exists no adjustment set \mathbf{W} for \mathbf{X}, \mathbf{Y} in \mathcal{M} .*

Proof. If the first edge $X \rightarrow D$ on some causal path to \mathbf{Y} in \mathcal{M} is not visible, then there exists a consistent DAG \mathcal{G} where there is a non-causal path between X and \mathbf{Y} via V that could only be blocked in \mathcal{M} by conditioning on D or some of its descendants. But such conditioning would violate the adjustment criterion in \mathcal{G} . \square

5.2 ADJUSTMENT CRITERION FOR MAGS

We now show that DAG adjustment criterion generalizes to adjustment amenable MAGs. The adjustment criterion and

⁴A counterexample is the graph $A \leftarrow X \rightarrow Y$, where we can safely assume that A is the ancestor of a selection variable. A sufficient and necessary condition for adjustment under selection bias is $\mathbf{Y} \perp\!\!\!\perp \mathbf{S} \mid \mathbf{X}$ (Barenboim et al., 2014), which is so restrictive that most statisticians would probably not even speak of “selection bias” anymore in such a case.

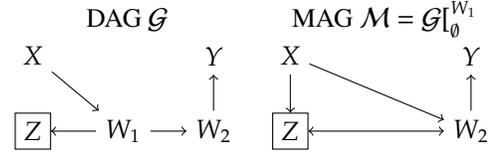

Figure 3: Illustration of the case in the proof of Theorem 5.8 where Z descends from W_1 which in a DAG \mathcal{G} is on a proper causal path from X to Y , but is not a descendant of a node on a proper causal path from X to Y in the MAG \mathcal{M} after marginalizing W_1 . In such cases, conditioning on Z will m -connect X and Y in \mathcal{M} via a proper non-causal path.

the constructive back-door criterion are defined like their DAG counterparts (Definitions 4.2 and 4.3), replacing d - with m -separation for the latter.

Theorem 5.8. *Given an adjustment amenable MAG $\mathcal{M} = (\mathbf{V}, \mathbf{E})$ and three disjoint node sets $\mathbf{X}, \mathbf{Y}, \mathbf{Z} \subseteq \mathbf{V}$, the following statements are equivalent:*

- (i) \mathbf{Z} is an adjustment relative to \mathbf{X}, \mathbf{Y} in \mathcal{M} .
- (ii) \mathbf{Z} fulfills the adjustment criterion (AC) w.r.t. (\mathbf{X}, \mathbf{Y}) in \mathcal{M} .
- (iii) \mathbf{Z} fulfills the constructive backdoor criterion (CBC) w.r.t. (\mathbf{X}, \mathbf{Y}) in \mathcal{M} .

Proof. The equivalence of (ii) and (iii) is established by observing that the proof of Theorem 4.5 generalizes to m -separation. Below we establish equivalence of (i) and (ii).

$\neg(ii) \Rightarrow \neg(i)$: If \mathbf{Z} violates the adjustment criterion in \mathcal{M} , it does so in the canonical DAG $\mathcal{C}(\mathcal{M})$, and thus is not an adjustment in \mathcal{M} .

$\neg(i) \Rightarrow \neg(ii)$: Let \mathcal{G} be a DAG with $\mathcal{G}_{\mathbf{L}_0}^{\mathbf{W}_1} = \mathcal{M}$ in which \mathbf{Z} violates the AC. We show that (a) if $\mathbf{Z} \cap Dpcp(\mathbf{X}, \mathbf{Y}) \neq \emptyset$ in \mathcal{G} then $\mathbf{Z} \cap Dpcp(\mathbf{X}, \mathbf{Y}) \neq \emptyset$ in \mathcal{M} as well, or there exists a proper non-causal path in \mathcal{M} that cannot be m -separated; and (b) if $\mathbf{Z} \cap Dpcp(\mathbf{X}, \mathbf{Y}) = \emptyset$ in \mathcal{G} and \mathbf{Z} d -connects a proper non-causal walk in \mathcal{G} , then it m -connects a proper non-causal walk in \mathcal{M} .

(a) Suppose that in \mathcal{G} , \mathbf{Z} contains a node Z in $Dpcp(\mathbf{X}, \mathbf{Y})$, and let $\mathbf{W} = PCP(\mathbf{X}, \mathbf{Y}) \cap An(Z)$. If \mathcal{M} still contains at least one node $W_1 \in \mathbf{W}$, then W_1 lies on a proper causal path in \mathcal{M} and Z is a descendant of W_1 in \mathcal{M} . Otherwise, \mathcal{M} must contain a node $W_2 \in PCP_{\mathcal{G}}(\mathbf{X}, \mathbf{Y}) \setminus An(Z)$ (possibly $W_2 \in \mathbf{Y}$) such that $W_2 \leftrightarrow A$, $X \rightarrow W_2$, and $X \rightarrow A$ are edges in \mathcal{M} , where $A \in An(Z)$ (possibly $A = Z$; see Fig. 3). Then \mathcal{M} contains an m -connected proper non-causal path $X \rightarrow A \leftrightarrow W \rightarrow W_2 \rightarrow \dots \rightarrow \mathbf{Y}$.

(b) Suppose that in \mathcal{G} , $\mathbf{Z} \cap Dpcp(\mathbf{X}, \mathbf{Y}) = \emptyset$, and there exists an open proper non-causal path from \mathbf{X} to \mathbf{Y} . Then there

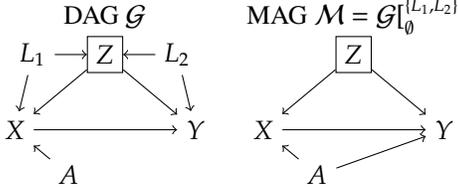

Figure 4: Case (b) in the proof of Theorem 5.8: A proper non-causal path $w_{\mathcal{G}} = X \leftarrow L_1 \rightarrow Z \leftarrow L_2 \rightarrow Y$ in a DAG is d -connected by Z , but the corresponding proper non-causal path $w_{\mathcal{M}} = X \leftarrow Z \rightarrow Y$ is not m -connected in the MAG, and its m -connected subpath $w'_{\mathcal{M}} = X \rightarrow Y$ is proper causal. However, this also renders the edge $X \rightarrow Y$ invisible, because otherwise A could be m -separated from Y by $\mathbf{U} = \{X, Z\}$ in \mathcal{M} but not in \mathcal{G} .

must then also be a proper non-causal walk $w_{\mathcal{G}}$ from some $X \in \mathbf{X}$ to some $Y \in \mathbf{Y}$ (Lemma 7.1), which is d -connected by Z in \mathcal{G} . Let $w_{\mathcal{M}}$ denote the subsequence of $w_{\mathcal{G}}$ formed by nodes in \mathcal{M} , which includes all colliders on $w_{\mathcal{G}}$. The sequence $w_{\mathcal{M}}$ is a path in \mathcal{M} , but is not necessarily m -connected by Z ; all colliders on $w_{\mathcal{M}}$ are in Z because every non- Z must be a parent of at least one of its neighbours, but there can subsequences U, Z_1, \dots, Z_k, V on $w_{\mathcal{M}}$ where all $Z_i \in Z$ but some of the Z_i are not colliders on $w_{\mathcal{M}}$. However, then we can form from $w_{\mathcal{M}}$ an m -connected walk by bypassing some sequences of Z -nodes (Lemma 7.2). Let $w'_{\mathcal{M}}$ be the resulting walk.

If $w'_{\mathcal{M}}$ is a proper non-causal walk, then there must also exist a proper non-causal path in \mathcal{M} (Lemma 7.1), violating the AC. It therefore remains to show that $w'_{\mathcal{M}}$ is not a proper causal path. This must be the case if $w_{\mathcal{G}}$ does not contain colliders, because then the first edge of $w_{\mathcal{M}} = w'_{\mathcal{M}}$ cannot be a visible directed edge out of X . Otherwise, the only way for $w'_{\mathcal{M}}$ to be proper causal is if all Z -nodes in $w_{\mathcal{M}}$ have been bypassed in $w'_{\mathcal{M}}$ by edges pointing away from \mathbf{X} . In that case, one can show by several case distinctions that the first edge $X \rightarrow D$ of $w'_{\mathcal{M}}$, where $D \notin Z$, cannot be visible (see Figure 4 for an example of such a case). \square

5.3 ADJUSTMENT SET CONSTRUCTION

In the previous section, we have already shown that the CBC is equivalent to the AC for MAGs as well; hence, adjustment sets for a given MAG \mathcal{M} can be found by forming the proper back-door graph \mathcal{M}_{XY}^{pbd} and then applying the algorithms from the previous section. In principle, care must be taken when removing edges from MAGs as the result might not be a MAG; however, this is not the case when removing only directed edges.

Lemma 5.9 (Closure of maximality under removal of directed edges). *Given a MAG \mathcal{M} , every graph \mathcal{M}' formed by removing only directed edges from \mathcal{M} is also a MAG.*

Proof. Suppose the converse, i.e. \mathcal{M} is no longer a MAG after removal of some edge $X \rightarrow D$. Then X and D cannot be m -separated even after the edge is removed because X and D are collider connected via a path whose nodes are all ancestors of X or D (Richardson and Spirtes, 2002). The last edge on this path must be $C \leftrightarrow D$ or $C \leftarrow D$, hence $C \notin An(D)$, and thus we must have $C \in An(X)$. But then we get $C \in An(D)$ in \mathcal{M} via the edge $X \rightarrow V$, a contradiction. \square

Corollary 5.10. *For every MAG \mathcal{M} , the proper back-door graph \mathcal{M}_{XY}^{pbd} is also a MAG.*

For MAGs that are not adjustment amenable, the CBC might falsely indicate that an adjustment set exists even though that set may not be valid for some represented graph. Fortunately, adjustment amenability is easily tested using the graphical criteria of Lemma 5.5. For each child D of \mathbf{X} in $Dpcp(\mathbf{X}, \mathbf{Y})$, we can test the visibility of all edges $\mathbf{X} \rightarrow D$ simultaneously using depth first search. This means that we can check all potentially problematic edges in time $O(n + m)$. If all tests pass, we are licensed to apply the CBC, as shown above. Hence, we can solve all algorithmic tasks in Table 1 for MAGs in the same way as for DAGs after an $O(k(n + m))$ check of adjustment amenability, where $k \leq |Ch(\mathbf{X})|$.

6 DISCUSSION

We have compiled efficient algorithms for solving several tasks related to m -separators in ancestral graphs, and applied those together with a new, constructive adjustment criterion to provide a complete and informative answer to the question when, and how, a desired causal effect can be estimated by covariate adjustment. Our results fully generalize to MAGs in the absence of selection bias. One may argue that the MAG result is more useful for exploratory applications (inferring a graph from data) than confirmatory ones (drawing a graph based on theory), as researchers will prefer drawing DAGs instead of MAGs due to the easier causal interpretation of the former. Nevertheless, in such settings the results can provide a means to construct more “robust” adjustment sets: If there are several options for covariate adjustment in a DAG, then one can by interpreting the same graph as a MAG possibly generate an adjustment set that is provably valid for a much larger class of DAGs. This might partially address the typical criticism that complete knowledge of the causal structure is unrealistic.

Our adjustment criterion generalizes the work of Shpitser et al. (2010) to MAGs and therefore now completely characterizes when causal effects are estimable by covariate adjustment in the presence of unmeasured confounders with multivariate exposures and outcomes. This also generalizes recent work by Maathuis and Colombo (2013) who provide a criterion which, for DAGs and MAGs without selection bias, is stronger than the back-door criterion but

weaker than ours. They moreover show their criterion to hold also for CPDAGs and PAGs, which represent equivalence classes of DAGs and MAGs as they are constructed by causal discovery algorithms. It is possible that the constructive back-door criterion could be generalized further to those cases, which we leave for future work.

7 APPENDIX

In this appendix, we prove Lemma 3.4 and two auxiliary Lemmas that are used in the proof of Theorem 5.8.

Proof of Lemma 3.4. Let us consider a proper walk $w = X, V_1, \dots, V_n, Y$ with $X \in \mathbf{X}, Y \in \mathbf{Y}$. If w does not contain a collider, all nodes V_i are in $\text{Ant}(\mathbf{X} \cup \mathbf{Y})$ and the walk is blocked by \mathbf{Z} , unless $\{V_1, \dots, V_n\} \cap \mathbf{R} = \emptyset$ in which case the walk is not blocked by \mathbf{Z}_0 either. If the walk contains colliders \mathbf{C} , it is blocked, unless $\mathbf{C} \subseteq \mathbf{Z} \subseteq \mathbf{R}$. Then all nodes V_i are in $\text{Ant}(\mathbf{X} \cup \mathbf{Y} \cup \mathbf{I})$ and the walk is blocked, unless $\{V_1, \dots, V_n\} \cap \mathbf{R} = \mathbf{C}$. Since $\mathbf{C} \subseteq \mathbf{Z}$ is a set of anteriors, there exists a shortest (possible containing 0 edges) path $\pi_j = V_j \rightarrow \dots \rightarrow W_j$ for each $V_j \in \mathbf{C}$ with $W_j \in \mathbf{X} \cup \mathbf{Y} \cup \mathbf{I}$ (it cannot contain an undirected edge, since there is an arrow pointing to V_j). Let $\pi'_j = V_j \rightarrow \dots \rightarrow W'_j$ be the shortest subpath of π_j that is not blocked by \mathbf{Z}_0 . Let w' be the walk w after replacing each V_j by the walk $V_j \rightarrow \dots \rightarrow W'_j \leftarrow \dots \leftarrow V_j$. If any of the W_j is in $\mathbf{X} \cup \mathbf{Y}$ we truncate the walk, such that we get the shortest walk between nodes of \mathbf{X} and \mathbf{Y} . Since π'_j is not blocked, w' contains no colliders except w'_j and all other nodes of w' are not in \mathbf{R} , w' is not blocked and \mathbf{Z}_0 is not a separator. \square

Lemma 7.1. *Given a DAG \mathcal{G} and sets $\mathbf{X}, \mathbf{Y}, \mathbf{Z} \subseteq \mathbf{V}$ satisfying $\mathbf{Z} \cap \text{Dpcp}(\mathbf{X}, \mathbf{Y}) = \emptyset$, \mathbf{Z} m -connects a proper non-causal path between \mathbf{X} and \mathbf{Y} if and only if it m -connects a proper non-causal walk between \mathbf{X} and \mathbf{Y} .*

Proof. \Leftarrow : Let w be the m -connected proper non-causal walk. It can be transformed to an m -connected path π by removing loops of nodes that are visited multiple times. Since no nodes have been added, π remains proper, and the first edges of π and w are the same. So if w does not start with a \rightarrow edge, π is non-causal. If w starts with an edge $X \rightarrow D$, there exists a collider with a descendant in \mathbf{Z} which is in $\text{De}(D)$. So π has to be non-causal, or it would contradict $\mathbf{Z} \cap \text{Dpcp}(\mathbf{X}, \mathbf{Y}) = \emptyset$.

\Rightarrow : Let π be an m -connected proper non-causal path. It can be changed to an m -connected walk w by inserting $C_i \rightarrow \dots \rightarrow Z_i \leftarrow \dots \leftarrow C_i$ for every collider C_i on π and a corresponding $Z_i \in \mathbf{Z}$. Since no edges are removed from π , w is non-causal, but not necessarily proper, since the inserted walks might contain nodes of \mathbf{X} . However, in that case, w can be truncated to a proper walk w' starting at

the last node of \mathbf{X} on w . Then w' is non-causal, since it contains the subpath $\mathbf{X} \leftarrow \dots \leftarrow C_i$. \square

Lemma 7.2. *Let $\mathcal{G} = (\mathbf{V}, \mathbf{E})$ be a DAG and let $w_{\mathcal{G}}$ be a walk from $X \in \mathbf{V}$ to $Y \in \mathbf{V}$ that is d -connected by $\mathbf{Z} \subseteq \mathbf{V}$. Let $\mathcal{M} = \mathcal{G}_{\mathbf{L}}^{\mathbf{L}}$, where $\mathbf{L} \subseteq \mathbf{V} \setminus (\mathbf{Z} \cup \mathbf{X} \cup \mathbf{Y})$. Let $w_{\mathcal{M}} = V_1, \dots, V_{n+1}$ be the subsequence of $w_{\mathcal{G}}$ consisting only of the nodes in \mathcal{M} . Then \mathbf{Z} m -connects X and Y in \mathcal{M} via a path along a subsequence $w'_{\mathcal{G}}$ formed from $w_{\mathcal{G}}$ by removing some nodes of \mathbf{Z} (possibly $w'_{\mathcal{G}} = w_{\mathcal{G}}$).*

Proof. (Sketch) The subsequences removed from $w_{\mathcal{M}}$ correspond to maximally long inducing walks in $w_{\mathcal{G}}$ with respect to \mathbf{L} . An inducing walk is a collider connected path on which all nodes are ancestors of one of the endpoints, and all non-colliders are in \mathbf{L} . The endpoints of inducing walks with respect to \mathbf{L} must be adjacent to each other in \mathcal{M} (similar to Richardson and Spirtes, 2002, for inducing paths); It is easy to see that all \mathbf{Z} -nodes which are not colliders on $w_{\mathcal{M}}$ can be removed in this way, e.g. $X \leftarrow Z_1 \leftrightarrow Z_2 \rightarrow Y$ can be truncated to X, Y because there must have been an inducing walk in \mathcal{G} via Z_1, Z_2 . Additionally, it can be necessary to remove nodes that are colliders on $w_{\mathcal{M}}$, e.g. if $w_{\mathcal{M}} = X \leftarrow Z_1 \rightarrow Z_2 \leftarrow Y$ and $Z_2 \in \text{An}(X)$, then $w_{\mathcal{G}}$ must have been an inducing walk, and $w'_{\mathcal{M}}$ contains only X and Y even though Z_2 is a collider. To obtain the Lemma, it remains to be shown that no new colliders are created when bypassing nodes in this way. This is done by case distinctions; e.g., in the example $w_{\mathcal{M}} = X \leftarrow Z_1 \rightarrow Z_2 \leftarrow Y$ and $Z_2 \in \text{An}(X)$, we also have $Y \in \text{An}(X)$ and hence $w'_{\mathcal{M}}$ cannot be $X \rightarrow Y$ or $x \leftrightarrow y$. \square

Abstract

This paper studies the problem of revising beliefs using uncertain evidence in a framework where beliefs are represented by a belief function. We introduce two *new* Jeffrey's rules for the revision based on two forms of *belief kinematics*, an evidence-theoretic counterpart of probability kinematics. Furthermore, we provide two distance measures for belief functions and show that the two belief kinematics are optimal in the sense that they minimize their corresponding distance measures.

1 INTRODUCTION

Reasoning about uncertainty is a fundamental issue for Artificial Intelligence [HALPERN, 2005]. Numerous approaches have been proposed, including Dempster-Shafer theory of belief functions [SHAFER, 1976] (also called the theory of evidence or simply *DS* theory). Ever since the pioneering works by Dempster and Shafer, the theory of belief functions has become a powerful formalism in Artificial Intelligence for knowledge representation and decision-making.

In this paper, we study the revision of beliefs using uncertain evidence and we represent beliefs as belief functions. Our main contribution is to introduce two *new* Jeffrey's rules for the revision based on two different forms of *belief kinematics*, an evidence-theoretic counterpart of probability kinematics [JEFFREY, 1983]. The first rule, called *inner* revision, generalizes the geometric conditionalization rule, and the other, *outer* revision, generalizes the Dempster rule of conditioning. These two Jeffrey's rules specify uncertain evidence in terms of the *effect* it has on beliefs once accepted, and the specification is actually a function of both evidence strength and beliefs held prior to obtaining evidence. Once new evidence is accepted, a prior belief function bel on a frame Ω of discernment is revised to a

new posterior belief function bel' on the same frame. This method requires us to specify *uncertain* evidence by providing a belief function bel_e on a coarser frame with less distinctions of the attention. This coarser frame is actually based on a partition of the frame Ω and hence is represented as a subalgebra \mathcal{B} of the powerset 2^Ω of Ω whose atoms forming a partition of Ω .

The principle of belief kinematics on \mathcal{B} says that, although the prior belief function bel and the posterior one bel' may disagree on propositions in \mathcal{B} , they agree on their *relevance* to all propositions in 2^Ω . Providing a reasonable representation of the notion of relevance in belief kinematics is the main challenge in this paper. For each of the two new Jeffrey's rules, we formalize a form of belief kinematics and characterize relevance in this belief kinematics by a *conditional belief function* on Ω with respect to the coarsening frame $\langle \Omega, \mathcal{B} \rangle$. Our definition of conditional belief functions differs from Dempster's rule of conditioning [SHAFER, 1976] in that our definition depends on the coarsening frame $\langle \Omega, \mathcal{B} \rangle$ while Dempster's rule doesn't. Our conditional belief functions are natural generalizations of classical conditional probability functions and provide a measure of the relevance of any proposition in \mathcal{B} to all propositions in 2^Ω .

In this paper, we incorporate the above principle of belief kinematics into the two *new* Jeffrey's rules in the theory of belief functions by satisfying the following constraints:

- (Constraint 1) These two rules should be a natural generalization of Jeffrey's rule in probability theory, i.e., they should be the same as Jeffrey's rule in probability theory when the prior belief function bel is a probability function.
- (Constraint 2) On the coarsening frame $\langle \Omega, \mathcal{B} \rangle$, the posterior belief function bel' according to the rules should agree with the belief function bel_e that specifies the evidence.
- (Constraint 3) The revision rules should obey some natural evidence-theoretic generalization of probabil-

ity kinematics like the above belief kinematics.

Any Jeffrey's rule in *DS* theory should at least meet Constraint 1. Constraint 2 is Smets' distinguishing constraint **C1** [SMETS, 1993A]. Constraint 3 is the most important one and is the key point of this paper. We believe that this constraint for Jeffrey's rule in the theory of evidence is as important as the principle of probability kinematics is for Jeffrey's rule in probability theory. Unlike similar rules for belief functions found in the literature (See Section 5), our new Jeffrey's rules *naturally* transfer important properties of probabilistic belief revisions to the theory of evidence.

In order to show that the above revisions based on belief kinematics are optimal, we provide for each revision rule a distance measure for bounding belief changes due to the revisions and show that the belief function obtained according to the corresponding form of belief kinematics is the closest to the prior one among all belief functions satisfying Constraint 2.

2 JEFFREY'S RULE IN PROBABILITY THEORY

Let Pr be a probability function on a probability space $\langle \Omega, \mathcal{A} \rangle$ where \mathcal{A} is the Boolean algebra of subsets of Ω with the usual set operations. Suppose that new evidence suggests the desirability of revising Pr and that the total evidence determines a family \mathcal{E} of mutually exclusive and exhaustive subsets of Ω and a probability function Pr_e on the Boolean algebra \mathcal{B} of finite unions of elements of \mathcal{E} . Without loss of generality, we assume that $Pr_e(E) > 0$ for all $E \in \mathcal{E}$. The new posterior probability function Pr' on $\langle \Omega, \mathcal{A} \rangle$ proposed by *Jeffrey's rule* is as follows: for any $A \subseteq \Omega$,

$$Pr'(A) = \sum_{E \in \mathcal{E}} Pr(A|E)Pr_e(E) \quad (1)$$

A probability function Pr^* on the probability space $\langle \Omega, 2^\Omega \rangle$ is said to be obtained from Pr by *the principle of probability kinematics* on \mathcal{E} if, for any $E \in \mathcal{E}$,

$$Pr^*(A|E) = Pr(A|E) \text{ for every event } A \subseteq \Omega.$$

In other words, the principle of probability kinematics assumes that the conditional probability in every event A given any $E \in \mathcal{E}$ remains unchanged. This concept was proposed by Jeffrey [JEFFREY, 1983] to capture the notion that, even though Pr^* and Pr disagree on the probabilities of events in the *coarser* Boolean algebra \mathcal{B} , they agree on their *relevance* to every event A in \mathcal{A} .

Actually the above posterior probability function Pr' proposed by Jeffrey's rule in Eq. (1) is the *unique* probability revision Pr^* which satisfies the following two requirements [CHAN AND DARWICHE, 2003]:

- **(C1)**: probability kinematics on \mathcal{E} : for any $E \in \mathcal{B}$, $Pr^*(A|E) = Pr(A|E)$ for all $A \subseteq \Omega$;
- **(C2)**: $Pr^*(E) = Pr_e(E)$ for all $E \in \mathcal{B}$.

A distance measure D can be defined for probability functions as follows [CHAN AND DARWICHE, 2002]: for any two probability functions Pr_1 and Pr_2 ,

$$D(Pr_1, Pr_2) = \ln \max_{\omega \in \Omega} \frac{Pr_2(\omega)}{Pr_1(\omega)} - \ln \min_{\omega \in \Omega} \frac{Pr_2(\omega)}{Pr_1(\omega)}$$

Among all the probability functions that satisfy the above requirement **(C2)**, the posterior probability function Pr' proposed by Jeffrey's rule is the *closest* to Pr according to this distance measure [CHAN AND DARWICHE, 2003].

3 JEFFREY'S RULE IN DEMPSTER-SHAFER THEORY

3.1 BELIEF FUNCTIONS

Let Ω be a frame of discernment and $\mathcal{A} = 2^\Omega$ be the Boolean algebra of events. A *belief function* is a function $bel : \mathcal{A} \rightarrow [0, 1]$ satisfying the following conditions:

1. $bel(\emptyset) = 0$;
2. $bel(\Omega) = 1$; and
3. $bel(\bigcup_{i=1}^n A_i) = \sum_{\emptyset \neq I \subseteq \{1, \dots, n\}} (-1)^{|I|+1} bel(\bigcap_{i \in I} A_i)$ where $A_i \in \mathcal{A}$ for all $i \in \{1, \dots, n\}$.

A *mass assignment* (or *mass function*) is a mapping $m : \mathcal{A} \rightarrow [0, 1]$ satisfying

$$m(\emptyset) = 0, \sum_{A \in \mathcal{A}} m(A) = 1.$$

Shafer [SHAFER, 1976] has shown that a mapping $f : \mathcal{A} \rightarrow [0, 1]$ is a belief function if and only if its Möbius transform is a mass assignment. In other words, if $m : \mathcal{A} \rightarrow [0, 1]$ is a mass assignment, then it determines a belief function $bel : \mathcal{A} \rightarrow [0, 1]$ as follows:

$$bel(A) = \sum_{B \subseteq A} m(B) \text{ for all } A \in \mathcal{A}.$$

Moreover, given a belief function bel , we can obtain its corresponding mass function m as follows:

$$m(A) = \sum_{B \subseteq A} (-1)^{|A \setminus B|} bel(B), \text{ for all } A \in \mathcal{A}.$$

Intuitively, for a subset event A , $m(A)$ measures the belief that an agent commits *exactly* to A , not the total belief that an agent commits to A .

3.2 JEFFREY'S RULE IN THE THEORY OF EVIDENCE

In order to introduce the principle of belief kinematics, we need to set up a setting in terms of *refinements and coarsenings* of frames of discernments. The idea that one frame Ω of discernment is obtained from another frame Θ of discernment by splitting some or all of the elements of Θ may be represented mathematically by specifying, for each $\theta \in \Theta$, the subset $\omega(\{\theta\})$ of Ω consisting of those possibilities into which θ has been split. For this representation to be sensible, we need only require that the sets $\omega(\{\theta\})$ should constitute a disjoint partition of Ω . Given such a disjoint partition $\omega(\{\theta\})$, we may set

$$\omega(A) = \bigcup_{\theta \in A} \omega(\{\theta\})$$

for each $A \subseteq \Theta$; $\omega(A)$ will consist of all the possibilities in Ω that are obtained by splitting the elements of A , and the mapping $\omega : 2^\Theta \rightarrow 2^\Omega$ that is thus defined will provide a thorough description of the splitting. Such a mapping ω is called a *refining*. Whenever $\omega : 2^\Theta \rightarrow 2^\Omega$ is a refining, we call Ω a *refinement* of Θ and Θ a *coarsening* of Ω .

In this paper, we are particularly interested in the case when Θ is the set of equivalence classes with respect to some partition Π of Ω . So the mapping $\omega(\{\Pi(w)\}) = \Pi(w)$ for each $w \in \Omega$ is a refining and Θ is a coarsening of Ω where $\Pi(w)$ is the equivalence class of w . We denote this special coarsening Θ of Ω as Ω/Π . On the other hand, Ω/Π may be regarded as a subalgebra \mathcal{B} of the powerset of Ω with the set of atoms of \mathcal{B} forming the partition Π of Ω . Our following definition of Jeffrey's rules in Dempster-Shafer theory is in terms of this type of presentation of the coarsening Ω/Π as $\langle \Omega, \mathcal{B} \rangle$. For example, $\Pi = \{\{w_1, w_2\}, \{w_3, w_4\}, \{w_5, w_6\}\}$ is a partition of $\Omega = \{w_1, w_2, w_3, w_4, w_5, w_6\}$. Then the associated subalgebra \mathcal{B} consists of the sets $\bigcup_{B \in \Pi} B$ with the atoms $\{w_1, w_2\}$, $\{w_3, w_4\}$ and $\{w_5, w_6\}$ in \mathcal{B} .

For each $A \subseteq \Omega$, we define

$$\mathbf{B}(A) := \bigcap \{B \in \mathcal{B} : A \subseteq B\}$$

In other words, $\mathbf{B}(A)$ is the least element of \mathcal{B} that contains A as a subset and hence is called the *upper approximation* of A in \mathcal{B} [SMETS, 1993A]. For the above example, if $A = \{w_1, w_3, w_5\}$, then $\mathbf{B}(A) = \Omega$.

Let $\langle \Omega, \mathcal{B} \rangle$ be a coarsening of Ω where \mathcal{B} is a subalgebra of the powerset 2^Ω of Ω with its atoms forming a partition of Ω . Suppose that $bel : 2^\Omega \rightarrow [0, 1]$ is a belief function on Ω with m as its corresponding mass assignment. Then the *derived mass assignment* $m_{\mathcal{B}}^{in}$ on the coarsening $\langle \Omega, \mathcal{B} \rangle$ can be obtained through the following formula: for any $B \in \mathcal{B}$,

$$m_{\mathcal{B}}^{in}(B) = \sum_{\mathbf{B}(A)=B, A \subseteq \Omega} m(A)$$

It is easy to see that, in the coarsening frame $\langle \Omega, \mathcal{B} \rangle$, $m_{\mathcal{B}}^{in}(B)$ measures the belief that commits exactly to B , not to any subset of B in \mathcal{B} . Let $bel_{\mathcal{B}}^{in}$ denote the corresponding belief function. It is easy to check that, for any $B \in \mathcal{B}$, $bel_{\mathcal{B}}^{in}(B) = bel(B)$. Intuitively, $bel_{\mathcal{B}}^{in}$ is the derived belief function on the coarsening frame of discernment with less distinctions. The beliefs in the same propositions in these two different frames with different distinctions should be the same as each other [SMETS, 1993B]. Correspondingly, since the resolution degree of the attention of the coarsening frame decreases, the mass assignment m has to change into $m_{\mathcal{B}}^{in}$.

For any A and B such that $A \subseteq B \in \mathcal{B}$ and $A \subseteq \Omega$, let $m_{/B}(A)$ denote $\sum_{E \subseteq B} m(A \cup E)$ and

$$m_{\mathcal{B}}^{out}(B) = \sum_{\mathbf{B}(E)=B, E \subseteq \Omega} m_{/B}(E).$$

It is easy to see that, if B is an atom of the subalgebra \mathcal{B} , then $m_{\mathcal{B}}^{in}(B) = bel(B)$ and $m_{\mathcal{B}}^{out}(B) = pl(B)$. Now we define two different *conditional belief functions* $bel_{\mathcal{B}}^{in}(\cdot|B)$ and $bel_{\mathcal{B}}^{out}(\cdot|B)$ on a given $B \in \mathcal{B}$ according to the above two different definitions of mass functions $m_{\mathcal{B}}^{in}$ and $m_{\mathcal{B}}^{out}$ on \mathcal{B} , respectively: for any $A \subseteq \Omega$,

(1) (Inner conditioning)

$$bel_{\mathcal{B}}^{in}(A|B) := \begin{cases} \frac{\sum_{A' \subseteq A, \mathbf{B}(A')=B} m(A')}{m_{\mathcal{B}}^{in}(B)}, & \text{if } m_{\mathcal{B}}^{in}(B) \neq 0, \\ \frac{|\{A' \subseteq A : \mathbf{B}(A')=B\}|}{|\{A' \subseteq \Omega : \mathbf{B}(A')=B\}|}, & \text{if } m_{\mathcal{B}}^{in}(B) = 0 \end{cases}$$

(2) (Outer conditioning)

$$bel_{\mathcal{B}}^{out}(A|B) := \begin{cases} \frac{\sum_{A' \subseteq A, \mathbf{B}(A')=B} m_{/B}(A')}{m_{\mathcal{B}}^{out}(B)}, & \text{if } m_{\mathcal{B}}^{out}(B) \neq 0, \\ \frac{|\{A' \subseteq A : \mathbf{B}(A' \cap B)=B\}|}{|\{A' \subseteq \Omega : \mathbf{B}(A' \cap B)=B\}|}, & \text{if } m_{\mathcal{B}}^{out}(B) = 0 \end{cases}$$

Note that both $bel_{\mathcal{B}}^{in}(\cdot|B)$ and $bel_{\mathcal{B}}^{out}(\cdot|B)$ are belief functions on 2^Ω for any $B \in \mathcal{B}$.

The superscripts *in* and *out* in the above notations are designated for the following two proposed revision rules: inner revision and outer revision. In particular, when B is an atom in the algebra \mathcal{B} , the above defined $bel_{\mathcal{B}}^{in}(\cdot|B)$ and $bel_{\mathcal{B}}^{out}(\cdot|B)$, are essentially the geometric conditionalization and the Dempster conditionalization of A on B , respectively. However, the essential difference of our above definitions of conditional belief functions from the well-known Dempster's rule of conditioning $bel(\cdot|B)$ [SHAFER, 1976] is that they depend on the coarsening frame and hence on the degree of resolution of the attention while Dempster's rule of conditioning does not and is derived from Dempster's rule of combination. Moreover, Dempster's rule of combination relies on a basic assumption that the combined evidences (or beliefs) play the same

role and hence the combination operation is *symmetric*. In contrast, in our study of revision of beliefs using uncertain evidence, we treat uncertain evidence in terms of *effect* it has on beliefs once accepted, which is a function of both evidence strength and beliefs held before the evidence is obtained. Hence the prior beliefs and uncertain evidence are intrinsically asymmetric. In this sense, our definition is a natural generalization of the classical Bayesian definition of conditional probabilities.

Lemma 3.1 *Let bel be a belief function on Ω with m its corresponding mass assignment and $\langle \Omega, \mathcal{B} \rangle$ a coarsening as above.*

1. *For any $A \subseteq \Omega$,*

$$bel(A) = \sum_{B \in \mathcal{B}} bel_{\mathcal{B}}^{in}(A|B)m_{\mathcal{B}}^{in}(B);$$

2. *If m_e is a mass assignment on $\langle \Omega, \mathcal{B} \rangle$, then the function $bel' : 2^{\Omega} \rightarrow [0, 1]$ defined as follows, for any $A \subseteq \Omega$,*

$$bel'(A) = \sum_{B \in \mathcal{B}} bel_{\mathcal{B}}^{in}(A|B)m_e(B)$$

is a belief function. In particular, for each $B \in \mathcal{B}$,

$$bel'(B) = \sum_{B' \in \mathcal{B}, B' \subseteq B} m_e(B').$$

In other words, if bel_e is the corresponding belief function of m_e on $\langle \Omega, \mathcal{B} \rangle$, then $bel'(B) = bel_e(B)$ for all $B \in \mathcal{B}$; namely, m_e is exactly the derived mass assignment $(m')_{\mathcal{B}}^{in}$ of bel' on the coarsening frame $\langle \Omega, \mathcal{B} \rangle$.

Proof. The first part is obvious. And the second part follows from the following fact: for any $B, B' \in \mathcal{B}$,

$$bel_{\mathcal{B}}^{in}(B'|B) := \begin{cases} 1, & \text{if } B \subseteq B' \\ 0 & \text{otherwise.} \end{cases}$$

QED

Lemma 3.2 *Let bel be a belief function on Ω with m its corresponding mass assignment and $\langle \Omega, \mathcal{B} \rangle$ a coarsening as above. If m_e is a mass assignment on $\langle \Omega, \mathcal{B} \rangle$, then the function $bel' : 2^{\Omega} \rightarrow [0, 1]$ defined as follows, for any $A \subseteq \Omega$,*

$$bel'(A) = \sum_{B \in \mathcal{B}} bel_{\mathcal{B}}^{out}(A|B)m_e(B)$$

is a belief function. In particular, for each $B \in \mathcal{B}$,

$$bel'(B) = \sum_{B' \in \mathcal{B}, B' \subseteq B} m_e(B').$$

In other words, if bel_e is the corresponding belief function of m_e on $\langle \Omega, \mathcal{B} \rangle$, then $bel'(B) = bel_e(B)$ for all $B \in \mathcal{B}$; namely, m_e is exactly the derived mass assignment $(m')_{\mathcal{B}}^{in}$ of bel' on the coarsening frame $\langle \Omega, \mathcal{B} \rangle$.

Proof. The first part is clear and the second follows from the following fact: for any $B, B' \in \mathcal{B}$,

$$bel_{\mathcal{B}}^{out}(B'|B) := \begin{cases} 1, & \text{if } B \subseteq B' \\ 0 & \text{otherwise.} \end{cases}$$

QED

Consider the problem of revising the belief function bel given uncertain evidence relating to a coarsening of Ω , which is represented as $\langle \Omega, \mathcal{B} \rangle$. One method of specifying the uncertain evidence is through the *effect* that it would have on beliefs once accepted. Specifically, according to the method, we have to specify uncertain evidence by providing the following constraint:

$$m'(B) = q_B, \text{ for each } B \in \mathcal{B} \quad (2)$$

where m' denotes the corresponding mass assignment of the new belief function bel' that results from accepting the given evidence. Also the specification can be represented as another belief function bel_e on $\langle \Omega, \mathcal{B} \rangle$ with m_e its corresponding mass assignment such that $m_e(B) = q_B$ for all $B \in \mathcal{B}$. To revise the belief function bel , we must therefore choose a *unique posterior* belief function that satisfies the above constraint. In order to achieve the uniqueness, we define next two forms of *belief kinematics*, the evidence-theoretic counterpart of the well-known probability kinematics [JEFFREY, 1983].

Definition 3.3 Suppose that bel and bel' are two belief functions on Ω , and m and m' are their corresponding mass assignments. Let $\langle \Omega, \mathcal{B} \rangle$ be a coarsening of Ω . The belief function bel' is said to be obtained from bel by *inner belief kinematics* on $\langle \Omega, \mathcal{B} \rangle$ if, for any $B \in \mathcal{B}$,

$$(bel')_{\mathcal{B}}^{in}(A|B) = bel_{\mathcal{B}}^{in}(A|B) \text{ for all } A \subseteq \Omega; \quad (3)$$

and it is said to be obtained from bel by *outer belief kinematics* on $\langle \Omega, \mathcal{B} \rangle$ if, for any $B \in \mathcal{B}$,

$$(bel')_{\mathcal{B}}^{in}(A|B) = bel_{\mathcal{B}}^{out}(A|B) \text{ for all } A \subseteq \Omega. \quad (4)$$

◁

Intuitively, the above principle of belief kinematics on $\langle \Omega, \mathcal{B} \rangle$ says that, even though bel and bel' may disagree on propositions on $\langle \Omega, \mathcal{B} \rangle$, they agree on their relevance to every event $A \subseteq \Omega$.

Now we define two revisions proposed by *Jeffrey's rule* as follows: for any $A \subseteq \Omega$,

$$1. \ bel'(A) = \sum_{B \in \mathcal{B}} bel_{\mathcal{B}}^{in}(A|B)q_B; \text{ and}$$

$$2. \ bel'(A) = \sum_{B \in \mathcal{B}} bel_{\mathcal{B}}^{out}(A|B)q_B$$

According to Lemmas 3.1 and 3.2, both revisions satisfy the above constraint (2), and are indeed belief functions. These two revisions are called *inner and outer revisions* and the resulting belief functions are denoted as $bel^{in'}$ and $bel^{out'}$ by adding the corresponding superscripts *in* and *out*, respectively. It is easy to see that the well-known Jeffrey's rule for probability functions is a special case of our more general rules here for belief functions. So, our Jeffrey's rules satisfy Constraint 1.

Theorem 3.4 *The new belief function $bel^{in'}$ given above is the one and only belief function that satisfies the constraint in Eq. (2) and that is obtained from bel by inner belief kinematics on the coarsening frame $\langle \Omega, \mathcal{B} \rangle$.*

Proof. According to Lemma 3.1, it suffices to show that the new posterior belief function $bel^{in'}$ obtained through Jeffrey's rule satisfies the condition for inner belief kinematics: for any $A \subseteq \Omega, B \in \mathcal{B}$,

$$bel_B^{in'}(A|B) = (bel^{in'})_B^{in}(A|B)$$

First note that, for any $A \subseteq \Omega$,

$$m^{in'}(A) = \sum_{B \in \mathcal{B}} \frac{q_B}{m_B^{in}(B)} l_B^{in}(A)$$

where $m^{in'}$ is the corresponding mass function of $bel^{in'}$ and

$$l_B^{in}(A) := \begin{cases} m(A), & \text{if } \mathbf{B}(A) = B \\ 0 & \text{otherwise.} \end{cases}$$

This follows directly from the following reasoning:

$$\begin{aligned} \sum_{A' \subseteq A} m^{in'}(A') &= \sum_{A' \subseteq A} \left(\sum_{B \in \mathcal{B}} \frac{q_B}{m_B^{in}(B)} l_B^{in}(A') \right) \\ &= \sum_{B \in \mathcal{B}} \left(\sum_{A' \subseteq A} \frac{q_B}{m_B^{in}(B)} l_B^{in}(A') \right) \\ &= \sum_{B \in \mathcal{B}} \left(\frac{\sum_{A' \subseteq A} l_B^{in}(A')}{m_B^{in}(B)} q_B \right) \\ &= \sum_{B \in \mathcal{B}} \left(\frac{\sum_{A' \subseteq A, \mathbf{B}(A')=B} m(A')}{m_B^{in}(B)} q_B \right) \\ &= \sum_{B \in \mathcal{B}} bel_B^{in'}(A|B) q_B \\ &= bel^{in'}(A) \end{aligned}$$

According to Lemma 3.1, $(m^{in'})_B^{in}(B) = \sum_{\mathbf{B}(A)=B, A \subseteq \Omega} m^{in'}(A) = q_B$ where $(m^{in'})_B^{in}$ is the derived mass assignment of $m^{in'}$ on $\langle \Omega, \mathcal{B} \rangle$. Next we use

this expression of $m^{in'}$ to proceed as follows:

$$\begin{aligned} (bel^{in'})_B^{in}(A|B) &= \frac{1}{q_B} \sum_{A' \subseteq A, \mathbf{B}(A')=B} m^{in'}(A') \\ &= \frac{1}{q_B} \sum_{A' \subseteq A, \mathbf{B}(A')=B} \sum_{B' \in \mathcal{B}} \frac{q_{B'} l_{B'}^{in}(A')}{m_{B'}^{in}(B')} \\ &= \frac{1}{q_B} \sum_{A' \subseteq A, \mathbf{B}(A')=B} \frac{q_B}{m_B^{in}(B)} m(A') \\ &= \frac{\sum_{A' \subseteq A, \mathbf{B}(A')=B} m(A')}{m_B^{in}(B)} \\ &= bel_B^{in'}(A|B) \end{aligned}$$

QED

Theorem 3.5 *The new belief function $bel^{out'}$ given above is the one and only belief function that satisfies the constraint in Eq. (2) and that is obtained from bel by outer belief kinematics on the coarsening frame $\langle \Omega, \mathcal{B} \rangle$.*

Proof. According to Part (1) of Lemma 3.1 and Lemma 3.2, it suffices to show that the new posterior belief function obtained through Jeffrey's rule satisfies the condition in outer belief kinematics, i.e., for any $B \in \mathcal{B}$,

$$(bel^{out'})_B^{in}(A|B) = bel_B^{out'}(A|B) \text{ for all } A \subseteq \Omega.$$

But this follows from a similar argument to that in the proof of Theorem 3.4.

QED

The above propositions tell us that the two Jeffrey's rules are obtained from belief kinematics and hence satisfies Constraint 3.

Example 3.6 The following example is adapted from the original one by Jeffrey [JEFFREY, 1983] (also [CHAN AND DARWICHE, 2003]). Assume that we are given a piece of cloth, where its color can be one of: green, blue, or violet. We want to know whether, on the next day, the cloth will be sold, or not sold. We denote the possible states as follows:

$$\begin{aligned} w_{1,g} &= (\text{sold}, \text{green}), & w_{0,g} &= (\text{not sold}, \text{green}) \\ w_{1,b} &= (\text{sold}, \text{blue}), & w_{0,b} &= (\text{not sold}, \text{blue}) \\ w_{1,v} &= (\text{sold}, \text{violet}), & w_{0,v} &= (\text{not sold}, \text{violet}) \end{aligned}$$

Our original belief bel is given by the following mass assignment m on $\Omega := \{w_{n,c} : n \in \{0, 1\}, c \in \{b, g, v\}\}$:

$$\begin{aligned} m(\{w_{1,g}\}) &= m(\{w_{1,b}\}) = m(\{w_{1,v}\}) = 0.1 \\ m(\{w_{0,g}\}) &= m(\{w_{0,b}\}) = m(\{w_{0,v}\}) = 0.15 \\ m(\{w_{1,g}, w_{0,b}\}) &= m(\{w_{1,b}, w_{0,v}\}) = 0.1 \\ m(\{w_{1,g}, w_{1,v}\}) &= 0.05 \end{aligned}$$

The possible states w_c of colors denote $\{w_{1,c}, w_{0,c}\}$ for all $c \in \{g, v, b\}$. Let \mathcal{B} be a subalgebra of the powerset of Ω that consists of the propositions of the form $\bigcup_{B \subseteq \{w_b, w_g, w_v\}} B$. It is easy to see that $\langle \Omega, \mathcal{B} \rangle$ is a coarsening of $\langle \Omega, 2^\Omega \rangle$.

The derived mass assignment $m_{\mathcal{B}}^{in}$ on the coarsening frame $\langle \Omega, \mathcal{B} \rangle$ can be computed as follows:

$$\begin{aligned} m_{\mathcal{B}}^{in}(\{w_g\}) &= m_{\mathcal{B}}^{in}(\{w_b\}) = m_{\mathcal{B}}^{in}(\{w_v\}) = 0.25 \\ m_{\mathcal{B}}^{in}(\{w_g, w_b\}) &= m_{\mathcal{B}}^{in}(\{w_b, w_v\}) = 0.1 \\ m_{\mathcal{B}}^{in}(\{w_g, w_v\}) &= 0.05, \quad m_{\mathcal{B}}^{in}(\{w_b, w_g, w_v\}) = 0 \end{aligned}$$

Now we consider the conditional beliefs of a given proposition $A := \{w_{1,g}, w_{0,b}, w_{1,v}\}$ as an illustration. We obtain $bel(A) = 0.5$. According to our previous definition of inner conditioning, we have

$$\begin{aligned} bel_{\mathcal{B}}^{in}(A|\{w_g\}) &= \frac{2}{5}, & bel_{\mathcal{B}}^{in}(A|\{w_b\}) &= \frac{3}{5} \\ bel_{\mathcal{B}}^{in}(A|\{w_v\}) &= \frac{2}{5}, & bel_{\mathcal{B}}^{in}(A|\{w_g, w_b\}) &= 1 \\ bel_{\mathcal{B}}^{in}(A|\{w_g, w_v\}) &= 1, & bel_{\mathcal{B}}^{in}(A|\{w_b, w_v\}) &= 0 \\ bel_{\mathcal{B}}^{in}(A|\{w_b, w_v, w_g\}) &= \frac{1}{27} \end{aligned}$$

Assume that we now inspect the cloth by candlelight, and conclude that our belief on the color of the cloth should be:

$$\begin{aligned} bel_e(\{w_g\}) &= bel_e(\{w_b\}) = bel_e(\{w_v\}) = 0.2 \\ bel_e(\{w_g, w_b\}) &= bel_e(\{w_b, w_v\}) = 0.5 \\ bel_e(\{w_g, w_v\}) &= 0.6 \end{aligned}$$

The corresponding mass assignment m_e is as follows:

$$\begin{aligned} m_e(\{w_g\}) &= m_e(\{w_b\}) = m_e(\{w_v\}) = 0.2 \\ m_e(\{w_g, w_b\}) &= m_e(\{w_b, w_v\}) = 0.1 \\ m_e(\{w_g, w_v\}) &= 0.2 \end{aligned}$$

So, according to our definition of Jeffrey's rule, we have the new inner revision of belief in the event A :

$$bel^{in'}(A) = \sum_{B \in \mathcal{B}} bel_{\mathcal{B}}^{in}(A|B)m_e(B) = 0.58$$

Now we compute the outer revision of the belief in A . The mass assignment $m_{\mathcal{B}}^{out}$ on the coarsening frame $\langle \Omega, \mathcal{B} \rangle$ can be computed as follows:

$$\begin{aligned} m_{\mathcal{B}}^{out}(\{w_g\}) &= 0.4 = m_{\mathcal{B}}^{out}(\{w_v\}), m_{\mathcal{B}}^{out}(\{w_b\}) = 0.45 \\ m_{\mathcal{B}}^{out}(\{w_g, w_b\}) &= 0.1 = m_{\mathcal{B}}^{out}(\{w_b, w_v\}) \\ m_{\mathcal{B}}^{out}(\{w_g, w_v\}) &= 0.05, \quad m_{\mathcal{B}}^{out}(\{w_b, w_g, w_v\}) = 0 \end{aligned}$$

According to our previous definition of outer conditioning,

we have

$$\begin{aligned} bel_{\mathcal{B}}^{out}(A|\{w_g\}) &= \frac{1}{4}, bel_{\mathcal{B}}^{out}(A|\{w_b\}) = \frac{2}{9} \\ bel_{\mathcal{B}}^{out}(A|\{w_v\}) &= \frac{1}{8}, bel_{\mathcal{B}}^{out}(A|\{w_g, w_b\}) = 1 \\ bel_{\mathcal{B}}^{out}(A|\{w_g, w_v\}) &= 1, bel_{\mathcal{B}}^{out}(A|\{w_b, w_v\}) = 0 \\ bel_{\mathcal{B}}^{out}(A|\{w_b, w_v, w_g\}) &= \frac{1}{27} \end{aligned}$$

Hence we have

$$bel^{out'}(A) = \sum_{B \in \mathcal{B}} bel_{\mathcal{B}}^{out}(A|B)m_e(B) = \frac{151}{360}$$

4 MEASURES FOR BOUNDING BELIEF CHANGES

One important question relating to belief revision is that of measuring the extent to which a revision disturbs existing beliefs. In the following, we simulate the work by Chan and Darwiche [CHAN AND DARWICHE, 2002] by proposing for each Jeffrey's revision rule a distance measure for belief functions which can be used to bound the amount of belief changes induced by this revision using uncertain evidence and show that, according to this measure, the posterior belief function obtained by the corresponding belief kinematics is the closest to the original one among all belief functions that satisfy the constraint in Eq. (2).

Definition 4.1 Let bel and bel' be two belief functions over the same frame Ω of discernment. We define a measure between bel and bel' as follows:

$$D^{in}(bel, bel') = \ln \max_{A \subseteq \Omega} \frac{m'(A)}{m(A)} - \ln \min_{A \subseteq \Omega} \frac{m'(A)}{m(A)}$$

where $\frac{0}{0}$ is defined to be 1. It is easy to check that D^{in} is a distance (or metric), satisfying the three properties of distance and, whenever there is a subset A for which $m(A) = 0$ and $m'(A) > 0$ or vice versa, the distance $D^{in}(bel, bel')$ for the corresponding belief functions is equal to infinity. \triangleleft

Lemma 4.2 Let $\langle \Omega, \mathcal{B} \rangle$ be a coarsening of $\langle \Omega, 2^\Omega \rangle$. Assume that $bel^{in'}$ is obtained from bel by applying Jeffrey's rule according to inner belief kinematics (Eq. (3)), given the uncertain evidence specified by the set of posterior beliefs $(m^{in'})_{\mathcal{B}}^{in}(B) = q_B$, for $B \in \mathcal{B}$ where $(m^{in'})_{\mathcal{B}}^{in}$ is the derived mass assignment of $m^{in'}$, the corresponding mass assignment of $bel^{in'}$, on $\langle \Omega, \mathcal{B} \rangle$.

1. For any $A \subseteq \Omega$, if $\mathbf{B}(A) = B$, then

$$\frac{m^{in'}(A)}{m(A)} = \frac{(m^{in'})_{\mathcal{B}}^{in}(B)}{m_{\mathcal{B}}^{in}(B)}.$$

2. The distance $D^{in}(bel, bel')$ between bel and $bel^{in'}$ is given by

$$D^{in}(bel, bel^{in'}) = \ln \max_{B \in \mathcal{B}} \frac{q_B}{m_B^{in}(B)} - \ln \min_{B \in \mathcal{B}} \frac{q_B}{m_B^{in}(B)}$$

Proof. The first part follows from the following observation: for any $A \subseteq \Omega$ and $B \in \mathcal{B}$,

$$\begin{aligned} \frac{\sum_{\mathbf{B}(A')=B, A' \subseteq A} m^{in'}(A')}{\sum_{\mathbf{B}(A')=B, A' \subseteq A} m(A')} &= \frac{(bel^{in'})_B^{in}(A|B)(m^{in'})_B^{in}(B)}{bel_B^{in}(A|B)m_B^{in}(B)} \\ &= \frac{(m^{in'})_B^{in}(B)}{m_B^{in}(B)} \end{aligned}$$

The second equality comes from the condition for inner belief kinematics. QED

The following theorem says that the principle of inner belief kinematics can be viewed as a principle for minimizing belief change with respect to the metric D^{in} .

Theorem 4.3 *For the belief functions bel and $bel^{in'}$ in Lemma 4.2, $bel^{in'}$ is the closest to bel according to the above distance measure D^{in} among all possible belief functions that agree with $bel^{in'}$ on the propositions in the subalgebra \mathcal{B} .*

Proof. Suppose that m is the corresponding mass assignment of bel . Let bel'' be any belief function with m'' as its corresponding mass assignment that satisfies the constraint: $(m'')_B^{in}(B) = (m^{in'})_B^{in}(B)$ for all $B \in \mathcal{B}$. Let $B_{max} = \operatorname{argmax}_{B \in \mathcal{B}} \left(\frac{(m^{in'})_B^{in}(B)}{m_B^{in}(B)} \right)$ and $B_{min} = \operatorname{argmin}_{B \in \mathcal{B}} \left(\frac{(m^{in'})_B^{in}(B)}{m_B^{in}(B)} \right)$. Define $r_{max} = \max_{A \subseteq \Omega} \frac{m''(A)}{m(A)}$. Then we have the following inequality:

$$\begin{aligned} r_{max} m_B^{in}(B_{max}) &= r_{max} \sum_{\mathbf{B}(A)=B_{max}, A \subseteq \Omega} m(A) \\ &\geq \sum_{\mathbf{B}(A)=B_{max}, A \subseteq \Omega} \frac{m''(A)}{m(A)} m(A) \\ &= \sum_{\mathbf{B}(A)=B_{max}, A \subseteq \Omega} m''(A) \\ &= (m'')_B^{in}(B_{max}) \\ &= (m^{in'})_B^{in}(B_{max}) \end{aligned}$$

So we have shown that $r_{max} \geq \frac{(m^{in'})_B^{in}(B_{max})}{m_B^{in}(B_{max})}$. Similarly, we can define $r_{min} = \min_{A \subseteq \Omega} \frac{m''(A)}{m(A)}$ and show that $r_{min} \leq \frac{(m^{in'})_B^{in}(B_{min})}{m_B^{in}(B_{min})}$. Therefore, the distance measure

between bel and bel'' is:

$$\begin{aligned} D^{in}(bel, bel'') &= \ln r_{max} - \ln r_{min} \\ &\geq \ln \frac{(m^{in'})_B^{in}(B_{max})}{m_B^{in}(B_{max})} - \ln \frac{(m^{in'})_B^{in}(B_{min})}{m_B^{in}(B_{min})} \\ &= \ln \max_{B \in \mathcal{B}} \frac{(m^{in'})_B^{in}(B)}{m_B^{in}(B)} - \ln \min_{B \in \mathcal{B}} \frac{(m^{in'})_B^{in}(B)}{m_B^{in}(B)} \\ &= D^{in}(bel, bel') \end{aligned}$$

The last equality follows from Lemma 4.2.

QED

Now we define a distance D^{out} for the outer revision. The essential difference of D^{out} from the above D^{in} for the inner revision is that D^{out} depends on the associated coarsening frame.

Definition 4.4 *Let bel and bel' be two belief functions over the same frame Ω of discernment. We define a measure between bel and bel' with respect to a coarsening $\langle \Omega, \mathcal{B} \rangle$ as follows:*

$$D^{out}(bel, bel') = \ln \max_{A \subseteq \Omega} \frac{m'(A)}{m_{/\mathbf{B}(A)}(A)} - \ln \min_{A \subseteq \Omega} \frac{m'(A)}{m_{/\mathbf{B}(A)}(A)}$$

where $\frac{0}{0}$ is defined to be 1. It is easy to check that D^{out} is a distance (or metric), satisfying the three properties of distance. ◁

Lemma 4.5 *Let $\langle \Omega, \mathcal{B} \rangle$ be a coarsening of $\langle \Omega, 2^\Omega \rangle$. Assume that $bel^{out'}$ is obtained from bel by applying Jeffrey's rule according to the outer belief kinematics, given the uncertain evidence specified by the set of posterior beliefs $(m^{out'})_B^{in}(B) = q_B$, for $B \in \mathcal{B}$ where $(m^{out'})_B^{in}$ is the derived mass assignment of $m^{out'}$, the corresponding mass assignment of $bel^{out'}$, on $\langle \Omega, \mathcal{B} \rangle$.*

1. For any $A \subseteq \Omega$, if $\mathbf{B}(A) = B$, then

$$\frac{m^{out'}(A)}{m_{/\mathbf{B}(A)}(A)} = \frac{(m^{out'})_B^{in}(B)}{m_B^{out'}(B)}.$$

2. The distance $D^{out}(bel, bel')$ between bel and bel' is given by

$$D^{out}(bel, bel') = \ln \max_{B \in \mathcal{B}} \frac{q_B}{m_B^{out'}(B)} - \ln \min_{B \in \mathcal{B}} \frac{q_B}{m_B^{out'}(B)}$$

Proof. The first part follows from the following observation: for any $A \subseteq \Omega$ and $B \in \mathcal{B}$,

$$\begin{aligned} \frac{\sum_{\mathbf{B}(A')=B, A' \subseteq A} m^{out'}(A')}{\sum_{\mathbf{B}(A')=B, A' \subseteq A} m_{/\mathbf{B}(A')}(A')} &= \frac{(bel^{out'})_B^{in}(A|B)(m^{out'})_B^{in}(B)}{bel_B^{out'}(A|B)m_B^{out'}(B)} = \frac{(m^{out'})_B^{in}(B)}{m_B^{out'}(B)} \end{aligned}$$

The second equality comes from the condition for outer belief kinematics. QED

The following theorem says that the principle of outer belief kinematics can be viewed as a principle for minimizing belief change with respect to D^{out} .

Theorem 4.6 For the belief functions bel and $bel^{out'}$ in Lemma 4.5, $bel^{out'}$ is the closest to bel according to the above distance measure D^{out} among all possible belief functions that agree with $bel^{out'}$ on the propositions in the subalgebra \mathcal{B} .

Proof. Suppose that m is the corresponding mass assignments of bel . Let bel'' be any belief function with m'' as its corresponding mass assignment that satisfies the constraint: $(m'')_{\mathcal{B}}^{in}(B) = (m^{out'})_{\mathcal{B}}^{in}(B)$ for all $B \in \mathcal{B}$. Let $B_{max} = \operatorname{argmax}_{B \in \mathcal{B}} (\frac{(m^{out'})_{\mathcal{B}}^{in}(B)}{m_{\mathcal{B}}^{out}(B)})$ and $B_{min} = \operatorname{argmin}_{B \in \mathcal{B}} (\frac{(m^{out'})_{\mathcal{B}}^{in}(B)}{m_{\mathcal{B}}^{out}(B)})$. Define $r_{max} = \max_{A \subseteq \Omega} \frac{m''(A)}{m_{/\mathcal{B}(A)}(A)}$. Then we have the following inequality:

$$\begin{aligned} r_{max} m_{\mathcal{B}}^{out}(B_{max}) &= r_{max} \sum_{\mathcal{B}(A)=B_{max}, A \subseteq \Omega} m_{/\mathcal{B}(A)}(A) \\ &\geq \sum_{\mathcal{B}(A)=B_{max}, A \subseteq \Omega} \frac{m''(A)}{m_{/\mathcal{B}(A)}(A)} m_{/\mathcal{B}(A)}(A) \\ &= \sum_{\mathcal{B}(A)=B_{max}, A \subseteq \Omega} m''(A) \\ &= (m'')_{\mathcal{B}}^{in}(B_{max}) \\ &= (m^{out'})_{\mathcal{B}}^{in}(B_{max}) \end{aligned}$$

So we have shown that $r_{max} \geq \frac{(m^{out'})_{\mathcal{B}}^{in}(B_{max})}{m_{\mathcal{B}}^{out}(B_{max})}$. Similarly, we can define $r_{min} = \min_{A \subseteq \Omega} \frac{m''(A)}{m_{/\mathcal{B}(A)}(A)}$ and show that $r_{min} \leq \frac{(m^{out'})_{\mathcal{B}}^{in}(B_{min})}{m_{\mathcal{B}}^{out}(B_{min})}$. Therefore, the distance measure between bel and bel'' is:

$$\begin{aligned} D^{out}(bel, bel'') &= \ln \max_{A \subseteq \Omega} \frac{m''(A)}{m_{/\mathcal{B}(A)}(A)} - \ln \min_{A \subseteq \Omega} \frac{m''(A)}{m_{/\mathcal{B}(A)}(A)} \\ &= \ln r_{max} - \ln r_{min} \\ &\geq \ln \frac{(m^{out'})_{\mathcal{B}}^{in}(B_{max})}{m_{\mathcal{B}}^{out}(B_{max})} - \ln \frac{(m^{out'})_{\mathcal{B}}^{in}(B_{min})}{m_{\mathcal{B}}^{out}(B_{min})} \\ &= \ln \max_{B \in \mathcal{B}} \frac{(m^{out'})_{\mathcal{B}}^{in} B}{m_{\mathcal{B}}^{out}(B)} - \ln \min_{B \in \mathcal{B}} \frac{(m^{out'})_{\mathcal{B}}^{in} B}{m_{\mathcal{B}}^{out}(B)} \\ &= D^{out}(bel, bel') \end{aligned}$$

The last equality follows from Lemma 4.5.

QED

Example 4.7 Now, by using Lemmas 4.2 and 4.5, we compute the distances between bel and bel' in Example 3.6:

$$\begin{aligned} D^{in}(bel, bel') &= \ln 1 - \ln \frac{1}{4} \\ &= 2 \ln 2 \\ D^{out}(bel, bel') &= \ln 4 - \ln \frac{4}{9} \\ &= 3 \ln 3 \end{aligned}$$

5 RELATED WORKS AND CONCLUSION

Although belief revision in probability theory is fully studied and researchers have generally agreed on the standard form of Jeffrey's rule, the corresponding revision rule in evidence theory has seldom been adequately addressed and there is not yet any standard form of this rule that has been universally recognized. Although all the forms of Jeffrey's rule in the theory of evidence in the literature are generalizations of this rule in probability theory, none of them satisfies all of the three natural constraints proposed in this paper. Usually they satisfy some constraints but do not satisfy the others. In particular, none of these forms in the literature has considered the revision of beliefs using uncertain evidence from the perspective in this paper viewing Jeffrey's rule as a form of the evidence-theoretic counterpart of probability kinematics, which should be the essence of Jeffrey's rule in Dempster-Shafer theory [WAGNER, 1992]. Moreover, none of those Jeffrey's rules in DS -theory in the literature has provided any distance measures for bounding belief changes due to revision and our work is the first to achieve that. Our distance measures for belief functions are adapted from the one for revision of probabilistic beliefs using uncertain evidence as *virtual certain evidence* according to Pearl's method [PEARL, 1988] and hence different from those distances for belief functions in the literature [JOUSSELME AND MAUPIN, 2012].

Jeffrey's rules for belief functions in the literature are proposed from different perspectives. Shafer [SHAFER, 1981] has studied Jeffrey's rule. He proposed that its generalization can be found in Dempster's rule of combination. His proposal doesn't fit with Constraint 2 and we agree with Smets [SMETS, 1993A] that Constraint 2 is more important in the spirit of Jeffrey's updating than Shafer's proposal. In addition, Wagner [WAGNER, 1992] studied Jeffrey's rule in evidence theory from the perspective of viewing belief functions as lower envelopes. So his perspective is quite different from our proposal in term of mass functions.

Dubois and Prade [DUBOIS AND PRADE, 1991, DUBOIS AND PRADE, 1993] investigated updating and revision rules in a variety of uncertainty models including belief functions. They proposed the following form of Jeffrey's rule in DS theory:

$bel'(A) = \sum_{B \in \mathcal{B}} \frac{bel(A \cup \bar{B}) - bel(\bar{B})}{pl(\bar{B})} m_e(B)$. This form is one of several Jeffrey's rules studied by Ichihashi and Tanaka ([ICHIHASHI AND TANAKA, 1989]). Ma and others ([MA ET AL., 2010] and in more detail [MA ET AL., 2011]) proposed three different revision rules, namely the inner, outer and modified outer revisions. In particular, their modified outer revision generalizes Jeffrey's rule of updating in probability theory, Dempster's rule of conditioning and a form of AGM revision. Their rules work in a more general setting when the incoming input is a *general* mass function. They consider the *information content* associated with an epistemic state represented by some belief function rather than the *full specification* as in our paper. A belief function bel_1 is less informed than another one bel_2 if bel_2 is a specialization of bel_1 . They formalize the success postulate as requiring that the posterior belief function bel' be a specialization of the prior one bel . According to their viewpoint, if bel_1 and bel_2 are both defined on the same algebra \mathcal{A} and bel_1 is a specialization of bel_2 , then they are considered to be consistent with each other. However, according to our idea, they are inconsistent if they are not the same. We take the readaptation as revision [SMETS, 1993A]. Halpern [HALPERN, 2005] provided another form of belief-function revision rule: $bel'(A) = \sum_{i=1}^n bel_e(B_i) bel(A|B_i)$ where $(B_i)_{i=1}^n$ is a family of mutually exclusive and exhaustive subsets of Ω . His generalization is in terms of belief functions instead of mass functions. So it is quite different from ours. Moreover, bel' in his revision rule is not necessarily a belief function unless bel_e is a probability function. But, according to our proposal, uncertain evidence should be specified by a belief function bel_e . None of the above mentioned forms of Jeffrey's rules in *DS*-theory satisfies Constraint 2.

Our proposed Jeffrey's rules actually *improve* the two rules called source-conditioning and data-conditioning by Smets [SMETS, 1993A] especially the source-conditioning rule there. The motivation for the rule is not well justified and Smets' constraints for this rule are not well-defined. In Smets' Constraint **C2F**, bel should satisfy the requirement that, for any $X, Y \subseteq \Omega$, if $\mathbf{B}(X) = \mathbf{B}(Y)$, $\frac{bel(X)}{bel(Y)} = \frac{bel'(X)}{bel'(Y)}$. But generally bel' does not satisfy this requirement. Consider the above Example 3.6 and the proposition A . Let $A' = \{w_{0,g}, w_{1,b}, w_{0,v}\}$. Obviously, $\mathbf{B}(A) = \mathbf{B}(A') = \Omega$. However, $\frac{bel(A)}{bel(A')} = 1 \neq \frac{29}{18} = \frac{bel'(A)}{bel'(A')}$. The two forms of belief kinematics in this paper correct and improve the two constraints **C2F** and **C3F** in [SMETS, 1993A] (Parts (1) of Lemmas 4.2 4.5), respectively. Benferhat and others [BENFERHAT ET AL., 2011] studied Jeffrey's rule in a *possibilistic* framework using the possibilistic counterparts of probability kinematics, which is similar to our approach in this paper. But, our theory for belief functions here covers their approach in the quantitative possibilistic setting.

The following are some other constraints for defining Jeffrey's rules in Dempster-Shafer theory [MA ET AL., 2011]:

- (Constraint 4) When the incoming information is certain, the proposed Jeffrey's rule should be the same as Dempster's rule of conditioning.
- (Constraint 5) The proposed rule should satisfy some natural form of minimal change principle.
- (Constraint 6) The revision rule should preserve the new evidence.

We summarize our contributions in this paper by listing in a table the above major proposed Jeffrey's rules and their satisfied constraints:

Table 1: Summary

Constraint \ Rule	1	2	3	4	5	6
Shafer's rule	✓			✓		✓
Modified outer revision rule by Ma et al.	✓			✓	✓	✓
Halpern's rule	✓			✓		
Smets' rule of source-conditioning	✓	✓				✓
Smets' rule of data-conditioning	✓	✓		✓		✓
Our rule of inner revision	✓	✓	✓		✓	✓
Our rule of outer revision	✓	✓	✓	✓	✓	✓
